Diagnosing AHF is critical step as patient present with signs and symptoms, and need to differentiate AHF from other overlapping conditions. Electrocardiogram (ECG), chest X-ray, elevated natriuretic peptides, and echocardiography are the most important initial investigations. In the absence of pulmonary edema, arterial desaturation may or may not be present. Brain natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) used in emergency department for patient with undifferentiated dyspnea. BNP has both diagnostic and prognostic role and released from myocytes in response to volume overload. In doubtful case, BNP < 100 pg/mL rules out heart failure and >400 pg/mL strongly suggests heart failure, though these are only guide and NT-proBNP have similar role but different half-life and cut-off value than BNP.

EMERGENCY DEPARTMENT TREATMENT

Most of the time, patient with AHF present in emergency department in very distress state and needs rapid initiation of treatment. Obtain intravenous access. Cardiac monitoring, pulse oximetry, and oxygen supplementation should be started immediately. Appropriate laboratory studies should be performed. *Early initiation of noninvasive positive pressure ventilation (NIPPV) and appropriate pharmacological therapy are the basics of AHF therapy in emergency department.*

- Noninvasive positive pressure ventilation reduces the afterload (by reducing transmural pressure of entire left ventricle)
- Noninvasive positive pressure ventilation reduces preload (by increasing intrathoracic pressure and reducing venous return)
- Reducing both preload and afterload significantly benefits the acutely failing heart
- Finally, by these mechanisms, NIPPV reduces work of breathing and improves oxygenation.
- Bilevel positive airway pressure (BiPAP) and continuous positive airway pressure (CPAP) have similar benefits, start with initial setting of iPAP/ePAP—10/5 mm Hg for BiPAP and 10 mm Hg for CPAP.

Hemodynamic Monitoring

In patients with AHF, hemodynamic monitoring may provide valuable information and guide titration of pressor agents and the need for mechanical circulatory support. Hemodynamic monitoring is strongly recommended to help reevaluate optimization of filling pressures and systematic vascular resistance while oral agents are adjusted during weaning from inotropic infusions in patients who appear to be dependent on them. It is not recommended as a routine practice, if a patient is responding to the usual treatment. In a carefully selected patient, a good beside echocardiography can yield useful information regarding cardiac hemodynamic and can be used repeatedly. As discussed in classification section, the patient with AHF can be categorized into three subgroups on the basis of systolic blood pressure on presentation in emergency department. Further clinical approach is based on hypotensive/hypertensive/normotensive AHF (**Fig. 1**).

High-risk features: Poor response to therapy, inadequate urine output, uncontrolled BP (SBP < 90/>200 mm Hg), elevated troponin, tachycardia, high respiratory rate, and high urea creatine hypoxia in spite of early NIPPV.

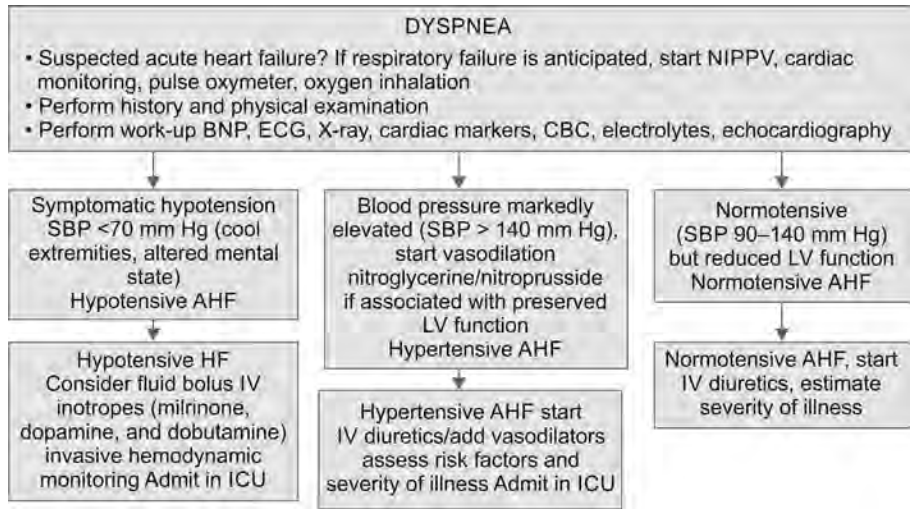
Nonhigh-risk features: Good response to therapy, adequate urine output, controlled blood pressure, and negative troponin.

PHARMACOLOGIC THERAPY

Diuretics, IV vasodilators, and IV inotropes are the major drugs used during acute management of decompensated heart failure.

Diuretics

Loop diuretic is generally considered as the first-line therapy. They are effective and well tolerated. Rapid IV administration of furosemide may rarely cause ototoxicity. A common problem is under dosing with these drugs. When glomerular filtration rate (GFR) is reduced, higher doses must be used because they are secreted in the proximal tubule and act from the luminal side on the loop of Henle. Thiazides and spironolactone are weaker diuretics and may be ineffective when GFR is below 40 mL. In patients with more advanced heart failure, distal tubule reabsorption may limit the efficacy of loop diuretics. In this situation, a *combination of metolazone and loop*



(AHF: acute heart failure; BNP: brain natriuretic peptide; CBC: complete blood cell; ECG: electrocardiogram; IV: intravenous; ICU: intensive care unit; LV: left ventricular; SBP: systolic blood pressure)

FIG. 1: Approach to acute heart failure.

diuretics is very effective. However, potassium levels need to be watched for carefully with this combination as hypokalemia may occur and can precipitate ventricular arrhythmias. Muscle aches are common with brisk diuresis. Most patients with heart failure receive potassium-sparing ACE inhibitors and frequently spironolactone also. In patients with diabetes and renal dysfunction, hyperkalemia can result in this situation. Potassium-rich fruits and salt substitutes containing potassium are often given to these patients and can further aggravate hyperkalemia. Metabolic alkalosis, increased uric acid, hyponatremia, and neurohormonal activation are the other side effects of potent diuretics and need to be watched for.

In certain patients when IV diuretics have suboptimal effect, IV infusion of loop diuretics are beneficial. Ultrafiltration and other form of dialysis may be useful in patients with inadequate diuresis and are very useful in patients who have difficulty achieving diuresis with conventional medications.

Intravenous Vasodilators

After diuretics, IV vasodilator is the most useful medicine for acute management of heart failure. They reduce filling pressures, increase cardiac output, and reduce mitral regurgitation, resulting in immediate improvement of symptoms. When used carefully, they generally do not increase heart rate or result in arrhythmias unless there is severe hypotension.

- *Nitroglycerine*: This is one of the safest and most widely used agents in AHF for both acute ischemia and heart failure due to ischemia or vasoconstriction. The individual responses are highly variable and thus require careful monitoring. *Nitroglycerine indicated in features of pulmonary congestion/edema, BP > 90 mm Hg. Start with 10–20 μg/min and increase to 200 μg/min*. Headache and tachycardia may occur in some patients and tolerance on continuous use.
- *Nitroprusside*: This was the first vasodilator to be used in heart failure and is very effective in patients with severe hypertension with increased systemic vascular resistance. Nitroprusside hypertensive HF congestion/edema BP > 90 mm Hg. Start with 0.3 μg/kg/min and increase to 5 μg/kg/min. The onset and offset of action are very rapid with a half-life of approximately 2 minutes. Once filling pressures are nearly normal, further vasodilator may not be necessary. Its major limitation is hypotension, gastrointestinal and central nervous system (CNS) side effects from cyanide toxicity which are more likely to occur with impaired hepatic perfusion or hepatic dysfunction and in patients receiving large doses for >48 hours. Reduction and cessation of nitroprusside are generally enough to treat this complication.
- *Nesiritide*: It is a recombinant form of BNP and lowers filling pressures and improves symptoms in decompensated heart failure. Nesiritide should be started with features of pulmonary congestion/edema BP > 90 mm Hg, bolus 2 μg/kg + infusion 0.015–0.03 μg/kg/min. Hypotension is major concern so blood pressure needs to be monitored because it has a longer half-life of 18 minutes. Bradycardia and headache may occur occasionally. It potentiates the effect of concomitant diuretics. This effect may persist after infusion is stopped. It has been shown to be effective for decreasing filling pressures and relieving symptoms.
- *Angiotensin receptor neprilysin*: A recent welcome addition is a new drug called angiotensin receptor and neprilysin inhibitor. This is an oral drug which upon ingestion breaks down into valsartan [angiotensin receptor blocker (ARB)] and sacubitril, which inhibits neprilysin. Neprilysin is a natural enzyme which results in breakdown of natriuretic peptides. Thus, the administration of this drug results in elevated levels of natriuretic peptides due to inhibition of their breakdown and ARB valsartan. In recent trials, this drug has shown dramatic results in reducing mortality and morbidity in chronic heart failure and currently a trial is under way to assess its efficacy in AHF.

Intravenous Inotropic Agents

Though widely used, inotropic agents pose their own problems. They are associated with more tachyarrhythmias and ischemic events. Also, the efficacy of diuretics and tolerability of ACE inhibitors may be overestimated in the presence of inotropic stimulation. This may prolong hospitalization or increase the chances of early rehospitalization. The appropriate use of

inotropic agents therefore is in a situation when they provide benefits not offered by initial therapies. They should be used until the cause of hypotension and deranged hemodynamic profile has been elucidated till diuresis becomes effective in patients with refractory heart failure and till renal, lung, or liver functions have improved significantly. Tapering of inotropes at times becomes difficult due to hypotension and in this situation temporary or permanent discontinuation of β-blockers and ACE inhibitors in severely compromised patients may help. Despite all these limitations, they are still extremely useful, especially in situations where despite adequate therapy congestion or hypotension is persistent.

- *Dobutamine*: This is the most commonly used inotropic agent. It stimulates β-adrenergic receptor with little effect on alpha-adrenergic receptors so that contractility is increased with peripheral and pulmonary vasodilation. Cardiac output is increased, filling pressures are reduced, and diuresis is potentiated. However, it causes tachycardia, especially in patients with atrial fibrillation and also results in increased ventricular arrhythmias and ischemia. When indicated the lowest dose possible should be used. Increase in diuresis and improvement in renal function can be seen at 1–2 μg/kg/min. Treatment for more severe hypoperfusion requires higher doses and tachyphylaxis is generally seen. Maximum doses are usually 10–15 μg/kg/min. Occasionally, its prolonged administration is accompanied by increased eosinophil count, skin rash, and eosinophilic myocarditis.
- *Dopamine*: Dopamine stimulates β-receptors, α-receptors, and dopaminergic receptors that cause vasodilation in renal and peripheral vasculature. At doses up to 5 μg/kg/min, it is predominantly vasodilatory. After 5 μg/kg/min, α-receptor stimulation dominates, resulting is vasoconstriction. Dopamine also causes release of norepinephrine, resulting in independent stimulation of α- and β-receptors. In low doses, its beneficial effects are clinically similar to dobutamine with similar adverse effects. It is usually indicated in rapidly changing situations in which modest inotropy and vasodilation may be adequate but further increase in pressure is required. In this situation, one can start with 4 μg/kg/min and wean off when a dose of 3 μg/kg/min is reached. There is no significant advantage of combining dobutamine and dopamine for enhanced renal function in heart failure and it increases the risk of arrhythmias and ischemia.
- *Milrinone*: Milrinone increases cyclic adenosine monophosphate (AMP) by inhibiting its breakdown rather than increasing its production through stimulation of β-receptor. It acts synergistically with β-agent stimulating to achieve further increase in cardiac output than either agent alone. These are more effective than β-adrenergic agent, when β-blockers have already been given. The degree to which cardiac output increases and systemic resistance decreases is variable and therefore some patients may exhibit predominant vasodilator. Thus, there is a significant incidence of hypotension with milrinone unlike dobutamine. It results in lesser tachycardia than dopamine and dobutamine but has a similar incidence of arrhythmias and ischemia. It has a longer half-life of 6 hours unlike dopamine and dobutamine which are in minutes. It is generally started as an infusion at a dose of 0.5 μg/kg/min and titrated up to a maximum of .75 μg/kg/min. It is excreted renally and therefore in renal dysfunction dose adjustment is needed. Its prolonged use can increase its half-life to up to 18 hours. Therefore, after discontinuing, its infusion at least 48 hours of observation is required.
- *Epinephrine and norepinephrine*: These are full β-receptor agonists, which increase contractility, heart rate and peripheral resistance while promoting arrhythmias and ischemia. They can provide significant additional short-term inotropic and blood pressure support over minutes to hours before other therapies. Kidney failure, hepatic failure, and gangrene can result from the use of these agents. When fatal hypotension is imminent, they are used at a starting dose of 0.1 μg/min. This can be preceded by a stat dose of 0.25 mg of epinephrine to maintain survival for a brief period. Boluses of calcium may be helpful particularly in the presence of conditions that may lower serum calcium such as transfusions, dialysis, and cardiopulmonary bypass. They are highly arrhythmogenic and may exaggerate ongoing myocardial necrosis.
- *Vasopressin:* It is used to potentiate the use of catecholamines in patients who remain severely hypotensive despite high dose pressor support. It can be used for hours to days in doses of 0.052–0.1 unit/min. When added to norepinephrine, it can result in about 30 mm Hg increase in systolic blood pressure. It is sometimes associated with profound water diuresis. As with other vasoconstrictors, it can result in ischemic injury and necrosis of organs and limbs.

MECHANICAL ASSISTANCE

In a small minority of patients with rapid deteriorating hemodynamic which threatens their survival, a quick, aggressive support for stabilization or for definitive intervention is required. The goal in these cases is stabilization of patient to a point at which definitive intervention or surgical therapy can be offered or spontaneous recovery occurs. It is important to identify these patients quickly the evidence of this situation usually includes more than one of the following:

- Systolic blood pressure below 75 mm Hg
- Cardiac index below 1.5–1.8 L/min/m^2
- Along with systemic acidosis with positive lactate levels, anuria, obtundation, and shock with rise of transaminase level and altered sensorium
- Escalation of therapy would include more intense inotropic support with epinephrine at escalating doses. Vasopressin is frequently added as well, as discussed previously. For the patients with otherwise robust health, consultation regarding surgical options should be obtained immediately.

Intra-aortic Balloon Pump

The role of intra-aortic balloon pump (IABP) for intermediate stabilization has been well established for cardiogenic shock caused by acute myocardial infarction. The pump is usually inserted while other therapies are underway by the bedside or in the cardiac catheterization suite. When it can be performed expeditiously, balloon pump insertion seems reasonable for other cases of cardiogenic shock with underlying coronary artery disease. For cardiogenic shock of other causes, its role is less clear, and plans for insertion should not detract from progress to more definitive intervention. Some experts advocate its use for stabilization of medical therapy and anesthesia regardless of cause, whereas others believe that

it offers little benefit for patients without epicardial coronary artery disease and moreover, increases the risk of vascular and infectious complications.

Extracorporeal Membrane Oxygenator and LV-assist Devices

These are available in some specialized centers used judiciously; they are lifesaving as a bridge to recovery, surgery, or heart transplant.

DISPOSITION

Postdischarge mortality and morbidity is high in patient with AHF. In the absence of definitive guidelines whom to discharge safely, various factors other than clinical status should be taken in account like their socioeconomic and understanding about health. High-risk features or nonhigh-risk features described earlier play important role in deciding the safe discharge of patient after therapy. So patient can be discharged, if high-risk features are absent, precipitants of AHF are identified and adequately treated, baseline parameters have been achieved, follow-up discharged plan is in place, and condition is low risk in view of clinician.

SUMMARY

Acute heart failure is one of the common presentations in emergency department, usually critically ill and needs rapid initiation of therapy. In contrast to traditional teaching, not all patients are with volume overload. Clinical approach is largely based on hypertensive, hypotensive, and normotensive classification. NIPPV diuretics vasodilators and inotropic support (in hypotensive AHF) are the mainstay of the therapy. Mechanical support [IABP and extracorporeal membrane oxygenator (ECMO)] not used as routine therapy.

68 CHAPTER

Cardiac Arrhythmias: Identification and Management

Ives Hubloue, Jamal Yusuf

INTRODUCTION

Cardiac arrhythmias or dysrhythmias are a group of abnormalities of the heart rate and or rhythm originating from abnormalities in the electric conduction system. They can occur in adults (most common) as well as in children. Most of the arrhythmias are harmless but some of them can cause serious complications (e.g., stroke) and/or life-threatening events such as sudden cardiac death. Arrhythmias can be divided in two main groups—(1) Bradycardias when the heart rate (corresponding to ventricular rate) is below 60 beats/min; and (2) Tachycardias when the heart rate exceeds 100 beats/min (in adults). In children, the normal range for the heart rate is different and depends on age. The choice of the treatment depends on various factors (life-threatening versus nonlife-threatening arrhythmia) and includes medications, medical procedures (e.g., defibrillation and pacemaker), and/or surgery.

BRADYARRHYTHMIAS

Etiology

Bradycardia could be due to either intrinsic or extrinsic causes or a combination of the two. The most important *intrinsic cause* is age-related degenerative disease. Other intrinsic causes include ischemia affecting sinus node or conduction tissue, infiltrative diseases (e.g., sarcoidosis and amyloidosis), collagen vascular diseases [e.g., systemic lupus erythematosus (SLE)], congenital heart diseases affecting sinus node or conduction system [e.g., congenitally corrected transposition of the great arteries (ccTGA)], infections (e.g., diphtheritic myocarditis), genetic cardiomyopathies, primary genetic conduction disorders, postcardiac surgery, and post-catheter ablation. *Extrinsic causes* include vagotonia due to physical conditioning or in vasovagal reflex or carotid sinus hypersensitivity. Rate-limiting drugs (e.g., beta-blockers), dyselectrolytemia (e.g., hyperkalemia), metabolic derangements (e.g., hypothyroidism), and raised intracranial pressure are some other extrinsic causes that need to be kept in mind while evaluating a case of bradycardia; the clinical and electrocardiogram (ECG) manifestation of each of these is unique enough to provide a hint to the alert mind and help guide further testing.

Symptoms

Symptoms of bradycardia may be subtle and persistent due to a chronic low-output state (easy fatigability, poor functional capacity, exertional dyspnea, cognitive impairment, and dizziness) or episodic and dramatic in intermittent bradycardias (syncope or presyncope associated with traumatic falls).

Classification

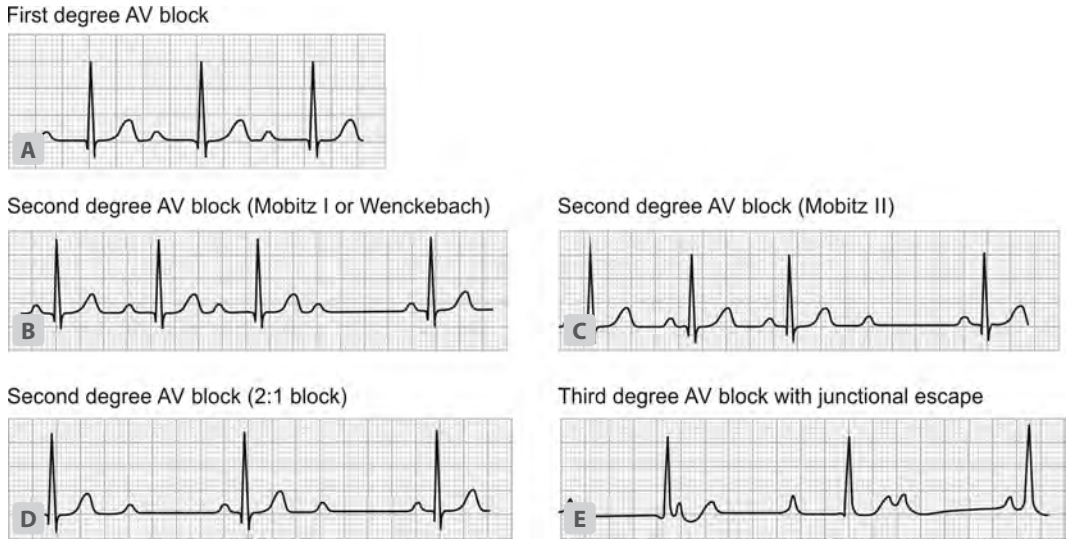
The most useful classification of bradyarrhythmia is based on the site of abnormality in impulse generation and/or propagation. Broadly, there are two groups:

1. Abnormalities of sinus node and intra-atrial conduction (includes abnormalities in impulse generation as well as conduction)
2. Abnormalities at level of AV node and below (includes abnormalities in impulse conduction only)

Abnormalities of Sinus Node and Intra-atrial Conduction (Includes Abnormalities in Impulse Generation as well as Conduction)

- *Sinus bradycardia*: In an adult, sinus bradycardia is diagnosed when there are <60 P-waves per minute on the ECG (or P-P interval of >1 second), with a regular P-P interval, every P-wave being followed by a QRS interval, PR interval between 0.12 and 0.2 seconds and a normal P-wave axis (upright in leads I and II, inverted in aVR). When the P-wave axis is consistently abnormal (beyond 0–75°), it generally indicates that there is sinus arrest and an alternative atrial pacemaker has taken over (atrial rhythm rather than sinus bradycardia). Persistent sinus bradycardia is frequently physiological (e.g., in well-conditioned athletes) or may be due to the effect of rate-limiting drugs such as beta-blockers. Conditions causing parasympathetic stimulation may lead to transient sinus bradycardia (as during a vasovagal episode). Symptomatic sinus bradycardia, when a part of sick sinus syndrome, may require a permanent pacemaker implant.

- *Sinus pause*: A sudden drop in the P-wave frequency indicates a sinus pause. This is to be differentiated from both, a sinus exit block and sinus arrhythmia. While sinus arrhythmia results in a gradual and cyclical change in P-P interval (frequently related to the respiratory cycle), sinus pauses are abrupt and noncyclical. On the other hand, a type II second degree sinoatrial (SA) exit block leads to an abrupt increase in the P-P interval, which is an exact multiple of the normal P-P interval; however, with superimposed sinus arrhythmia the differentiation between type II second degree SA exit block and a sinus pause may be difficult on the surface ECG. Practically though, this differentiation is not of much significance as the management of both would be on similar lines.
- *Sino-atrial exit block*: SA exit block refers to the delay in or inability of formed impulse to conduct to the right atrium. As the P-wave is generated on the surface ECG due to atrial depolarization, whether the impulse is not generated or whether it is generated but not conducted to the atrium, both manifest as dropped P waves. *SA exit block includes (**Figs. 1A** to **E**)*:
  - *First-degree SA exit block:* This is due to delayed conduction of the generated impulse to the right atrium; as no P wave is dropped it cannot be diagnosed from the surface ECG.
  - *Type I second degree SA exit block (Wenckebach):* This is due to progressive delay in impulse transmission to the atrium, finally resulting in a dropped impulse. It manifests on the surface ECG as progressive shortening of the P-P interval culminating in a dropped P wave, with the P-P interval preceding the dropped beat being the shortest. It is frequently mistaken for sinus arrhythmia.
  - *Type II second degree SA exit block:* This is manifested as abrupt increase in P-P interval, due to sudden blocked P wave, with the increased P-P interval being an exact multiple of normal P-P interval. As discussed earlier, this may at times be difficult to differentiate from a sinus pause on the surface ECG.
  - *Complete (type III) SA exit block*: None of the generated impulses is conducted to the atrium, resulting in complete absence of normal P waves. An atrial or junctional pacemaker may take over, providing an atrial escape rhythm (with abnormal P waves, as discussed in the section on sinus bradycardia) or a junctional escape rhythm (with no visible P waves).
- *Sinus arrest*: This is due to nongeneration of the sinus impulse, leading to complete absence of normal P waves. It is indistinguishable from type III SA exit block on the surface ECG; the two can only be distinguished with a sinus node electrode during electrophysiologic evaluation.
  i. *Hypersensitive carotid sinus syndrome*: The cardio-inhibitory type of hypersensitive carotid sinus syndrome is characterized by sinus arrest or complete SA exit block during carotid sinus stimulation, leading to a ventricular pause exceeding 3 seconds; less commonly the ventricular pause may be due to AV block. Patients with symptomatic ventricular pauses exceeding 3 seconds or documented asymptomatic pauses exceeding 6 seconds on prolonged monitoring, with little or no prodromal symptoms, leading to frequent syncope and falls, are most likely to benefit from a permanent pacemaker. A dual chamber pacemaker with a rate-drop algorithm and rate hysteresis is appropriate in this situation.
  ii. *Sick sinus syndrome*: Sick sinus syndrome refers to a combination of various sinus node abnormalities (pathological sinus bradycardia, prolonged sinus pauses, SA exit block, and sinus arrest); more than one of these may be seen at different times. *The brady-tachy syndrome*, characterized by alternation of paroxysms of rapid regular or irregular atrial tachyarrhythmias with periods of slow atrial and ventricular rates, is also a part of this spectrum. The anatomic basis of sick sinus syndrome may involve total or subtotal destruction of sinus node, areas of nodal-atrial discontinuity, inflammatory or degenerative changes in nerves and ganglia around the node, and pathologic changes in the atrial wall; occlusion of sinus node artery may have a role. Symptomatic patients of sick sinus syndrome are candidates for permanent pacemaker implant, with dual chamber pacing likely superior to ventricular-only pacing with regard to incidence of atrial fibrillation (AF) and pacemaker syndrome. Atrial-only pacing is



FIGS. 1A TO E: Sinoatrial exit blocks.

usually avoided for fear of pacing failure, in case patient goes on to develop AV conduction defect in future. Also, a recent trial has shown an increased incidence of paroxysmal AF as well as pacemaker reoperation with atrial-only pacing vis-à-vis dual chamber pacing. Tachy-brady syndrome patients require a combination of pacemaker for the bradycardia and pharmacotherapy for tachycardia control.

Abnormalities at Level of AV Node and Below Includes Abnormalities in Impulse Conduction Only

- *First-degree AV block*: Every atrial impulse is conducted to the ventricle, although with a delay, evident on the surface ECG as a prolongation of the PR interval beyond 0.2 seconds. PR intervals as long as one second have been noted, and may even exceed the P-P interval, a phenomenon known as skipped P waves. First-degree AV block may occur due to conduction delay in the AV node (A-H interval), in the His-Purkinje system (H-V interval), or at both sites. Uncommonly, equally delayed conduction over both bundle branches can produce PR prolongation without significant QRS widening. Occasionally, intra-atrial conduction delay can also prolong the PR interval. Practically, first-degree AV block with a normal QRS is most likely due to delay at AV node with a wide QRS, delay could be at the AV node or the His-Purkinje system or both. While first-degree AV block by itself is considered benign, select patients with marked PR prolongation (beyond 300 ms) and persistent symptoms owing to shortening of LV filling time and diastolic mitral regurgitation, may be considered for *DDD pacing*.
- *Mobitz type I second-degree AV block (Wenckebach)*: This is characterized by serial prolongation of the PR interval till a P wave is blocked completely. The increment in PR interval is maximum in the second beat of the Wenckebach group and each subsequent increment is progressively smaller. While a classic Wenckebach phenomenon is easy to recognize, certain caveats must be kept in mind. For one, a pure 2:1 AV block can be either type I or type II; if the QRS is normal, the block is more likely to be type I—a careful search for transition to 3:2 block at some stage (with PR prolongation in the second cycle) may be useful. Secondly, type I AV block with a high ratio of conducted beats (e.g., 8:7) may give an impression of having a constant PR interval due to the small increments in consecutive beats; here comparing the PR interval just before and just after the dropped beat readily reveals the variation in PR interval. Prognosis-wise, a type I AV block is more likely to be supra-Hisian, especially when accompanied with a narrow QRS, and have a relatively benign course.
- *Mobitz Type II second-degree AV block*: In Mobitz type II block, some P waves are blocked abruptly, but PR interval of the conducted beats is constant. Type II AV block is more likely to be infranodal, worsening with atropine, exercise or isoproterenol, and improving with carotid sinus massage. Infranodal blocks are more likely to progress to complete AV block as compared to blocks at level of AV node; and may present with Stokes-Adams attacks. Most cases require a permanent pacemaker implant once reversible causes are ruled out; a dual chamber pacemaker that maintains AV synchrony is an appropriate choice.
- *Third-degree (Complete) AV block*: Complete AV block is a type of complete AV dissociation, where none of the P waves is conducted to the ventricles; both atria and ventricles are controlled by independent pacemakers. Symptoms are predominantly governed by the stability and rate of escape rhythm. For blocks at the level of AV node (usually congenital), the escape focus is generally within or close to the His bundle—this focus is relatively more stable and can provide ventricular rates up to 60 beats/min. Acquired complete heart block is, however, frequently infra-Hisian, due to trifascicular involvement, and the distal escape foci can rarely provide rates beyond 40 beats/min. Acquired complete AV block, unless reversible, almost invariably requires permanent pacing; even where reversible causes are suspected, temporary pacing support needs to be provided. Congenital complete AV block may, however, be observed, without any intervention, if it is asymptomatic and the patient consistently has an escape rate above 50 beats/min with normal QRS duration and normal left ventricular function; whenever symptoms or high-risk features appear permanent, pacing is indicated.

Management

The trickiest aspect in the management of bradyarrhythmia is not implanting a pacemaker (which is possibly the simplest aspect); rather it is reaching an accurate diagnosis and then deciding whether or not to treat the condition in a given patient.

While persistent bradycardia is easy to diagnose from the resting ECG, the diagnosis of intermittent bradycardia can be elusive and the diagnostic modality needs to be chosen as per the patient's symptom frequency. When the symptoms occur on a daily basis, 24-hour Holter monitoring is likely to have a good yield. However, extended Holter or external loop recorder may be required for less frequent (e.g., weekly) symptoms and an implantable loop recorder may be required for occasional symptoms (frequency less than once a month). A carotid sinus massage (in absence of contraindications) may prove useful in patients above 40 years of age, when carotid sinus hypersensitivity is suspected. While evaluating a patient for symptoms of intermittent bradycardia (e.g., syncope) other causes with similar presentation must also be ruled out (e.g., tachyarrhythmias, severe aortic stenosis, etc.).

Once a diagnosis of bradyarrhythmia is established, the next step is correlating it with the patient's symptoms. This is because benefit of treatment is much better established when bradycardia is shown to reproduce the symptoms in a given patient; otherwise there always lies the possibility that the bradycardia is an incidental finding and the symptoms are due to a different etiology. However, the same is easier said than done; and frequently patients are implanted a permanent pacemaker based on reasonable level of suspicion even when recorded bradyarrhythmic events have not reproduced the symptoms. In this scenario, it is worthwhile to have a lower threshold for treatment of advanced AV blocks vis-à-vis sinus node dysfunction.

Once a decision to treat a persistent or recurrent bradyarrhythmia (not attributable to reversible causes) is taken, drug therapy has no role; the choice is only of the type of pacemaker to be implanted. The choice of pacemaker device and specific algorithms (for conditions like carotid sinus hypersensitivity) has already been discussed in the relevant

sections. Suffice to say that as of date, with the exception of patients with permanent AF, dual chamber pacing is preferable to single chamber pacing; cost constrains, however, must be taken into account.

TACHYARRHYTHMIAS

Clinical Presentation

Signs and symptoms related to the tachyarrhythmia may include shock, hypotension, heart failure, shortness of breath, chest pain, acute myocardial infarction, palpitations, and/or decreased level of consciousness. Tachyarrhythmias are broadly characterized as supraventricular tachycardia (SVT), defined as a tachycardia in which the driving circuit or focus originates, at least in part, in tissue above the level of the ventricle (i.e., sinus node, atria, AV node, or His bundle) and ventricular tachycardia (VT), defined as a tachycardia in which the driving circuit or focus solely originates in ventricular tissue or Purkinje fibers. Because of differences in prognosis and management, the distinction between SVT and VT is critical early in the acute management of a tachyarrhythmia. In general (with the exception of idiopathic VT), VT often carries a much graver prognosis, usually implies the presence of significant heart disease, results in more profound hemodynamic compromise, and therefore requires immediate attention and measures to revert to sinus rhythm. On the other hand, SVT is usually not lethal and often does not result in hemodynamic collapse; therefore, more conservative measures can be applied initially to convert to sinus rhythm.

Electrocardiographic Diagnosis

The ECG is the most important tool in arrhythmia analysis. An electrophysiological study is more definitive, however, is not available at every center. Initially, a 12-lead ECG and a long continuous recording with use of the lead that shows distinct P waves (usually leads II, III, aVF, V_1, or aVR) is recorded and analyzed. The ECG obtained during an episode of arrhythmia may be diagnostic by itself, obviating the need for further diagnostic testing. **Flowchart 1** depicts an algorithm for diagnosis of specific tachyarrhythmias from the 12-lead ECG. The following important questions are to be asked in order, while analyzing an ECG with a tachyarrhythmia. Once these questions have been addressed, one needs to assess the significance of the arrhythmia in view of the clinical setting. Should it be treated, and if so, how?

- *What is the QRS duration?* In general, if the QRS is narrow (duration <120 ms, referred to as narrow-complex tachycardias) during the tachycardia, the ventricle is being activated via the normal His-Purkinje system and thus the origin of the tachycardia is supraventricular. A wide QRS (duration exceeding 120 ms) during tachycardia suggests VT or a SVT in specific scenarios. SVT with a concurrent bundle branch block (BBB) or intraventricular conduction defect can produce wide-complex tachycardias despite a supraventricular origin. A narrow-complex tachycardia almost always makes the diagnosis of SVT, but a wide-complex tachycardia can be supraventricular or ventricular. Fusion or capture beats and AV dissociation are diagnostic of VT but are often not present or are difficult to detect.
- *What is regularity of rhythm?* An irregularly irregular rhythm point toward AF. A regular or a regularly irregular rhythm can be seen in either SVT's or VT's.
- *What is characteristic of P waves?* P-wave morphology, association with QRS complexes, atrial rate, P-R and R-P intervals and the response of the P waves to carotid sinus massage, or adenosine further helps to narrow down the differential diagnosis of the tachyarrhythmia.

SUPRAVENTRICULAR TACHYCARDIAS

A SVT is a paroxysmal tachycardia arising above the level of His bundle. It is a commonly encountered tachycardia in emergency department. Sinus tachycardia and paroxysmal supraventricular tachycardia (PSVT) are mostly without complication easily manageable. Atrial flutter and AF are serious tachycardias. Patient with multifocal atrial tachycardia (MAT) usually has underlying pulmonary or cardiac disease. PSVT is classified on the basis of the specific conduction pathway involved: atrioventricular reentry tachycardia (AVRT) and atrioventricular nodal reentry tachycardia (AVNRT).

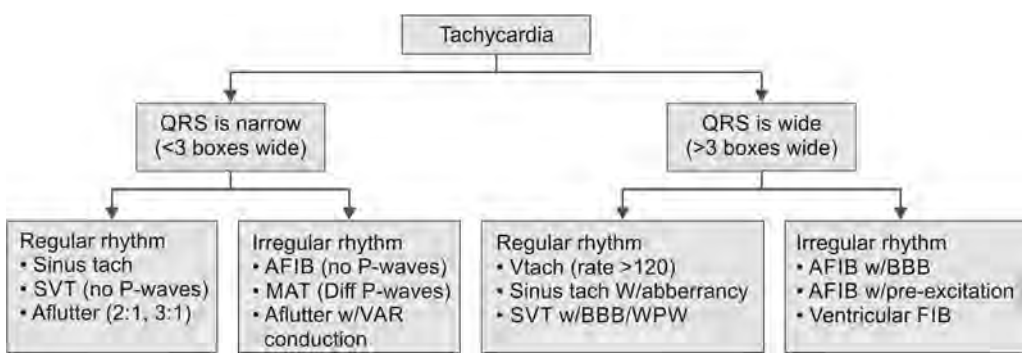
Clinical Presentation

Common complaints by patient are Increased heart beats anxious feeling, dizziness, chest heavy ness/discomfort, and pulsatile feeling in neck breathlessness.

Supraventricular tachycardia is usually seen in a structurally normal heart and in the presence of precipitating factors such as excessive intake of coffee, alcohol, or thyroid dysfunction.

Clinical Approach of a Patient with a SVT

A detailed patient's history physical examination is important to rule out structural heart disease (**Table 1**). History regarding duration and frequency of episodes, possible precipitating factors (caffeine, exercise, etc.) History of heart and lung



FLOWCHART 1: A simplified approach to tachyarrhythmias.

TABLE 1: Differentiating features of SV tachycardia.

Tachycardia	*Age*	*Underlying conditions*	*Presentation*	*Baseline ECG*
Paroxysmal SVT	All ages	Structurally normal heart	Fast onset and offset palpitation	Preexcitation common in AVRT
Atrial fibrillation **Atrial flutter** **Multifocal atrial tachycardia**	>50 years	HTN, IHD, RHD, pulmonary disease	Abrupt onset and offset irregular palpitation	LVH repolarization abnormalities
Sinus tachycardia	10–30 years	Normal heart	Progressive onset and slow termination	Normal

(AVRT: atrioventricular reentry tachycardia; ECG: electrocardiogram; HTN: hypertension; IHD: Ischemic heart disease; LVH: left ventricular hypertrophy; RHD: rheumatic heart disease)

disease should be obtained, SVT is sudden in onset and offset. Sinus tachycardia accelerates and decelerates gradually.

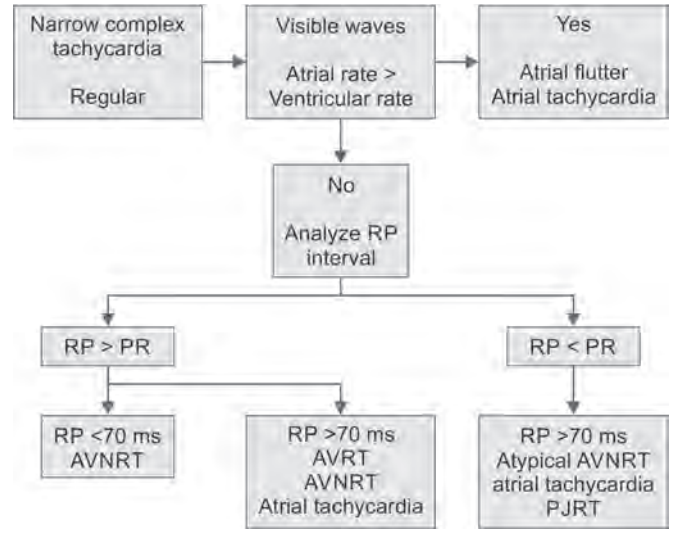
An echocardiography is helpful to rule out structural heart disease. Laboratory investigations such as serum electrolytes, thyroid profile can identify precipitating factors. *An Electrophysiological study (EPS) is done to identify the exact mechanism of the arrhythmia and catheter ablation is reserved for patients with drug resistant SVT, SVT associated with syncope, wide QRS tachycardia and individuals who do not wish to take long term medications.*

Electrocardiographic Findings

Supraventricular tachycardias present with narrow complex tachycardia with QRS duration of <120 ms. Few cases of SVT cases can have a QRS duration of >120 ms (**Flowchart 2**).

Types of Supraventricular Tachycardia

- *Atrioventricular Nodal Reentry Tachycardia:* AV nodal reentry tachycardia has a rate between 150 and 230 beats/min. The R-R interval is regular and a retrograde P wave may be present. The retrograde P wave may be difficult to distinguish in the standard ECG trace. PSVT may produce aberrant conduction and a widened QRS The reentrant pathway is functionally permitted by a fast and slow pathway that exists within the AV node.
- *Atrioventricular reentry tachycardia:* AVRT is due to a concealed AV bypass tract which creates the re-entrant circuit. The AV bypass tract usually allows retrograde conduction only.
- *Sinus node and intra-atrial reentry tachycardia (IART):* IART is commonly seen in postcardiac surgery patients caused by reentry in sinus node and atria, respectively.
- *Wolff–Parkinson–White syndrome (WPW):* Activation of ventricular muscle by impulses originating in atria and conducted by bypass tracts causes preexcitation. Many forms of aberrant connections are possible. These patients present with episodic SVT. Specific ECG abnormalities can be elicited: PR interval < 120 ms, delta wave—slurring of the initial part of QRS complex, QRS duration >120 ms, an association of WPW is seen with mitral valve prolapse syndrome (MVPS), ischemic heart disease (IHD), hypertrophic obstructive cardiomyopathy (HOCM), sick sinus syndrome, Epstein's anomaly, and rheumatic fever.



FLOWCHART 2: Electrocardiographic approach to narrow complex tachyarrhythmia.

Treatment of Supraventricular Tachycardia

Vagal Maneuvers

Carotid sinus massage stimulates baroreceptors triggering a reflexive increase in the activity of the vagal nerve and sympathetic withdrawal. Both of these causes, a slowing conduction through the AV node, thus helping in blocking reentry. A physical examination to rule out a carotid bruit is necessary. Resuscitation equipment should be ready. Attach the monitor for continuous ECG monitoring. Pressure is applied in a firm circular manner at the level of the cricoid cartilage for about 5 seconds. Repeat the procedure on the opposite side, if the tachyarrhythmia persists.

Drug Therapy

Antiarrhythmic drugs which are helpful for immediate control and long-term maintenance therapy are summarized in **Tables 2** and **3**.

Catheter Ablation

Catheter ablation has a very high success rate (>95%) and a low recurrence rate (<5%) in patients with accessory pathways.

TABLE 2: Drugs therapy for immediate control of SVT.

Drugs	*Doses*	*Side effects*
	SVT without preexcitation	
Adenosine	Give 6 mg rapid intravenous followed by fluid bolus; if no response within 1–2 min, give 12 mg more	Facial flushing, chest pain, and hypotension common; transient asystole bronchospasm, atrial fibrillation, and ventricular fibrillation
Verapamil	5 mg every 3–5 min, to max 15 mg	Hypotension, heart block, and inotropic effect negative
Diltiazem	0.25 mg/kg of body weight over a 2-min period; if no response, additional dose of 0.35 mg/kg over a 2-min period; maintenance infusion of 5–15 mg/h	Hypotension, heart block, and inotropic effect negative
Metoprolol	5 mg over a 2-min period; up to 3 doses in 15 min	Hypotension, heart block, and bradycardia bronchospasm
	SVT with preexcitation or WPW with AF	
Procainamide	30 mg/min continuous infusion to a maximal dose of 17 mg/kg (maintenance infusion of 2–4 mg/min)	Hypotension, widening of QRS complex, torsade de pointes
Flecainide	2 mg/kg over a 10-min period	Negative inotropic effect conducting atrial flutter, widening of QRS
Ibutilide	*If ≥60 kg*: 1 mg over a 10-min period *If <60 kg*: 0.01 mg/kg over a 10-min period Repeat once if no response after 10 min	Prolongation of QT interval, torsade de pointes

TABLE 3: Drugs for long-term management of SVT.

Drugs	*Doses*	*Side effects*	*Contraindication*
		SVT without preexcitation	
Beta-blockers			
Metoprolol	50–200 mg daily	Hypotension and heart block	Asthma, CHF
Atenolol	80–240 mg daily		
Calcium channel blockers			
Diltiazem	180–360 mg daily	Hypotension and heart block	CHF
Verapamil	120–480 mg daily		
Digoxin	0.125–0.375 mg daily	Digitalis toxicity	Preexcitation
		SVT with preexcitation	
First-line drugs			
Flecainide	100–300 mg daily	VT enhanced AV nodal conduction interaction with digoxin	Ischemic and structural heart disease
Propafenone	450–900 mg daily		
Second-line drugs			
Amiodarone	200 mg daily	Skin discoloration thyroid dysfunction GI pulmonary and hepatotoxicity corneal deposit tremor optic neuritis	
Sotalol	160–320 mg daily	Hypotension heart block bradycardia	

Complications of catheter ablation include perforation, bleeding, AV fistula, venous thrombosis, pulmonary embolism, myocardial perforation, valve damage, systemic embolism and rarely, death.

VENTRICULAR TACHYCARDIAS

Ventricular tachycardias are the common cause for sudden cardiac death. They are aberrant cardiac rhythms from single premature ventricular complexes (PVC) to sustained monomorphic VT, polymorphic VT, and ventricular fibrillation (VF). Ischemic and dilated cardiomyopathies are the common cause for VT. Patient should be investigated for the presence of underlying structural heart disease as the prognosis depends on it.

Clinical Approach of a Patient with a Wide Complex Tachycardia

QRS >120 ms in ECG is called wide complex tachycardia and are common in clinical practice. Wide QRS complex is seen in VT, SVT with aberrancy or BBB, and SVT with antegrade conduction over an accessory pathway (preexcited tachycardia). Drug toxicities and electrolyte imbalances are also presenting as QRS abnormalities.

Medical history and physical examination are very important and helpful in diagnosis. A history of angina, myocardial infarction, or congestive cardiac failure is strong indicators for the presence of VT. Young patients are more likely to have idiopathic VT. Hemodynamic tolerance for the arrhythmia is a poor guide to diagnosis as both SVT and VT can present with hemodynamic collapse. On the contrary, idiopathic VT's may be well-tolerated hemodynamically.

Clinical examination of the patient can help in differentiating and categorizing these patients. Clinical signs of AV dissociation include 'cannon A' wave in the jugular venous pulse, variability in the intensity of the first heart sound and variability in arterial blood pressure. Vagal maneuvers that result in termination of tachycardia indicate the presence of SVT. However, these tests are not very reliable as a few VT's can also terminate with vagal maneuvers.

Electrocardiographic Findings

Various electrocardiographic features are suggestive of VT (**Table 4**):

- Atrioventricular dissociation, fusion or capture beats, QRS width [left bundle branch block (LBBB) >160 ms and right bundle branch block (RBBB) >140 ms]
- Extreme left axis, concordance in all precordial leads, LBBB morphology with right axis deviation

Types of Ventricular Tachycardia

Monomorphic Ventricular Tachycardia

Various structural heart diseases are known to predispose to monomorphic VT. The scars present in the myocardium act as substrates for reentry. Large ventricular scars seem to predispose more frequent VT's. The most common substrate for VT is ventricular scarring related to IHD, which is present in approximately 60% of patients. Patients with dilated cardiomyopathies, ARVC, prior cardiac surgery (particularly for correction of congenital anomalies or valve surgery), sarcoidosis, or hypertrophic cardiomyopathy can also have ventricular scarring and VT.

Polymorphic Ventricular Tachycardia

Polymorphic VT or torsade de pointes is characterized by a changing of the QRS morphology from beat to beat. The term literally means "twisting of points." It is commonly a sustained arrhythmia often requiring emergency cardioversion. It can be self-limiting in some patients. Evaluation of the underlying substrate for polymorphic VT is important. Acute ischemia is common cause of polymorphic VT in most cases. Other conditions associated with polymorphic VT are long QT syndrome and Brugada syndrome. Coronary angiography is an important investigation to exclude ischemia. Correction of electrolyte abnormalities is also a very important step. Special consideration should be given to hypokalemia and hypomagnesemia. Stabilization of heart failure is of utmost importance. Amiodarone is also effective in controlling episodes of polymorphic VT.

Management of Ventricular Tachycardias

Acute Management

The initial management of a patient with sustained monomorphic VT caused by underlying structural heart disease is determined by the nature of the symptoms and the patient's hemodynamic state. Patients presenting with hemodynamic instability, myocardial ischemia, and pulmonary edema should be promptly electrically cardioverted. Reversible causes of VT, such as electrolyte imbalances, acute ischemia, hypoxia, and drug toxicities should be corrected.

In patients who are hemodynamically stable, pharmacological reversion of VT can be attempted. Lidocaine is the first-line agent and is very useful in the setting of myocardial ischemia. In other settings, especially in patients with slow and stable VT not related to ischemia, the efficacy of lidocaine is limited. Intravenous procainamide is a better choice in such patients. Procainamide has the ability to rapidly slow and terminates VT in the nonischemic setting. Use of procainamide is limited by hypotension, which occurs in approximately 20% of these individuals. Overall, it is acutely effective in 75% patients. Amiodarone is also useful, but its onset of action is slower than lidocaine or procainamide. If used it should be loaded with an intravenous dose and still the results of acute termination studies have been variable. However, at many centers' amiodarone is preferred as it is less likely to produce hypotension and prolong QTc predisposing to torsade de pointes.

Secondary Prevention

Recurrence of VT is frequent problem. Medical therapy can also be beneficial in the secondary prevention of VT. Mexiletine can be used as a second-line therapeutic agent for recurrent ventricular arrhythmias, particularly in combination

TABLE 4: ECG differences between SVT and VT.

Features in favor of SVT	*Features in favor of VT*
• Initiation with a premature P wave	• Initiation with a premature QRS complex
• Tachycardia complexes identical to those in resting rhythm	• Tachycardia beats identical to PVCs during sinus rhythm
• Long-short" sequence preceding initiation	• "Short-long" sequence preceding initiation
• Changes in the P-P interval preceding changes in the R-R interval	• Changes in the R-R interval preceding changes in the P-P interval
• QRS contours consistent with aberrant conduction (V_1 and V_6)	• QRS contours inconsistent with aberrant conduction (V_1 and V_6)
• Slowing or termination with vagal maneuvers	• AV dissociation or other non-1:1 AV relationship
• Onset of the QRS to its peak (positive or negative) <50 ms	• Onset of the QRS to its peak (positive or negative) ≥50 ms
• Fusion beats, capture beats QRS duration ≤0.14 s	• QRS duration >0.14 s, left axis deviation (especially −90–180°)

(PVC: premature ventricular complex; SVT: supraventricular tachycardia; VT: ventricular tachycardia)

TABLE 5: Classification of antiarrhythmic drugs.			
Class I: Membrane stabilizing (Na channel blockers) • Class I A—Moderately prolong conduction • Class I B—Minimal effect on conduction • Class I C—Marked prolongation of conduction	**IA** • Quinidine • Procainamide • Disopyramide	**IB** • Lidocaine • Mexiletine	**IC** • Propafenone • Flecainide
Class II (blockade of β-adrenergic receptors)	• Propranolol • Esmolol • Sotalol (Class III properties also)		
Class III (prolongation of repolarization)	• Amiodarone • Dronedarone • Dofetilide • Ibutilide		
Class IV (calcium channel blockers)	• Verapamil • Diltiazem		
Drugs for paroxysmal supraventricular tachycardia	• Adenosine • Digoxin		

with other antiarrhythmic medications (**Table 5**), although adverse effects can limit its use. Catheter ablation is an option in patients who have recurrent VT or shocks in spite of optimal medical therapy or who have unacceptable side effects with medical therapy. Catheter ablation can also be lifesaving in patients with incessant VT. Catheter ablation is also beneficial in controlling recurrent VT in patients with dilated cardiomyopathies and ARVD. Implantable cardioverter-defibrillators (ICDs) effectively treat ventricular arrhythmias. But ICDs provide inappropriate shocks and can produce a huge psychological impact as well as increase mortality.

SUMMARY

Cardiac arrhythmia is a common terminology used for any of a heterogeneous group of conditions in which there is abnormal electrical activity in the heart. Clinical presentation of arrhythmias may vary from mild, i.e., only irritating symptoms such as an awareness of the heart beating very fast to potentially life-threatening conditions such as a stroke or cardiac arrest. Emergency physician must keep in mind that an arrhythmia is only part of a patient's presentation, and before analyzing the arrhythmia the patient should be assessed and airway, breathing, and circulation (ABC) must be maintained. Systematic approach when managing an arrhythmia, finding the components of the ECG complex and their relationship can simplify its description. Knowledge of how arrhythmia treatments work makes their effects on the patient clearer. The ability of emergency physician to follow clear and scientifically derived guidelines for management of cardiac arrhythmias optimizes the patient's chances of survival.

69
CHAPTER

Cardiomyopathies

Jamal Yusuf, Saurabh Sharma, Bhushan Shah

INTRODUCTION

Cardiomyopathies are a group of diseases of various etiologies in which cardiac structure, myocardial functions, and electrical properties of the heart are grossly disturbed. In 2006, American heart association scientific statement proposed the following definition:

> *"Cardiomyopathies are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electric dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders."*

Primary cardiomyopathies are generally familial and myocardium is affected most common causes of primary cardiomyopathies are summarized in **Table1**. AHA classified primary cardiomyopathies as genetic, mixed, and acquired. Secondary cardiomyopathies usually involve heart muscle and mostly associated with systemic cause **Table 2**.

PATHOPHYSIOLOGY

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is characterized by a thickened but nondilated left ventricle in the absence of another cardiac or systemic condition (e.g., aortic valve stenosis, systemic hypertension, and some expressions of physiologic athlete's heart) capable of producing the magnitude of left ventricular (LV) hypertrophy evident. Left ventricular outflow tract (LVOT) obstruction is major hallmark of the disease with dynamic gradient of 30 mm Hg at rest or with exercise. It is caused by systolic anterior motion (SAM) of mitral valve resulting in contact with ventricular septum in mid systole due to drag effect, ultimately resulting in dynamic subaortic obstruction. HCM has autosomal dominant inheritance and is known to be caused by mutations in genes encoding proteins for thick and thin filaments of cardiac sarcomere. Most commonly β-myosin heavy chain (MYH7) and myosin-binding protein C (MYBPC3) genes are involved.

Dilated Cardiomyopathy

The European Cardiac Society has defined dilated cardiomyopathy (DCM) as dilatation of the left or both ventricles that is not explained by abnormal loading conditions or coronary artery disease. It is characterized by cardiac enlargement with normal thickness of ventricular walls and varying extents of fibrosis resulting in systolic and varying degrees of diastolic dysfunction. It can be caused by genetic mutations (usually autosomal dominant inheritance), toxins, e.g., alcohol and myocarditis.

Arrhythmogenic Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterized by fibrofatty replacement of the myocardium.

TABLE 1: Primary cardiomyopathies.

Genetic	*Mixed (genetic and nongenetic)*	*Acquired*
• Hypertrophic cardiomyopathy • Arrhythmogenic right ventricular cardiomyopathy • Left ventricular noncompaction • Glycogen storage disease • Conduction system defects *(Long QT syndrome, Short QT syndrome Brugada syndrome)* • Mitochondrial myopathies • Ion channel disorders	• Dilated cardiomyopathies • Restrictive nonhypertrophied cardiomyopathy	• Inflammatory (myocarditis) • Stress-provoked (Takotsubo) • Peripartum • Tachycardia induced • Infants of insulin-dependent diabetic mothers

TABLE 2: Causes of secondary cardiomyopathies.	
Infectious causes	Viral (Adenovirus, Coxsackie virus, HIV, CMV, and influenza virus), bacterial (streptococci), spirochaetal (syphilis), Rickettsia, parasitic (trypanosomiasis-Chagas disease)
Toxins	Ethanol. Chemotherapeutic agents *(doxorubicin)*, antiretroviral agents *(zidovudine and didanosine)*, phenothiazines, cocaine, and methamphetamine
Deposition disease	Amyloidosis and hemochromatosis
Autoimmune disorders	Scleroderma, systemic lupus erythematosus, rheumatoid arthritis, and dermatomyositis
Metabolic	• Endocrine disorders-*(diabetes mellitus, hypothyroidism, hyperthyroidism)* • Nutritional *(thiamine, carnitine, and selenium) and electrolytes (hypophosphatemia and hypocalcemia)*
Neuromuscular dystrophies	Muscular dystrophies, Friedreich's ataxia

TABLE 3: Clinical features of cardiomyopathies with systolic and diastolic dysfunctions.	
Cardiomyopathies with systolic and diastolic dysfunction	**Cardiomyopathies with diastolic dysfunction**
Dilated cardiomyopathies: Presents with congestive heart failure, chest pain, and regurgitation murmur with left ventricular hypertrophy and poor R wave progression in electrocardiograph	**Hypertrophic cardiomyopathies**: Presents with dyspnea, chest pain palpitation, syncope pulsus bisferiens, and ejection systolic murmur with features of left ventricular hypertrophy and large septal Q wave in electrocardiograph
Myocarditis: Presents with fever tachycardia, chest pain, and myalgias with nonspecific ST-T changes in electrocardiograph	**Restrictive cardiomyopathies**: Presents with feature of heart failure with preserved ejection fraction with low voltage QRS conduction abnormalities and atrial fibrillation

It is caused by mutations in genes encoding plakophilin 2 (*PKP2)*, desmoglein 2 *(DSG2),* and desmoplakin (*DSP)*. There is increasing incidence of LV involvement as well.

Restrictive Cardiomyopathies

It is characterized by nondilated left or right ventricle with diastolic dysfunction. It is mainly caused by cardiac amyloidosis, cardiac sarcoidosis, or hemochromatosis. Amyloidosis is caused by the extracellular deposition of a misfolded protein as amyloid which causes cardiac dysfunction. Sarcoidosis is a multisystem granulomatous disease of unknown etiology. Noncaseating granulomas are the histological hallmark. It frequently invades the conduction system and causes atrioventricular block and sometimes sudden death.

Other Cardiomyopathies

Exact pathophysiology of *takotsubo cardiomyopathy* is not known. It is hypothesized that emotional and physical stress result in release of catecholamines and neuropeptide Y which have direct cardioinhibitory effects and result in acute microvascular dysfunction. *Left ventricular noncompaction (LVNC)*—LVNC is caused by premature arrest of normal myocardial compaction resulting in persistence of embryonic trabeculated myocardium.

CLINICAL PRESENTATION

The cardiomyopathies usually present in emergency department as signs of systolic or diastolic ventricular dysfunctions. Dyspnea, angina syncope, heart failure (HF) arrhythmias, and sudden cardiac death (SCD) are common features and summarized in **Table 3**.

- *Dyspnea*: It is frequent presenting complaint in patients with cardiomyopathy and may be due to either systolic or diastolic dysfunction as manifestation of HF with reduced ejection fraction (EF) or with preserved EF respectively.
- *Angina*: Frequently patients with HCM can present with exertional angina due to dynamic LVOT obstruction. *Syncope*—syncope can be exertional as in HCM due to LVOT obstruction or can be arrhythmic, e.g., due to VT which may be the first presentation in many of the cardiomyopathies. *Sudden cardiac death*—many of the cardiomyopathies such as ARVC, HCM, amyloidosis, and sarcoidosis can present catastrophically as SCD.
- *Heart failure:* Cardiomyopathies frequently present with HF with reduced EF, e.g., DCM, LVNC, ARVC, burnt out HCM, or with HF with preserved EF, e.g., restrictive cardiomyopathies (RCM) and HCM.
- *Arrhythmias*: Cardiomyopathies frequently present with arrhythmias, e.g., VT, VF which may be life threatening, e.g., in HCM, ARVC, amyloidosis, and sarcoidosis.
- *Heart block:* It is commonly seen in sarcoidosis due to conduction system involvement requiring permanent pacemaker implantation.
- *Stroke and thromboembolism*: These are frequent in LVNC. However, there is no consensus on anticoagulation in LVNC patients.

DIAGNOSTIC EVALUATION

Echocardiography

Echocardiographic evaluation is the first step in diagnosis and is fairly accurate in recognition of these cardiomyopathies.

- *Systolic dysfunction*: It is characterized by a decrease in myocardial contractility. Cardiac output is maintained by LV enlargement and Frank-Starling relationship resulting in higher stroke volume. However, when these compensatory mechanisms fail cardiac output decreases, resulting in HF. Systolic dysfunction is characteristic of DCM. It is also seen in end stage HCM due to progressive LV wall thinning.
- *Diastolic dysfunction*: It is characterized by dysfunction in LV relaxation resulting in filling abnormalities and elevated filling pressures. It may or may not be accompanied by systolic dysfunction. It is characteristically seen in HCM and restrictive cardiomyopathy.

- *Hypertrophic cardiomyopathy* is characterized by LV wall thickness of 15 mm or more. Doppler imaging generally reveals resting gradient of 30 mm Hg or more. SAM of mitral valve can be easily seen on M-mode echocardiogram.
- *Dilated cardiomyopathy* is seen as varying degrees of LV dilation with systolic and diastolic dysfunction.
- *Arrhythmogenic cardiomyopathy* is characterized by regional RV akinesia, dyskinesia, or aneurysm. *Left ventricular noncompaction* is seen as thick noncompacted layer of myocardium with deep recesses.
- *Restrictive cardiomyopathy* is characterized by biatrial enlargement with diastolic dysfunction with preserved systolic function. Amyloidosis is generally characterized by LV hypertrophy and speckled appearance of the myocardium. Sarcoidosis is seen as marked thinning and increased echogenicity of basal septum which is characteristic, however, at times it seen as global LV hypokinesia with LV dysfunction.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (CMRI) is very helpful in diagnosis as well as risk stratification. In cases of borderline hypertrophy, CMRI may be helpful in differentiating HCM from athlete's heart. CMRI reveals late gadolinium enhancement (LGE) in HCM. LGE >15% of LV mass is independent predictor of SCD in HCM and its presence should be considered as need for implantation of ICD (implantable cardioverter defibrillator) for primary prevention of SCD. In LVNC, >20% of LV mass is trabeculated is one of the criteria for diagnosis along with ratio of noncompacted to compacted layer of 2.3:1. CMRI is very accurate in assessing RV dilatation and dysfunction, thus making it useful in diagnosis of ARVC. CMRI has very high spatial and soft tissue resolution. It can differentiate myocardial edema and scar. It is one of the preferred imaging modalities in sarcoidosis. Circumferential subendocardial LGE most noted at the base and middle of the ventricle is frequently seen in cardiac amyloidosis on CMRI.

Other Diagnostic Tools

Positron emission tomography (PET) imaging helps in measuring disease activity and monitoring response to treatment particularly in cardiac sarcoidosis and other inflammatory conditions.

Holter monitoring helps in risk stratification for SCD in cardiomyopathies. Multiple or repetitive nonsustained VT in HCM is independent predictor of SCD. Nonsustained or sustained ventricular tachycardia of left bundle-branch morphology with superior axis is one of the major criteria for ARVC diagnosis.

TREATMENT

Treatment of acute HF is described in another chapter "acute HF" while *chronic HF drug therapy consists of diuretics, angiotensin-converting enzyme inhibitors (ACEI) β-blockers* and other drugs summarized in **Table 4** mainstay of treatment for HF with reduced EF (HFREF) or preserved EF (HFPEF).

Prevention of Sudden Cardiac Death

Implantable cardioverter defibrillator implantation for both primary preventions based on risk stratification and secondary prevention should be undertaken. For patients with recurrent ventricular tachycardia, epicardial catheter ablation may be effective in ARVC. *Mechanical circulatory support (MCS), e.g., left ventricular assist devices (LVAD)* can be considered in patients with intractable HF as destination therapy or as bridge to transplant. Patients with intractable HF may require cardiac transplantation.

TABLE 4: Drug therapy for cardiomyopathies with systolic and diastolic dysfunction.

Diuretics	*Furosemide* 20–40 mg once or twice up to total dose of 600 mg/day, *torsemide* 10–20 mg once up to total of 200 mg/day
β-blockers	*Carvedilol* 3.125 mg BD up to 25 mg BD, bisoprolol 1.25 mg BD up to 10 mg OD, and metoprolol succinate 12.5–25 mg OD target dose of 200 mg OD
Angiotensin-converting enzyme (ACE) inhibitors	*Enalapril* 2.5 mg daily up to max of 10 mg daily, *ramipril* 1.25–2.5 mg OD up to max 10 mg OD
Angiotensin II receptors blockers (ARBs)	*Valsartan* 40 mg BD up to 160 mg BD, losartan 12.5 mg to 50 mg OD
Mineralocorticoid receptor antagonists	*Spironolactone* 12.5–50 mg OD, eplerenone 25–50 mg OD
Angiotensin receptor neprilysin inhibitor (ARNI)	*Sacubitril/valsartan* 50 mg BD up to max of 200 mg BD has been shown to beneficial in patients with Heart failure with reduced ejection failure (HFREF)
Selected patients of dilated cardiomyopathy (DCM) with left bundle branch block (LBBB) may benefit from cardiac resynchronization therapy (CRT)	

Specific Treatment

- *Surgical myomectomy* is indicated in patients of HCM who remain symptomatic despite optimal medical management. Alcohol septal ablation can be considered in patients with prohibitive surgical risk. Novel pharmacotherapy with mavacamten, allosteric modulator of cardiac β-myosin, shows promise in relieving LVOT obstruction by causing reversible inhibition of actin myosin cross bridging.
- *Radiofrequency (RF) ablation* is a novel technique for septal reduction and can be used in patients with coronary anatomy unsuitable for alcohol septal ablation, but carries higher risk of complete heart block. Primary amyloidosis is treated with chemotherapy aimed at plasma cells. Familial amyloidosis is treated with liver transplantation and investigational therapies like tafamidis. Treatment of cardiac sarcoidosis includes glucocorticoids supplemented with other immunosuppressive agents (methotrexate, azathioprine, cyclophosphamide, and infliximab).

MECHANICAL CIRCULATORY SUPPORT

Mechanical circulatory support devices are mechanical pumps designed to assist or replace the function of either the left (LVAD) or the right ventricle, or both ventricles, of the heart. European Society of Cardiology 2016 Recommendations for implantation of MCS in patients with refractory HF *are as* bridge to

transplant, and as destination therapy. A preimplant creatinine clearance of <30 mL/min/m^2 is associated with a 22% 3-month mortality in recipients of a continuous-flow LVAD, and is a contraindication to durable LVAD implantation. The presence of portal hypertension with liver cirrhosis is a contraindication to initiating MCS support. High-fixed PVR (thresholds vary from 3 to 6 wood units) is a contraindication to heart transplantation and consequently to use of LVAD. Eligibility criteria for LVAD implantation are discussed in **Box 1**.

Design of the Ventricular Assist Device

Ventricular assist devices share a number of basic components **Figure 1**. All systems for left-sided support of an inflow cannula that drains blood from the heart (from the LV apex or from the left atrium via the right superior pulmonary vein or transseptal approach) to the pump and an outflow cannula that carries blood back to the arterial system by way of the aorta or femoral, axillary, or carotid artery. The power supply for implantable pumps is delivered through a percutaneous lead that traverses the skin and connects the external power system with the internal pump. The external components of an implantable system consist of a power source and a small, portable computer (controller) that controls device speed and monitors device function. Various devices are discussed in **Table 5**.

BOX 1: Eligibility criteria for implantation of left ventricular assist device (LVAD).

Patients with >2 months of severe symptoms despite optimal medical and device therapy and more than one of the following:

- LVEF < 25% and, if measured, peak VO_2 <12 mL/kg/min
- ≥3 HF hospitalizations in previous 12 months without an obvious precipitating cause
- Dependence on intravenous inotropic therapy
- Progressive end organ dysfunction (worsening renal and/or hepatic function) due to reduced perfusion and not to inadequate ventricular filling pressure (PCWP ≥ 20 mm Hg and SBP ≤ 80–90 mm Hg or CI ≤ 2 L/min/m^2)
- Absence of severe right ventricular dysfunction together with severe tricuspid regurgitation

(CI: cardiac index; HF: heart failure; LVEF: left ventricular ejection fraction; PCWP: pulmonary capillary wedge pressure; SBP: systolic blood pressure; VO_2: oxygen consumption)

Device Management and Complications

- *Measuring blood pressure*: Use of a Doppler and a peripheral blood pressure cuff is the most effective means to measure blood pressure. When compared to an automated blood pressure, palpation, and auscultation, Doppler was more highly correlated with the blood pressure obtained simultaneously from direct measurement with an arterial catheter. The narrow pulse pressure observed with continuous flow LVADs minimizes the distinction between systolic and diastolic pressure, often making them imperceptible. If the peripheral pulse is not detectable, the first sound detected with a Doppler can be considered the mean arterial pressure. Detection of a palpable pulse should prompt consideration for device malfunction or insufficient pump speed.
- *Managing hypotension in LVAD Patient*: For hemodynamically unstable (hypotension and features of hypoperfusion) LVAD patient, auscultate the precordium, "whirr" sound indicates functioning of LVADs while absence of any sound indicates mechanical failure of LVADs. Do not disconnect anything, search for cause, and check batteries. Small boluses of normal saline can be given followed by inotropes (dopamine or dobutamine), if conditions not improved. Perform basic electrocardiograph, laboratory tests, and bedside Doppler. Assessment for gastrointestinal (GI) bleed and over anticoagulation should be done. Once bleeding is ruled out, pulmonary embolism or device thrombosis can be treated by heparin or tissue plasminogen activator. Chest compression can dislodge

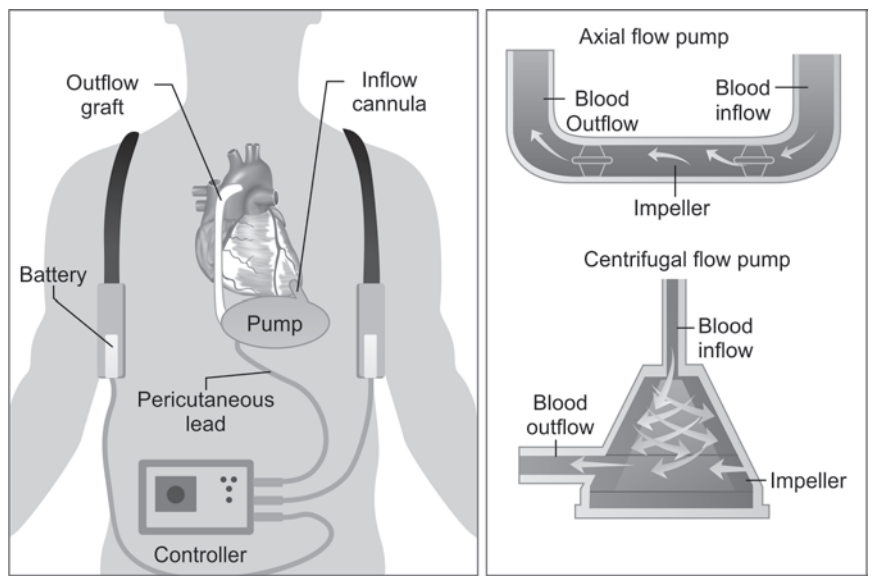

FIG. 1: Configuration of current era durable left ventricular assist devices (LVADs). Durable LVADs are implanted with the inflow cannula of the pump positioned at the left ventricular apex connected to either an axial flow or centrifugal flow device. The outflow graft is positioned in the aorta to provide flow via a continuous flow mechanism.

TABLE 5: Long-term durable mechanical circulatory support (MCS) devices.

Device	*Pump mechanism*	*Pump energy source*	*Ventricle supported*
HeartMate 3 (St Jude Medical, Minneapolis)	Continuous flow rotary pump with centrifugal design and magnetic levitation of internal impeller	• Electric motor • Power to pump delivered via percutaneous lead with external power source and computer controller	• Left ventricle • Implantable pump with intrapericardial placement
HeartMate II (St Jude Medical)	Continuous flow rotary pump with axial design with mechanical pivot support of internal impeller	• Electric motor • Power to pump delivered via percutaneous lead with external power source and computer controller	• Left ventricle • Implantable pump requiring preperitoneal pocket
HVAD (Medtronic, Minneapolis)	Continuous flow rotary pump with centrifugal design with magnetic and hydrodynamic levitation of internal impeller	• Electric motor • Power to pump delivered via percutaneous lead with external power source and computer controller	• Left ventricle • Implantable pump with intrapericardial placement • No preperitoneal pocket required
Syncardia TAH-t (SynCardia Systems, Tucson, Arizona)	Pulsatile, volume displacement (50-cc and 70-cc displacement devices)	• Pneumatic • Patient tethered to portable drive unit	Biventricular support orthotopic placement with removal of both ventricles

BOX 2: Complications of left ventricular assist device (LVAD).

- Intrinsic to the pump and its constituents:
  - Pump malfunction, controller faults, driveline faults, and short-shield malfunction
  - Related to the patient's native heart condition
  - Arrhythmias, valve insufficiency, and RV failure
- Pump-patient interface:
  - GI bleeding (acquired von Willebrand disease), infection, pump thrombosis, anemia (from bleeding or hemolysis due to erythrocyte destruction from pump, thromboembolism (stroke, pulmonary embolism, and mesenteric ischemia specially in suboptimal anticoagulation)
  - Treatment of infection is on lines of sepsis management with volume resuscitation and antibiotics. In general, LVAD-related bloodstream infections are difficult to eliminate and frequently require pump exchange or transplantation

the LVAD, and ventricular rupture and bleeding can occur. Clinical judgment should be used if chest compression is absolutely necessary and excessive deep compression should be avoided. Defibrillator pads should not be placed over LVADs drive line while using defibrillation/cardioversion as per advanced cardiac life support protocol. Complications of LVADs can be broadly divided as in **Box 2**.

- *Anticoagulation*: Contemporary LVADs are managed with both an anticoagulant (therapeutic INR 2–3) and an antiplatelet agent (aspirin).

SUMMARY

Cardiomyopathies are diverse group of conditions with varied presentations ranging from HF to SCD. Great deal of progress has been made in imaging and diagnosis of these conditions with understanding of genetics and pathophysiology. Patients presenting with cardiomyopathy need precise diagnosis utilizing the imaging modality available and risk stratification for further treatment.

70
CHAPTER

Valvular Emergencies

Rahul Mehrotra, Mayank Gupta

INTRODUCTION

"If one can hear a heart murmur in the middle of a hectic emergency department, then, by definition the murmur is significant".

This popular dictum highlights the importance of picking a murmur in the busy emergency room (ER). There are several reasons why this over simplified approach has been recommended. Out of all the emergencies encountered in the ER, a cardiac lesion giving rise to a murmur is perhaps one of the less common ones and hence likely to be missed. Besides, it is quite difficult to listen to a murmur in the hustle and bustle of the busy and noisy ER, some of which are very soft and require quiet surroundings to be audible. All murmurs are not pathological and need to be classified before deciding the significance. Murmurs need to be classified in terms of the timing (systolic, diastolic, or continuous), duration, pitch, frequency, response to certain maneuvers, etc. All these are clearly not possible to elicit given the emergency scenario and also an ER physician is not expected to be conversant with all these details. Very often the intensity of the murmur is not proportional to the severity or criticality of the lesion. For example, a diastolic murmur of acute aortic regurgitation (AR) due to proximal aortic dissection involving the aortic valve can be very soft and quite easily be missed.

As such this simplistic approach of considering any murmur picked up in the ER to be significant, rather than dismissing it or analyzing it for significance, appears as a useful strategy. It ensures that no patient with an important cardiac lesion is missed out. Besides, it also captures the frustration emergency physicians feel when trying to diagnose or manage valvular pathologic conditions with familiar yet limited tools, such as the stethoscope, chest radiograph, bedside ultrasound, and electrocardiogram (ECG).

It should be remembered that, more often, a valvular pathologic condition is a chronic, sideline issue that, nevertheless, needs to be taken into account when managing patient's other pressing needs which brings him/her to the ER. Sometimes though, the emergency physician makes a first diagnosis of a problematic heart valve by noting a previously unmentioned murmur on physical examination. *At other times, patients present to the emergency department (ED) with a known valvular disease and the valvular pathologic conditions may be at the very root of the patient's chief complaint, for example, in aortic stenosis causing syncope or acute left-sided valve failure leading to hemodynamic collapse.*

It is thus important for the ER physicians to have a working knowledge of the various cardiac diseases which can present as murmur and the approach that one needs to follow for the different types of murmurs. We discuss these concepts along with four important and common conditions which may be encountered by the ER physicians.

GENERAL CONCEPTS OF A CARDIAC MURMUR

Murmurs are generally classified as systolic, diastolic, or continuous depending on their presence in the cardiac cycle. The gap between the first and second heart sound represents systole and that between second and the subsequent first sound represents diastole. Continuous murmurs pass through/overlap with the second heart sound starting from systole. Further the systolic and diastolic murmurs are graded as depicted in **Table 1**.

Although attention needs to be paid to all murmurs picked up in the ER without any background explanation, some degree of triage can be performed if the ER physician is experienced enough. Apart from auscultation, using stethoscope, echocardiography is of paramount value in this scenario and can rapidly help to resolve the etiology of the valvular lesion,

TABLE.1: Grading of systolic and diastolic murmurs.

Systolic murmurs	***Diastolic murmurs***
Grade 1/6: Barely audible	Grade 1/4: Barely audible
Grade 2/6: Faint, but immediately audible	Grade 2/4: Faint but immediately audible
Grade 3/6: Easily heard	Grade 3/4: Easily heard
Grade 4/6: Easily heard and associated with a palpable thrill	Grade 4/4: Very loud
Grade 5/6: Very loud, heard with a stethoscope lightly on the chest	
Grade 6/6: Audible without stethoscope directly on the chest wall	

the severity of lesion causing the murmur, and associated cardiac abnormalities. There are unique advantages offered by echocardiography which make it an indispensable tool in this scenario. It is extremely safe, versatile, portable (can be carried in the ER), and the results are available instantly. Apart from echocardiography, ECG and chest X-ray are useful adjuncts that should be utilized in most patients.

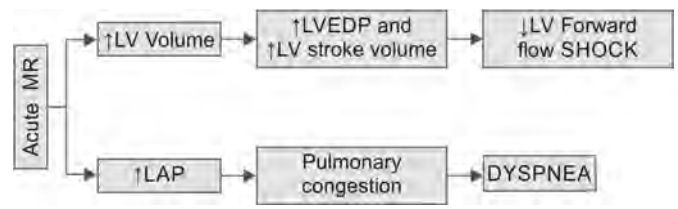
In case of chronic valvular heart diseases, the general teaching is that all symptomatic murmurs need to be evaluated further, usually by echocardiography, either immediately or at a later date. Similarly, no follow-up is needed if the murmur is midsystolic, grade II or softer, and thought to be innocent or functional by an experienced listener (**Flowchart 1**). On the contrary, an asymptomatic murmur that is diastolic, continuous, holosystolic, late systolic, and associated with ejection clicks, or that radiates to the neck or back needs to be evaluated by echocardiography.

In an emergency setting, however, this approach cannot be recommended and the decision has to be individualized based on the expertise in interpreting the murmur, availability of echocardiography facility, the history and hemodynamic status of the patient, etc. The best approach is usually to resolve any murmur heard in the ER before discharging the patient. *We discuss here four important lesions that can present in the ER with murmur.*

ACUTE MITRAL REGURGITATION

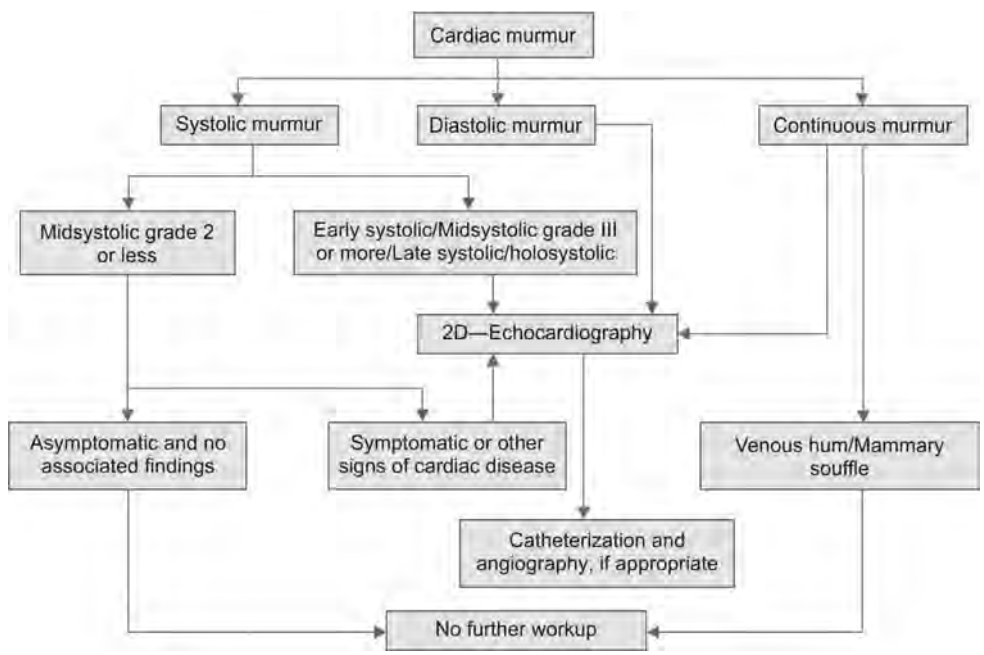
Acute mitral regurgitation (MR) is a medical and surgical emergency. Patients usually present to ED with acute severe decompensated heart failure due to the sudden pressure and volume over load imposed on a previously normal left atrium. In addition, there is an acute drop in the forward cardiac output because a major proportion of the blood pumped by the left ventricles regurgitates into the left atrium instead of flowing forward into the aorta (**Flowchart 2**). However, acute MR is often misdiagnosed as an acute pulmonary disease in the ED because of severe dyspnea, an abnormal chest radiograph and the absence of a clearly audible cardiac murmur. Acute MR typically can also be "silent," without any murmur, because of the equalization of left ventricular (LV) and left atrial pressure in midsystole.

Patients with acute MR generally present with complaints of sudden onset of severe shortness of breath with signs of congestive cardiac failure and cardiogenic shock. On examination, a hyperdynamic cardiac impulse can be palpated, along with a palpable S3, which represents a prominent LV filling wave. On auscultation, the first heart sound, S1 may be diminished while an S3 may be present as a result of increased blood flow across the mitral valve. As discussed earlier, a soft early systolic murmur that may diminish or disappear in late systole may be heard. *A systolic murmur may be entirely absent even with severe regurgitation in patients with* LV *systolic dysfunction or low systemic blood pressure*. However, in view of the clinical scenario, when the differential diagnosis includes acute MR, echocardiography can be used to confirm the diagnosis. Usually, a transthoracic echocardiogram (TTE) performed at the bedside may be sufficient to detect an acute severe MR on color Doppler but sometimes, in extremely eccentric or splayed jets, transesophageal echocardiography (TEE) will be required to detect the true severity of MR and also determine the possible etiology. The vena contracta width measurement and density of the continuous wave Doppler signal are the simplest techniques to quickly determine if significant MR is present. The continuous wave Doppler regurgitant flow velocity curve often shows the characteristic triangular (instead of rounded) shape due to a rapid decline



(LAP: left atrial pressure; LVEDP: left ventricular end diastolic pressure; LV: left ventricle)

FLOWCHART 2: Pathophysiology of acute mitral regurgitation.



FLOWCHART 1: Approach to cardiac murmurs.

in late systolic velocity reflecting the abrupt increase in left atrial pressure. There can be several etiologies responsible for causing an acute severe MR (**Table 2**). The specific features and the associated echocardiographic findings are highlighted in (**Table 3**). Acute ischemic MR is associated with a poor short-term and long-term prognosis even if the degree is only mild or moderate. Emergency coronary revascularization can reduce the magnitude of regurgitation. In patients with acute secondary MR or when the patient is too ill for immediate surgical intervention, pharmacological afterload reduction or use of mechanical circulatory support such as intra-aortic balloon pump (IABP), may be required as a bridge to recovery or to late surgical therapy, with an exception in cases of takotsubo cardiomyopathy and hypertrophic cardiomyopathy.

TABLE 2: Etiology of acute mitral regurgitation.

Acute ischemic MR	• Systolic leaflet tethering related to sudden onset severe LV dysfunction • Moderate MR progress to severe MR
Ischemic papillary muscle rupture	Associated with inferior wall MI often fatal
Infective endocarditis	Rapid valve destruction due to leaflet rupture or chordae rupture in known endocarditis
Iatrogenic	Balloon-induced trauma secondary to PTMC and TAVI/LVAD-induced trauma
Others	• Chest trauma (penetrating and nonpenetrating) • SLE • SAM in patient with takotsubo cardiomyopathy

(PTMC: percutaneous transvenous mitral commissurotomy; TAVI: transcatheter aortic valve implantation; LVAD: left ventricular assist device; SLE: systemic lupus erythematosus; SAM: systolic anterior motion of mitral leaflet)

TABLE 3: 2D echo finding of aortic regurgitation according to etiology.

Papillary muscle rupture	A ruptured muscle papillary head (observed as a triangular mass) swings back and forth between the left atrium and the left ventricle with the entire leaflet prolapsing into the left atrium in systole
Ischemic MR	Leaflet tethering along with a wall motion abnormality in the region of the culprit coronary artery and characteristics leaflet "tenting" due to papillary muscle displacement
Post TAVR	A pigtail catheter or a guidewire in the left ventricle may inadvertently hook the chordae, resulting in substantial MR
LVAD	Frequent echocardiographic evaluation of the position of the transaortic ventricular assist devices are recommended both for optimal positioning for flow and to ensure that they do not affect the mitral apparatus
Takotsubo cardiomyopathy	Apical ballooning and hyper dynamic LV basal wall induce abnormal mitral valve motion in the acute phase with the color Doppler echocardiograph showing turbulent flow due to outflow tract obstruction and the posteriorly directed by MR jet

ACUTE AORTIC REGURGITATION

Patients with acute AR, present with an abrupt onset of symptoms chiefly dyspnea, pulmonary edema, hypotension, or cardiogenic shock and may be confused with pulmonary disease as common with all acute left-sided regurgitant lesions. Acute AR may result from not just the pathology of the aortic valve, but also the aortic root, or both (**Box 1**). The pathophysiology behind symptoms related to acute AR is mainly the consequence of rise in left ventricular end diastolic pressure (LVEDP) secondary to acute AR causing signs and symptoms of cardiac failure (**Flowchart 3**).

So, a patient with acute AR will not have widened pulse pressure seen in chronic AR, because forward stroke volume (and therefore systolic blood pressure) is reduced which help us differentiating acute AR from chronic AR. One may hear a soft S1 with S3 along with brief soft diastolic murmur or a systolic flow murmur. There may be loud P2 if pulmonary hypertension sets in. One should always rule out aortic dissection if a patient present with severe chest pain along with acute AR.

Electrocardiogram shows sinus tachycardia with nonspecific ST-T wave changes but may show ischemic changes if the aortic dissection affects the coronary ostia.

Chest X Ray typically shows signs of pulmonary edema with normal heart size since the lesion is acute. However, if there is cardiomegaly, it strongly suggests chronic disease with acute worsening. Similarly, widened mediastinum on chest X-ray with acute AR usually suggests acute aortic Dissection.

Echocardiography is an important tool to evaluate acute AR with holodiastolic flow reversal in abdominal aorta and premature mitral valve closure being the hallmark of a severe lesion. Aortic dissection in echocardiography is characterized by a flap in the aorta. However, if a transthoracic study is not conclusive, TEE can reveal the mechanism and severity of the regurgitation.

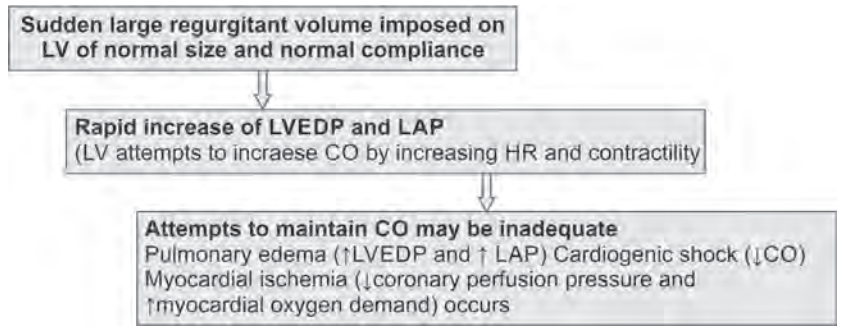
The treatment for acute AR is aortic valve repair or replacement. Medical therapy can stabilize the patient's condition before surgery, but it is not a substitute for surgery. Vasodilators such as sodium nitroprusside can be used to improve forward flow, and inotropic agents such as dobutamine can improve the patient's cardiac output. IABPs tend to be contraindicated in acute AR, because balloon inflation during diastole may impair LV hemodynamics. IABP use is specifically contraindicated in cases of aortic dissection.

PROSTHETIC HEART VALVE THROMBOSIS

Prosthetic heart valve (PVT) thrombosis (obstructive and nonobstructive) is a life-threatening complication that requires

BOX 1: Etiology for acute AR.

- Type A dissection
- Ruptured fenestration
- Blunt Trauma
- Endocarditis
- Prosthetic valve dysfunction
- Iatrogenic injury secondary to instrumentations



Sudden large regurgitant volume imposed on LV of normal size and normal compliance
Rapid increase of LVEDP and LAP
(LV attempts to incraese CO by increasing HR and contractility
Attempts to maintain CO may be inadequate
Pulmonary edema (↑LVEDP and ↑ LAP) Cardiogenic shock (↓CO)
Myocardial ischemia (↓coronary perfusion pressure and
↑myocardial oxygen demand) occurs

(LV: left ventricle; LVDP: left ventricle end diastolic pressure; LAP: left atrial pressure; CO: cardiac output)

FLOWCHART 3: Pathophysiology of acute AR.

immediate diagnosis and treatment. Despite advances in valve technology and improvements in anticoagulation therapy, the incidence of PVT ranges from 0.1% to almost 6% per patient-year for left-sided valves and up to 20% for tricuspid valves. PVT with or without prosthetic valve (PV) dysfunction is a complex *multifactorial phenomenon* which involves *three main factors involved in endovascular thrombus formation (1) surface factors, (2) hemostasis, and (3) hemodynamics-related factors* (**Table 4**).

Patients with a PV dysfunction with or without thrombosis may present with progressive dyspnea and signs of heart failure or systemic embolization**.** Normal caged valves, because of smaller orifice produce some degree of obstruction causing systolic ejection murmur, while tilting disk valves do not occlude their outflow tract completely when closed, allowing some back flow causing low intensity diastolic murmur along with metallic click. Therefore, presence of a diastolic murmur >2/4 grade or absence of metallic click is considered pathological (indicating valve thrombosis). Arterial thromboembolism (TE) after surgical or transcatheter heart valve replacement should be considered prosthesis-related until proven otherwise. Arterial TE manifests with signs and symptoms related to the arterial territory occluded by the embolism such as stroke or transient ischemic attack, acute peripheral ischemia, acute mesenteric ischemia, or acute ischemic kidney injury. PV dysfunction should be suspected in patients with symptoms of acute or subacute onset associated with an increase in transprosthetic gradient across the PHV compared with the last echocardiographic follow-up.

Transthoracic echocardiography is helpful for evaluating PV hemodynamics and valve motion (**Table 5**). However, TEE is superior to transthoracic echocardiography for evaluating PV dysfunction, regardless of the valve type (mechanical or tissue).

In patients with inconclusive transthoracic and TEE findings (which may be rather frequent), multidetector CT provides an accurate evaluation of the PV structure and functional status. Determination of the etiology of the PV dysfunction is the first step in defining subsequent treatment, i.e., surgery, thrombolytic therapy, and anticoagulation, since PV dysfunction can be a life-threatening situation.

The *management strategy (Surgery, thrombolytic therapy and/or anticoagulation)* depends on several factors. The recent European Society of Cardiology (ESC) guidelines recommend surgery on urgent or emergent basis in critically ill patient with no serious co morbidities as class I recommendation and a class II A recommendation in large >10 mm nonobstructive mechanical valve thrombosis. However, in places where surgery is not available or in high-risk patients or in thrombosis of right-sided prosthesis, *fibrinolysis with rTPA [10 mg bolus plus 90 mg over 90 minutes with unfractionated heparin (UFH)] or streptokinase (1,500,000 U in 60 minutes without UFH) should be considered (class II A recommendation).* Anticoagulation using vitamin K antagonist (VKA) or UFH has class I recommendation in patients with bioprosthetic heart valve (BHV) thrombosis and surgery should be considered when anticoagulation fails. However, reoperation has class I recommendation in patient whom there is significant increase in transprosthetic gradient across the BHV or there is significant regurgitation. Transcatheter valve-in-valve implantation in the aortic position should be considered by the heart team depending on the risk of reoperation and the type and size of prosthesis, has class II recommendation.

TABLE 4: Main causative factors for prosthetic valve thrombosis.

Surface factors	*Hemostatic factors*	*Hemodynamic factors*
• Incomplete prosthesis • Endothelialization • Leaflet damage • Stent fracture/ malposition	• HIT • Hypercoagulable state • Suboptimal anticoagulation	• Low cardiac output • Prosthesis hemodynamic profile • Hyper viscosity

(PVT: prosthetic valve thrombosis; HIT: heparin-induced thrombocytopenia)

TABLE 5: 2D echocardiography for PHV thrombosis.

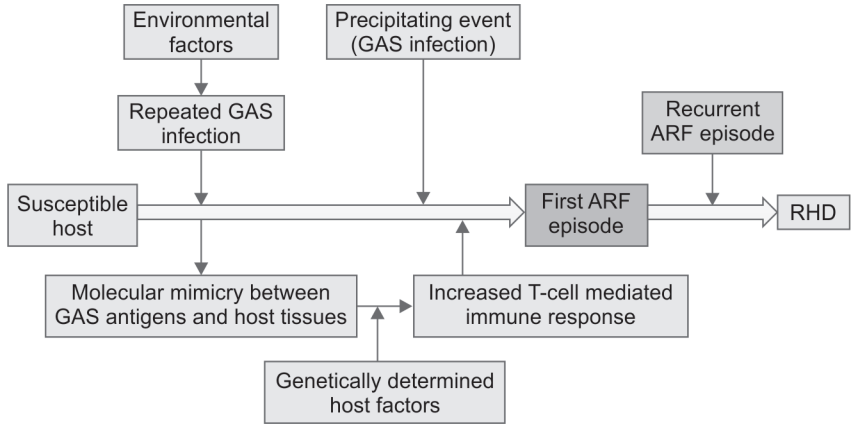
Predictors of MHV thrombosis	*Predictors of BHV thrombosis*
• Increased transvalvular gradient (aortic Pmax ≥ 50 mm Hg, Mitral Pmean ≥ 10 mm Hg) • Presence of occlusive mobile mass on prosthetic valve • An international normalized ration (INR) ≤ 2.5	• >50% increase in mean echo Doppler gradient from baseline within 5 years • Paroxysmal AF • Increased valve cusp thickness • Abnormal cusp mobility

(AF: atrial fibrillation; PHV: prosthetic heart valve)

ACUTE RHEUMATIC FEVER

Rheumatic fever is the leading cause of acquired heart disease in children and young adults worldwide. Initiated by a pharyngeal infection with *group A beta-hemolytic streptococci (GAS)* and following a latent period of approximately 2–3 weeks, the illness is characterized by acute inflammation of the heart, joints, skin, subcutaneous tissue, and central nervous system. Pathologically, the inflammatory process causes damage to collagen fibrils and connective tissue ground substance (i.e., fibrinoid degeneration), and thus rheumatic fever is classified as a connective tissue or collagen vascular disease (**Flowchart 4**). The incidence of rheumatic fever varies from 0.2 to 0.75/1,000/year schoolchildren 5–15 years of age.

A typical patient with an attack of acute rheumatic fever (ARF) is in the age group of 5–15 years and present to the ER with high-grade fever along with complaints of, migratory polyarthritis, often affecting the knees, ankles, and elbows, sparing the small joints of the hands, feet, and hips. Sydenham's chorea, although rare, may occur as an isolated manifestation of ARF. It is characterized by uncoordinated movements of the extremities and face. When it occurs after puberty, it is generally found in women. Carditis associated with murmurs from valvulitis usually is present within the first 3 weeks of ARF. The most common valvular lesion is MR causing an apical pansystolic murmur. AR is less common. Stenotic lesions are uncommon in the early stages of the disease, but a transient apical mid-diastolic murmur (Carey-Coombs) may occur in association with the murmur of MR. The patient may complain of chest discomfort from pericarditis, but isolated myocarditis or pericarditis without valvulitis is rarely seen in ARF. Subcutaneous nodules are often present over the extensor surfaces of joints of the elbows, knees, wrists, or ankles but may also appear on the Achilles tendon, occiput, and spinous processes and they may be associated with carditis. Erythema marginatum is a nonpruritic, annular rash most often found on the trunk and limbs, is usually asymptomatic and can progress to lesions with a raised border and central clearing. Although no specific test exists to confirm a diagnosis of rheumatic fever, the diagnosis is usually made using the clinical criteria first formulated in 1944 by T Duckett Jones. Since then the criteria have undergone multiple modifications, with the most recent revision by the American Heart Association (AHA) in 2015 (**Table 6**).



(GAS: group A streptococcal infection; RHD: rheumatic heart disease)

FLOWCHART 4: Pathogenesis of acute rheumatic fever.

TABLE 6: Ducket-Jones criteria.

	Low-risk population	*Moderate to high-risk population*
Major criteria	• Carditis • Arthritis (polyarthritis) • Chorea • Erythema marginatum • Subcutaneous nodule	• Carditis • Arthritis (monoarthritic, polyarthritis, and polyarthralgia) • Chorea • Erythema marginatum • Subcutaneous nodule
Minor criteria	• Polyarthralgias • Fever (≥38.5°C) • ESR > 60 mm and CRP ≥ 3.0 mg/dL • Prolonged PR interval	• Monoarthralgias • Fever (≥38.5°C) • ESR > 30 mm and CRP CRP ≥ 3.0 mg/dL • Prolonged PR interval

Joint manifestations are only considered in either the major or the minor category, but not in both categories in the same patient.

Annual acute rheumatic fever (ARF) incidence of ≤2 per 100,000 school-aged children or all-age rheumatic heart disease (RHD) prevalence of ≤1 per 1,000 people per year.

Polyarthralgia should only be considered as a major manifestation in moderate- and high-risk populations after exclusion of other causes.

C-reactive protein (CRP) value must be greater than the normal laboratory upper limit. In addition, because the erythrocyte sedimentation rate (ESR) might evolve during the course of ARF, peak ESR values should be used.

The aim of treatment of a proven attack of rheumatic fever is (1) to suppress the inflammatory response and thus minimize the effects of inflammation on the heart and joints, (2) to eradicate the GAS from the pharynx, (3) to provide symptomatic relief, and (4) to commence secondary prophylaxis. The choice of anti-inflammatory is among nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids. The appropriate dosages of anti-inflammatory agents are aspirin, 100 mg/kg/day in four or five divided doses to 60–70 mg/kg /days after symptom resolution in mild arthritis +/- carditis, and in moderate-to-severe case prednisone, 2 mg/kg/day for 2 weeks followed by tapering 2.5–5 mg every 3rd day after erythrocyte sedimentation rate (ESR) normalizes with overlapping aspirin for 12 weeks. Chorea is generally self-limiting, administration of carbamazepine or valproic acid can be considered in patients whose symptoms interfere with activities of daily living. Primary prevention of ARF requires therapy for GAS pharyngitis. Patients with ARF are at risk of developing recurrent disease in response to future upper respiratory tract infections caused by GAS. These individuals require continuous antibiotic prophylaxis for secondary prevention (**Table 7**).

SUMMARY

Ninety percent of the valvular heart disease is chronic with delayed onset of symptoms because of adaptation by the heart in form of dilatation or hypertrophy. In contrast to more common chronic presentation, acute valvular heart diseases present with dramatic symptoms and are potentially lethal. Since emergency physicians are the first point of contact in this situation, prompt diagnosis and correct treatment are essential to prevent high mortality and morbidity. The presence of a murmur is often the first clue to the presence of underlying valvular cardiac disorder. These are otherwise not very common for an ER physician to suspect. The following chapter reviews the approach to murmur and common valvular emergencies including physical diagnosis, 2D Echo findings, initial medical therapy, and definitive management.

TABLE 7: Drug therapy for prevention of acute rheumatic fever.

Antibiotics	*Administration*	*Dose*
Drug therapy for primary prevention of acute rheumatic fever		
Benzathine benzylpenicillin	Single intramuscular injection	1.2 million units, if weight <30 kg, reduce the dose by 50%
Penicillin VK	Oral for 10 days	250–500 mg three times daily for 10 days
Erythromycin ethyl succinate	Oral for 10 days	Varies with formulation
Drug therapy for secondary prevention of acute rheumatic fever		
Benzathine benzylpenicillin	Single intramuscular injection every 3–4 weeks	1.2 million units, if weight <30 kg, reduce the dose by 50% (600,000 units)
Penicillin VK	Oral	250 mg twice daily
Sulfonamides	Oral	1gram per day in patient of >30 kg 500 mg in patient of <30 kg
Erythromycin	Oral	250 mg/day

Cardiac Tamponade and Pericardiocentesis

71
CHAPTER

Laila Ali Hussein, Ayesha Almemari, Devendra Richhariya

OVERVIEW OF CARDIAC TAMPONADE

Cardiac tamponade is a complex situation in which accumulation of fluid occurs in pericardial space due to multifactorial cause. Symptoms ranging from minor to fatal situation and can be diagnosed on the basis of signs and symptoms in association with diagnostic imaging. It is very important to know if patient is in cardiac tamponade or not, so evaluate the patient of pericardial effusion for clinical manifestation of cardiac tamponade, take the help of echocardiographic imaging, and also ascertain the history if pericardial effusion developed rapidly or gradually. All these workups in patient of pericardial effusion to find out causes, which are helpful in preventing the cardiac arrest due to cardiac tamponade. Tamponade occurs when intrapericardial fluid accumulation appears more than ventricular diastolic pressure resulting in reduced myocardial compliance and intracardiac chambers. Thus, cardiac filling and cardiac output reduced. The main pathophysiology indicator of cardiac tamponade is equalization of diastolic pressures which can be confirmed by right heart catheterization.

ETIOLOGY

Various conditions can cause (**Box 1**) pericardial effusion followed by cardiac tamponade. Most commonly cause in which rapid progression occurs is traumatic while other medical cause of cardiac tamponade is gradual and more challenging to diagnose. Most common medical causes of cardiac tamponade includes malignancy, renal dysfunction, infection, connective tissue disorder, radiation, chemotherapy, or idiopathic source.

BOX 1: Causes of cardiac tamponade.

- Idiopathic
- Connective tissue disorder—systemic lupus erythematosus (SLE) and scleroderma
- Infection—viral, bacterial, fungal, and parasitic
- Malignancy
- Uremia
- Postmyocardial infarction
- Postoperative
- Radiation
- Traumatic

CLINICAL FEATURES

Apart from traumatic pericardial effusion, the signs and symptoms are neither specific nor sensitive for cardiac tamponade. A rapid deterioration and circulatory collapse should be anticipated if onset signs and symptoms are observed.

Beck triad—muffled heart sound, distended jugular vein, and hypotension pathognomonic for cardiac tamponade. This triad is more prominent in traumatic pericardial hemorrhage. Breathlessness is most common symptom followed by chest pain and palpitation. Tachycardia tachypnea distension of jugular venous pulses is common physical finding. Patient with tamponade may find exaggerated decrease in blood pressure with inspiration which is known as pulsus paradoxus but not pathognomonic of cardiac tamponade.

Findings on clinical examination which showed raised concern for deterioration are, agitation or altered mental status, worsening tachypnea (acidosis), decline in tachycardia (circulatory fatigue) poor extremities perfusion (cold and clammy), and pallor. Hypotension is late finding and not seen until impending cardiac arrest.

DIAGNOSTIC TESTING

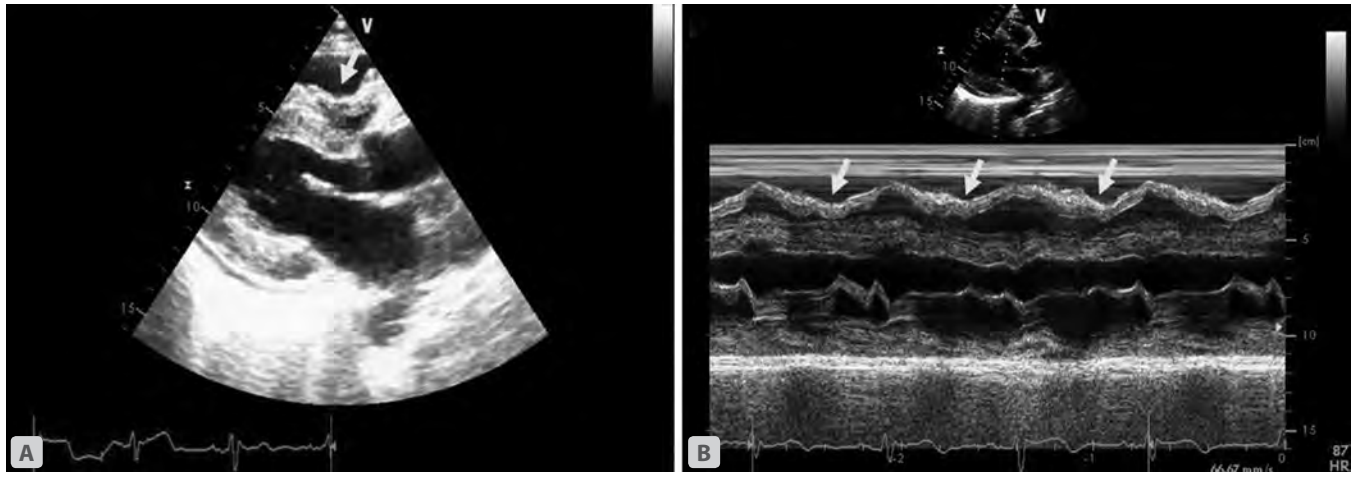
Every patient of chest pain and dyspnea should undergo basic testing of electrocardiogram (ECG), and chest radiograph. In ECG, common finding is tachycardia and low voltage. Electric alternans may present if large pericardial effusion. On chest X-ray *"water bottle heart sign"* enlarged cardiac silhouette is common findings (**Fig. 1**). Every patient of suspected pericardial effusion should be evaluated by echocardiography as per recommendation by American Society of Echocardiography,

FIG. 1: Chest X-ray "water bottle heart sign" enlarged cardiac silhouette.

American Heart Association, and American College of Cardiology. Advantages of echocardiography are its cost effectiveness, noninvasive, portable, and widely availability. For suspected cardiac tamponade, echocardiography is diagnostic modality of choice for evaluation. Bedside clinical finding and echocardiographic finding should be correlated well. Quantification by echocardiography alone might be unreliable.

Echocardiographic findings of cardiac tamponade are:

- Late diastolic RA collapse (**Figs. 2A** and **B**—2D image in apical four-chamber view, B- M-mode)
- Early diastolic RV collapse; (**Fig. 3**—2D image in PLAX view, B- M-mode)
- Significant respiratory variation in mitral inflow velocity (**Fig. 4**)
- Dilated, noncollapsing inferior vena cava (IVC) (**Figs. 5A** and **B**)



FIGS. 2A AND B: Late diastolic RA collapse; 2D image in apical four-chamber view, B- M-mode.

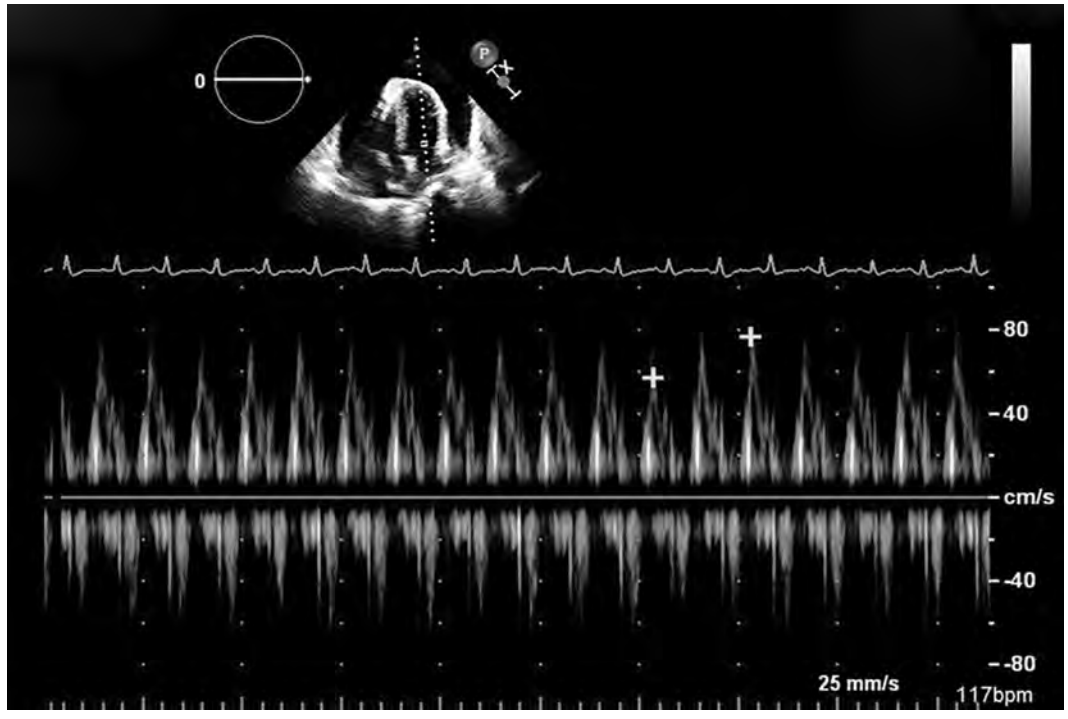


FIG. 3: Early diastolic RV collapse; 2D image in PLAX view, B- M-mode.

MANAGEMENT

Traumatic Cardiac Tamponade

Cardiac tamponade after blunt trauma chest often causes aortic dissection which is associated with high mortality. In this condition, time is very important for immediate interventions. Pericardiocentesis with controlled drainage can be attempted for stabilization. Another option is thoracotomy followed by evaluation of tamponade but it required lot of resources and trained specialist.

Hemodynamically Stable Cardiac Tamponade

Patient of cardiac tamponade, who has not yet suffered cardiovascular collapse, needs continuous cardiac monitoring, and requires resuscitation. These are temporary measure till the definitive therapy is instituted. Many patients are intravascularly hypovolemic. Initially volume challenge should be given with crystalloid fluid. Excessive amount of fluid should be avoided.

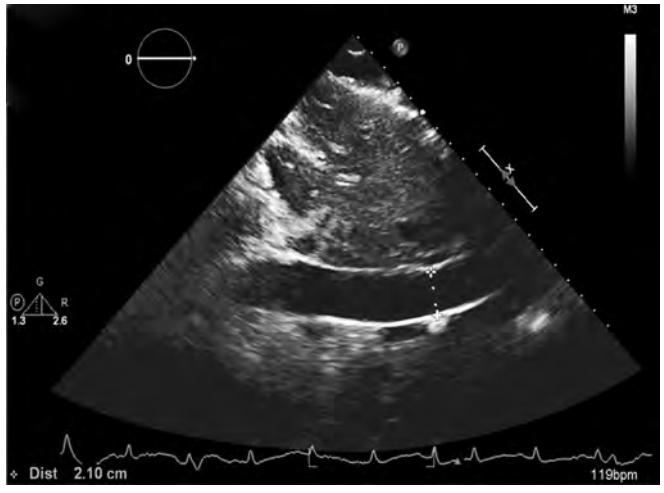

FIG. 4: Significant respiratory variation in mitral inflow velocity.

According to many studies, isoprenaline, dopamine, and dobutamine can be started so first-line agent to raise cardiac output. In case of cardiac tamponade, as no therapy is superior but mostly recommendation is initial use of dobutamine. Some researchers advocate vasopressors (e.g., norepinephrine) to improve blood pressure. The initiation of positive pressure ventilation may result catastrophic circulatory collapse due to increase of intrathoracic pressure and worsen venous return. So, mechanical ventilation may prove deadly in patient with cardiac tamponade.

Hemodynamically Unstable Cardiac Tamponade

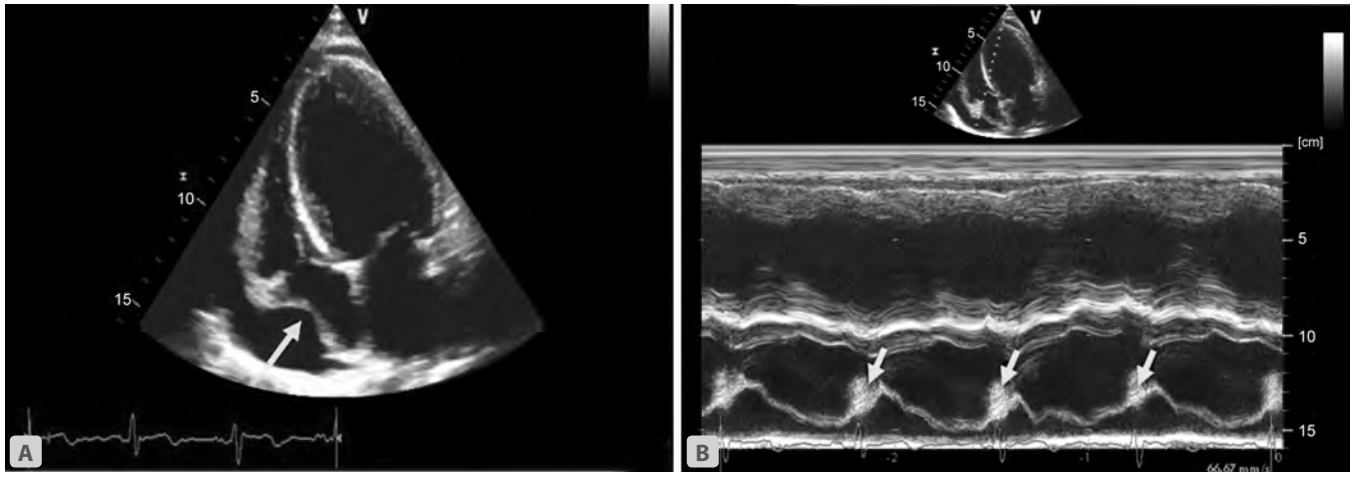
These patients can rapidly progressive to death, so these patients require urgent pericardiocentesis or operative repair. After evacuation of pericardial fluid, stability returns gradually. Evacuation of large amount of pericardial fluid is not advised. Large volume pericardial fluid leads to pulmonary edema and rapid respiratory compromise. In most causes, 50–100 mL of pericardial fluid is sufficient to restore hemodynamics.

PERICARDIOCENTESIS

For treating patient with cardiac tamponade, *three-step scoring system* (**Table 1**) has been developed by *European Society of Cardiology Working Group on Myocardial and Pericardial disease.* This scoring system is based on clinical signs and symptoms and echocardiographic findings**.** Scoring system can be used to identify the patient with immediate need of pericardiocentesis. Emergent pericardial drainage is required if score is 6 or above. Drainage can be postponed up to 48 hours if score is <6.

METHODS FOR REMOVAL OF PERICARDIAL FLUIDS

- Blind percutaneous drainage
- Ultrasound guided pericardial drainage



FIGS. 5A AND B: Dilated, noncollapsing inferior vena cava.

TABLE 1: Diagnosis of cardiac tamponade—three-step scoring system.

1. Score the etiology	*2. Score the clinical presentation*	*3. Score the imaging*
• Malignant disease 2 • Tuberculosis 2 • Recent radiotherapy 1 • Recent viral infection 1 • Recent PE history of pericardiocentesis 1 • Chronic end stage renal disease 1 • Immunosuppression 1 • Hypo- or hyperthyroidism 1 • Systemic autoimmune disease 1	• Breathlessness/tachypnea 1 • Orthopnea 3 • Hypotension 0.5 • Oliguria 1 • Pulsus paradoxus 2 • Pericardial chest pain/friction rub 0.5 each • Rapid worsening of symptoms 2 • Slow progression of disease wrire as 1	• Cardiomegaly on X-ray 1 • Electrical alternans 0.5 • Low voltage ECG 1 • Right atrial collapse 1 • Right ventricular collapse 1.5 • Inferior vena cava (IVC) plethora 1.5 • Respiratory flow variation of mitral valve1 • Swinging heart 1
Calculate the score of 1 + 2 + 3. If score is 6 or >6 perform immediate pericardiocentesis Urgent surgical management is required (irrespective of score) if type A aortic dissection, ventricular free wall rupture, uncontrolled iatrogenic hemopericardium, and severe recent chest trauma

- Percutaneous balloon pericardiotomy
- Surgical creation of pericardial window

Patient in emergency department who is hemodynamically unstable and crashing, first two methods are useful. Patient who is stable and whose tamponade is recurrent and gradual and procedure can be done as semielective with the help of cardiologist and cardiothoracic surgeon. Pericardiocentesis can be performed with a kit similar to central venous catheter kit which consists of 18-gauge spinal needle, 20 mL lock syringe and three-way stopcock. Complications are cardiac chamber perforation, coronary laceration, pneumothorax, intra-abdominal laceration, and hollow viscus injuries.

Blind Subxiphoid (Subcostal) Approach

If there is high clinical suspicion, patient rapidly deterioration, impending cardiac arrest or in pulseless electrical activity (PEA) and if ultrasonogram is not available, the safest approach in emergent situation is blind subxiphoid technique. Needle is inserted between xiphoid process and costal margin with a 30–45° angle towards left mid clavicle (**Fig. 6**).

As described earlier, central venous kit or pericardiocentesis kit if available can be used (**Fig. 7**). Initially, small amount of pericardial fluid should be aspirated so that hemodynamic can be improved and pigtail catheter can be placed which can allow further fluid removal if hemodynamic worsens.

Ultrasound-guided Approach

This is more accurate and safe method to remove pericardial fluid in cases of cardiac tamponade, if ultrasound is available (**Fig. 8**). With the help of ultrasound, largest fluid pocket is identified and aspiration is monitored in real-time throughout the entire procedure. In this process, experienced operator and good hand eye coordination is required. Ultrasound-guided approach is associated with less complications.

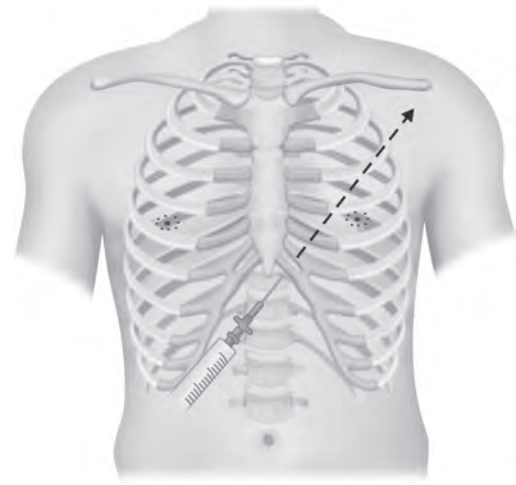

FIG. 6: Subxiphoid approach for pericardiocentesis.

FIG. 7: Emergency department pericardiocentesis kit.

SUMMARY

Traumatic cause of cardiac tamponade (rapidly developing accumulation) presents with hypotension and precipitates

FIG. 8: Ultrasound-guided pericardiocentesis.

death if not diagnosed in time, so in this special situation of cardiopulmonary resuscitation, high index of suspicion is needed. Signs and symptoms of the cardiac tamponade are found nonspecific. With the frequent use of point-of-care ultrasound, even new users can detect pericardial effusion very early and helpful during cardiopulmonary resuscitation. Right atrial and ventricular collapse, plethora of IVC swinging heart, and respiratory variation in mitral flow are highly suggestive of cardiac tamponade.

Once the cardiac tamponade is diagnosed, patient condition should be monitored very closely. Fluid challenge should be given very cautiously, appropriate medication should be given if needed. But lives can only be saved, if skilled team leader diagnoses the cardiac tamponade condition very early and performs immediate pericardiocentesis for stabilization of hemodynamics and patient gets definitive therapy.

72
CHAPTER

Cardiac Temporary Pacing

Kartikeya Bhargava

INTRODUCTION

Temporary pacing refers to electrical stimulation of cardiac chambers (usually ventricle, occasionally atrium) as part of the treatment of bradyarrhythmia or tachyarrhythmia. The underlying arrhythmia may be transient, intermittent, or persistent and the temporary pacing aims to establish adequate hemodynamics till the arrhythmia resolves completely or definitive therapy usually in the form of permanent pacing is performed. Though, most commonly, temporary pacing is performed as a lifesaving emergency measures in a patient with symptomatic bradycardia till a permanent pacemaker is implanted; there are many more indications of temporary pacing that will be discussed below.

TYPES OF TEMPORARY PACING

Temporary pacing is performed most commonly in the *ventricles* in order to provide adequate ventricular rate in patients with symptomatic atrioventricular (AV) block; but can also be performed in the *atrium* in patients with symptomatic bradycardia due to sinus node dysfunction or in patients with intact AV conduction and frequent supraventricular or ventricular tachyarrhythmias so as to prevent occurrence of the arrhythmias (ventricular fibrillation or polymorphic ventricular tachycardia) or overdrive treat the arrhythmia (supraventricular tachycardia) if it occurs. *Dual-chamber AV sequential* temporary pacing is often performed through epicardial wires in postoperative patients, though it can be performed transvenously to improve hemodynamic performance in certain patients with AV block such as those with acute inferior and right ventricular myocardial infarction (MI).

Temporary pacing can also be classified according to the route of electrical stimulation as follows:

- *Transvenous pacing*: The pacing lead **(Fig. 1)** is inserted in the right ventricle (or atrium) through a transvenous route from access via either femoral, internal jugular, or subclavian vein. It can be fluoroscopically guided or performed blindly in the emergency or intensive care unit (ICU).
- *Transcutaneous external pacing*: The pacing is performed noninvasively via transcutaneous adhesive patches placed on the chest wall in anteroposterior or anterolateral configuration connected to an external defibrillator with pacing capability. This means of stimulation is painful and used only when transvenous pacing is not immediately available and can be instituted in the emergency often as a bridge to transvenous pacing.
- *Epicardial pacing*: The pacing is performed usually in the postoperative period through temporary epicardial fine pacing wire electrodes implanted during cardiac surgery. The wires are usually removed before discharge from the hospital and hence this means is not available to the emergency physician.
- *Transesophageal pacing*: The pacing is performed through a flexible pacing electrode placed in the midesophagus (for atrial pacing) or the fundus of the stomach (for ventricular pacing). This approach is better tolerated in a conscious patient than transcutaneous pacing as it is painless but is not frequently used clinically.

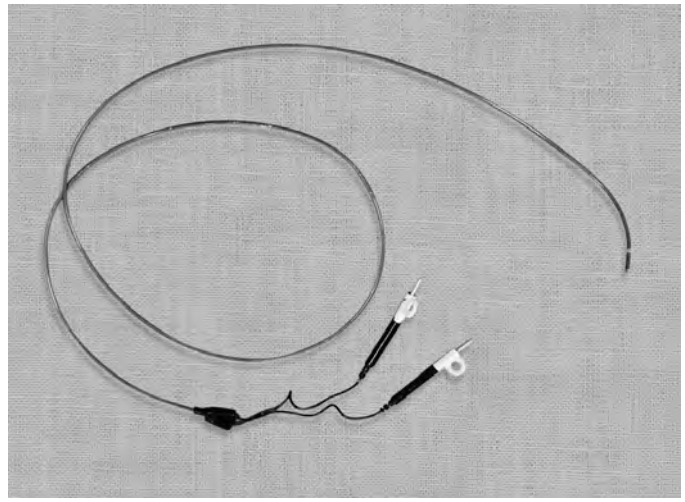

FIG. 1: *Transvenous temporary pacing lead*. The lead has two electrodes (distal tip and the proximal ring) at its tip and two connecting pins—distal and proximal at the other end where it connects with the pulse generator via a connecting cable.

INDICATIONS OF TEMPORARY PACING

Most commonly temporary pacing is performed as an emergency procedure in patients with symptomatic and/or life-threatening bradycardia, although many elective indications of temporary pacing also exist (**Box 1**). In general, emergency temporary pacing is reserved for patients with bradycardia who have recurrent syncope occurring at rest (mostly AV block), or hemodynamically instability or ventricular tachyarrhythmias due to bradycardia. The patients with sinus node dysfunction are usually not symptomatic at rest and if pacing is indicated, they can directly undergo permanent pacing. Temporary transvenous pacing poses the risks of not only infection but also damages to venous access sites that may potentially be needed for permanent pacing; and hence should be avoided if possible without compromising patient's safety.

Among patients with acute MI, one needs to be more proactive and aggressive with temporary pacing in those with anterior MI. Sinus bradycardia and AV block associated with acute inferior MI are usually hemodynamically well tolerated, responsive to drugs and fluids, not life-threatening and infrequently need temporary pacing. AV block in most patients with acute inferior MI recovers spontaneously with time and permanent pacing is only rarely necessary. On the other hand, bradyarrhythmias or new intraventricular conduction disturbances associated with acute anterior MI can result in unpredictable and sudden hemodynamic deterioration and warrant temporary pacing although, many of them may not require permanent pacing. Elective temporary pacing is usually required to cover for any pacing support in catheterization laboratories or surgical procedures in patients with high risk of AV block or bradycardia.

BOX 1: Indications of temporary cardiac pacing.

Emergency indications:

- Complete or second-degree (Mobitz II or advanced or high grade) atrioventricular block with recurrent syncope at rest as a bridge to permanent pacing
- Ventricular tachyarrhythmias related to bradycardia
- Bradyarrhythmias in acute myocardial infarction:
  - Ventricular asystole
  - Symptomatic or hemodynamically significant bradycardia unresponsive to atropine—sinus bradycardia or second-degree type 1 AV block
  - Complete AV block associated with hypotension, or wide QRS escape rhythm or ventricular arrhythmias
  - Mobitz type II AV block
  - Intraventricular conduction defects at high risk of unpredictable complete AV block or asystole even with absence of symptomatic bradycardia, e.g., new or indeterminate bifascicular block with prolonged PR interval, bilateral bundle branch block, and alternating bundle branch block
- Recurrent polymorphic ventricular tachycardia with or without QT prolongation not adequately controlled by drugs
- Recurrent monomorphic ventricular tachycardia or supraventricular tachycardia not controlled with drugs in order to overdrive treat the arrhythmia

Elective indications:

- Catheterization laboratory procedures with potential for requirement of temporary pacing support:
  - Pacemaker pulse generator replacement in patients with complete AV block or pacing dependence
  - Permanent pacemaker system explantation usually for infection
  - Immediately prior to permanent pacemaker or CRT device implantation in patients with AV block or left bundle branch block
  - Alcohol septal ablation for hypertrophic cardiomyopathy
  - Rota-ablation of coronary stenosis especially right coronary artery
  - Transcatheter aortic valve implantation
- Noncardiac surgery under general anesthesia in patients with high risk of AV block
- Cardiac surgery—epicardial pacing wires are routinely placed for any perioperative pacing requirement

TEMPORARY PACING PROCEDURE

Transvenous Pacing

The temporary pacing is best performed under fluoroscopic visualization in catheterization laboratory; however, it is often performed blindly at the bedside as an emergency procedure especially if catheterization laboratory facility is not available. Though, many routes of venous access, each with its advantages and disadvantages are available, the femoral vein (in catheterization laboratory) and the right internal jugular vein (bedside) are the most suitable and most commonly used approaches. In general, the subclavian veins especially the left should be avoided for temporary pacing since these may be needed in future for permanent pacemaker implantation.

The procedure entails placement of a venous sheath using Seldinger's technique taking all aseptic precautions in a sterile environment, positioning of the temporary pacing lead (**Fig. 1**) in the right ventricle (or atrium) preferably under fluoroscopy, connecting the lead to an external pulse generator **(Fig. 2)**, ensuring adequacy of electrical pacing parameters and finally securing the lead with sutures to the skin to avoid its displacement. Some experience is needed to negotiate the lead from the right atrium across the tricuspid valve in the right ventricle and echocardiography can sometimes be very useful in guiding the lead placement in absence of fluoroscopy at the bedside.

Transcutaneous Pacing

The external transcutaneous pacing can be easily performed without much learning curve using transcutaneous defibrillation patches (**Fig. 3**) and an external defibrillator (**Fig. 4**) with pacing capability. The patches can be placed preferably in anteroposterior configuration on the chest but an anterolateral configuration can be used in an emergency situation. Though, this means of pacing is painful and often requires the patient to be sedated; it can be very useful due to universal availability in emergency wards and coronary care units and ease of use. Moreover, this is often very useful to transfer a patient from a small nursing home to a facility with catheterization laboratory.

FIG. 2: *Temporary pacing pulse generator*. This is a single chamber pulse generator and has three knobs for adjusting pacing rate, output and sensitivity; light indicators for pace, sense, and low battery; switches to turn on or off; a port for connecting the cable and a battery that can be replaced. The model shown also has capability of delivering rapid pacing (beyond 180/min) mainly used for rapid atrial pacing to terminate supraventricular tachycardia or atrial flutter.

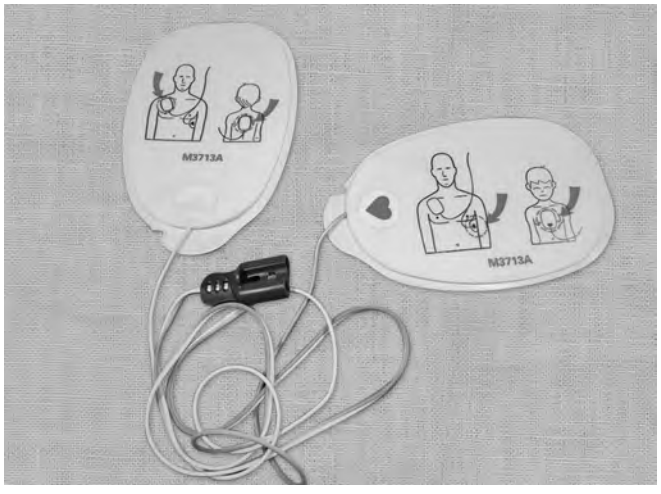

FIG. 3: *Transcutaneous patches for pacing and defibrillation*. The two patches are attached to the right anterior and left lateral (or posterior) chest wall as shown and are connected to the external defibrillator using the attached connecting cable.

FIG. 4: *External defibrillator*. The external defibrillator can deliver transcutaneous temporary pacing through patches shown in **Figure 3**. The rate and output of pacing can be adjusted as per the patients need, tolerability, and capture threshold.

BOX 2: Complications of temporary transvenous pacing.

- *Venous access-related complications*:
  - Hematoma and bleeding at puncture site, femoral pseudoaneurysm
  - Venous thrombosis and pulmonary embolism
  - Pneumothorax (internal jugular or subclavian puncture) or hemothorax
  - Infection at local puncture site
- *Lead placement related complications*:
  - Catheter knotting
  - Tricuspid valve injury
  - Myocardial perforation and cardiac tamponade
  - Air embolism
- *Pacing lead related and electrical issues*:
  - Lead dislodgement or disconnection
  - Cardiac perforation and tamponade
  - Extracardiac (phrenic nerve) stimulation
  - Increase pacing threshold
  - Ventricular arrhythmias—ectopics, and tachycardia due to mechanical effect of the lead or inappropriate pacing due to improper sensing

COMPLICATIONS OF TEMPORARY PACING

As with any invasive procedure, transvenous temporary pacing can also lead to complications in 14–20% of patients, the frequency of which increases with the duration of pacing. The complications may be related to the venous access, mechanical effects of the pacing lead or to the electrical issues (**Box 2**).

POSTPROCEDURE CARE

Care of the patient after temporary transvenous pacing in the emergency and ICUs is very important to prevent complications and recognize them promptly if they occur. *The salient points are mentioned below*:

- *Postprocedure and periodic chest X-ray and ECG*: A chest X-ray should be performed to ascertain the position of the pacing lead and also look for any pneumothorax or hemothorax. Similarly, an ECG should be performed postprocedure and repeated if needed to assess adequate sensing and pacing. If there are any doubts, an echocardiogram should be performed to look for lead position and presence of pericardial effusion.

- *Continuous ECG monitoring*: The patients with temporary pacemaker should have continuous ECG monitoring in order to promptly recognize any loss of pacing or occurrence of ventricular arrhythmias.
- *Checking electrical parameters,* system integrity and pulse-generator battery—at least once daily checking of sensing and pacing parameters, lead connections and need for battery change should be performed and adequacy of parameters programmed should be ensured. The pacing output should be programmed to at least three times the pacing threshold. The underlying rhythm should also be checked by gradually reducing the pacing rate to below intrinsic rate to assess the continued need for temporary pacing. Lack of pacing and asystole often occurs due to loose connections or rise in pacing threshold.
- *Care of the access site*: An occlusive dressing with antibiotic or antiseptic ointment should be performed at the site of puncture and sheath access to prevent infection. The dressing should be changed if soiled and once daily. If the sheath is in place, it should be flushed periodically with heparinized saline to prevent thrombosis.
- *Prevention of infection*: Prophylactic antibiotics that cover *Staphylococcus* should be used especially if a femoral route has been chosen for temporary pacing. If the temporary pacing is to be used for a prolonged period (>7 days) or any sign of local infection is seen, the pacing site and lead should be changed to prevent systemic infection.

SUMMARY

Temporary cardiac pacing involves electrical stimulation of the heart usually the ventricles in order to treat bradyarrhythmias and sometimes tachyarrhythmias and is commonly performed transvenously using a pacing lead and pulse generator. It should be used judiciously and only when necessary for an appropriate length of time in order to avoid its complications. Choice of the approach, the access site and the duration of pacing need to be individualized based on the patient's requirements and routine postprocedure care taken to prevent complications from this procedure.

73
CHAPTER

Postcardiac Surgery Emergencies

Yatin Mehta, Devendra Richhariya

INTRODUCTION

Cardiac surgery is an evolving surgical specialty which had significant morbidity and mortality in past, but with streamlining of the specialty by protocols for every aspect of cardiac surgery, the morbidity and mortality both have come down significantly in the last few decades. Quality surgical as well as anesthetic care with utmost attention to every detail can further improve the outcomes (**Box 1**).

PARAVALVULAR AORTIC/MITRAL REGURGITATION

If this is diagnosed immediately after coming off cardiopulmonary bypass (CPB) by transesophageal echocardiography (TEE), It requires going back on CPB and placing the valve in appropriate manner as to treat the paravalvular aortic regurgitation/mitral regurgitation (AR/MR). However, if it happens to be a delayed complication (delayed diagnosis or delayed presentation), it can also be treated in cardiac Catheterization laboratory by device closure of the regurgitation. Late paravalvular AR or MR (paravalvular leaks) is hemodynamically insignificant. However large ones lead to heart failure, intravascular hemolysis, and increased risk of infectious endocarditis. Hemolysis is also common in small paravalvular leaks. RE-DO surgeries are associated with very high risk while transcatheter closure devices techniques are less invasive and of immense use in high-risk patients**.** Other *diagnostic clues* are continuing sign and symptoms of heart failure in postoperative period (or even later) with evidence of hemolysis such as falling hematocrit, rising bilirubin elevated lactate dehydrogenase activity (LDH), changed reticulocyte counts, etc. The diagnosis is confirmed by echocardiography.

BOX 1: Common postcardiac surgery emergencies.

- Paravalvular aortic or mitral regurgitation
- Bleeding (bleeding requiring reexploration)
- Arrhythmias (atrial fibrillation and other dysrhythmias)
- Acute coronary syndrome (ACS) following surgery
- *Early tamponade*: Collection of blood around heart requiring reexploration of the chest
- Tension pneumothorax
- Stroke
- Acute kidney injury (AKI)
- Acute decompensated heart failure (ADCHF)/low cardiac output syndrome (LCOS)
- Respiratory failure

Treatment

Either surgical or using the transcatheter closure devices. Reoperation is the choice of procedure when paravalvular leaks are associated with significant dysfunction or mechanical instability of the prosthetic valve or associated with infective endocarditis. Transcatheter device closure is reserved for small paravalvular leaks.

BLEEDING

Excessive Bleeding

Considering the complexity of cardiac surgery, the inflammatory cascade generated by CPB machine and circuit, bleeding remains an issue which requires due attention. But with the institutional protocols being in place for the kind of patients who will need to be re-explored for bleeding, the decision-making is not difficult.

What is Significant Bleeding?

Various criteria have been used to define excessive bleeding, as a rough guide, it is the chest tube and mediastinal tube drainage of >200 mL/h for 4 hours, >1,000 mL in total, or a sudden drainage of 400 mL. Any sudden and significant increase in drainage is considered as a genuine reason to reexplore the mediastinum and chest because it signifies a disruption of surgical anastomosis or a slippage of clips or bleeding from aortic cannulation site. In pediatric cardiac surgeries, it is significant if the chest tube drainage and mediastinal tube drainage are >10 mL/kg in the first hour after the surgery or a total of >20 mL/kg over the first 3 hours after surgery.

BOX 2: Measures to prevent/control postcardiac surgery bleeding.

- Stop platelet inhibiting drugs in advance if possible (especially clopidogrel for 5–7 days)
- Avoid hypertension after aortotomy
- Rule out surgical cause and achieve hemostasis with reasonable speed (delaying closure also increases propensity to bleed)
- *Chest radiograph*: To get an idea of collection
- *Neutralize heparin*: More protamine is suggested in a dose of 0.5–1 mg/kg, if ACT is >150 seconds or the aPTT is more than 1.5 times control
- Warm the patient to above 36° as hypothermia is known to increase bleeding tendencies
- *Apply PEEP*: 5–10 cm H_2O. Although it has *not a proven role,* but it is still used with the theoretical rationale of a tamponade effect on the bleeders and oozing
- Desmopressin in the dose of 0.2–0.4 µg/kg intravenously is suggested when bleeding time is prolonged with expected platelet defect
- Epsilon aminocaproic acid in a bolus dose of 50 mg/kg, followed by 25 mg/kg/h is used as *antifibrinolytic prophylaxis*
- Similarly, tranexamic acid in a bolus dose of 10 mg/kg, followed by 1 mg/kg/h can be used as *antifibrinolytic prophylaxis*
- Platelet transfusion in pediatric is weight guided as a dose of *1 U/10 kg* when platelet count is less than 100,000/mm^3. However, in adult, platelet transfusion is not weight guided
- Fresh frozen plasma in a dose of *15 mL/kg is transfused when the* PT or aPTT is more than 1.5 times control
- Cryoprecipitate in dose of *1 U/4 kg when the* fibrinogen levels are >1 g/L or 100 mg/dL
- Recombinant *factor VIIa* with a risk of graft occlusion in CABGs
- *Acceptable limit*: Bleeding below 50 mL/h for 2 hours is acceptable to consider the patient for extubation

(ACT: activated clotting time; aPTT: activated partial thromboplastin time; CABG: coronary artery bypass grafting; PEEP: positive end-expiratory pressure; PT: prothrombin time)

At times, postoperatively cardiac surgery patients bleed more. In such cases, early diagnosis and intervention helps in preventing impairment hemodynamic, anemia, and impairment of hemostasis, tamponade, and reduction of innate coagulation factors (**Box 2**).

Cardiac surgery, especially because it involves heparin and at times the use of thrombolytics in preoperative period as in emergency coronary artery bypass graftings (CABGs) may end up with deranged hemostasis and hence increased bleeding. Also, the use of CPB leads to platelet destruction, dilutional coagulopathy, and activation of inflammatory and coagulation cascades. However, these are not the only factors leading to increased bleeding after any cardiac surgery. Approach to postcardiac surgery bleeding is summarized in **Flowchart 1**.

ARRHYTHMIAS

Atrial Fibrillation

Arrhythmias are one of the most common complications in the postoperative period of cardiac surgery. Postsurgically, the most common arrhythmia seen is atrial fibrillation (AF), occurs in nearly 30–40 % of patients; while the cause is poorly understood, the factors linked to the occurrence of AF are age, male sex, prior episode of AF, surgeries related to mitral valve, and a history of heart failure. AF has a strong association with increased mortality and morbidity in terms of stroke and prolonged hospital stay. *Risk factors for postsurgery AF are* fluid and electrolyte imbalance associated with the use of diuretics, enlargement of left atrium/right atrium because of stenosis or regurgitation of atrioventricular valves, left atrium enlargement associated with diastolic dysfunction, hypoxia, pulmonary emboli, and myocardial infarction.

Prophylaxis and treatment modalities can be achieved by amiodarone, magnesium, and/or beta-blockers. Normally, amiodarone is given first as a slow bolus and followed by infusion. Commonly is stable AF, so does not require DC shock as an emergent maneuver. Management of AF is rate control and if possible, conversion of rhythm to sinus rhythm, or rate control with anticoagulants. Amiodarone is relatively less depressant to the heart than other antiarrhythmic drugs. It is used in the dose of 150–300 mg intravenously to manage acute postoperative AF. Its use is therefore justified in patients with poor left ventricular (LV) function than other antiarrhythmic drugs.

Regimen for Amiodarone

As an intravenous infusion, 150 mg in 10 minutes, followed by 1 mg/min for 6 hours, followed by 0.5 mg/min for 18 hours. AF longing >48 justifies the use of echocardiography, preferably TEE to rule out LA clots. TEE should be done before any intervention to revert the rhythm. Use of thromboembolic prophylaxis in such cases is warranted. In those with risk factors such as previous stroke, heart failure, diabetes mellitus (DM), and advanced age, warfarin is used with a target international normalized ratio (INR) between 2 and 3.

Ventricular Fibrillation

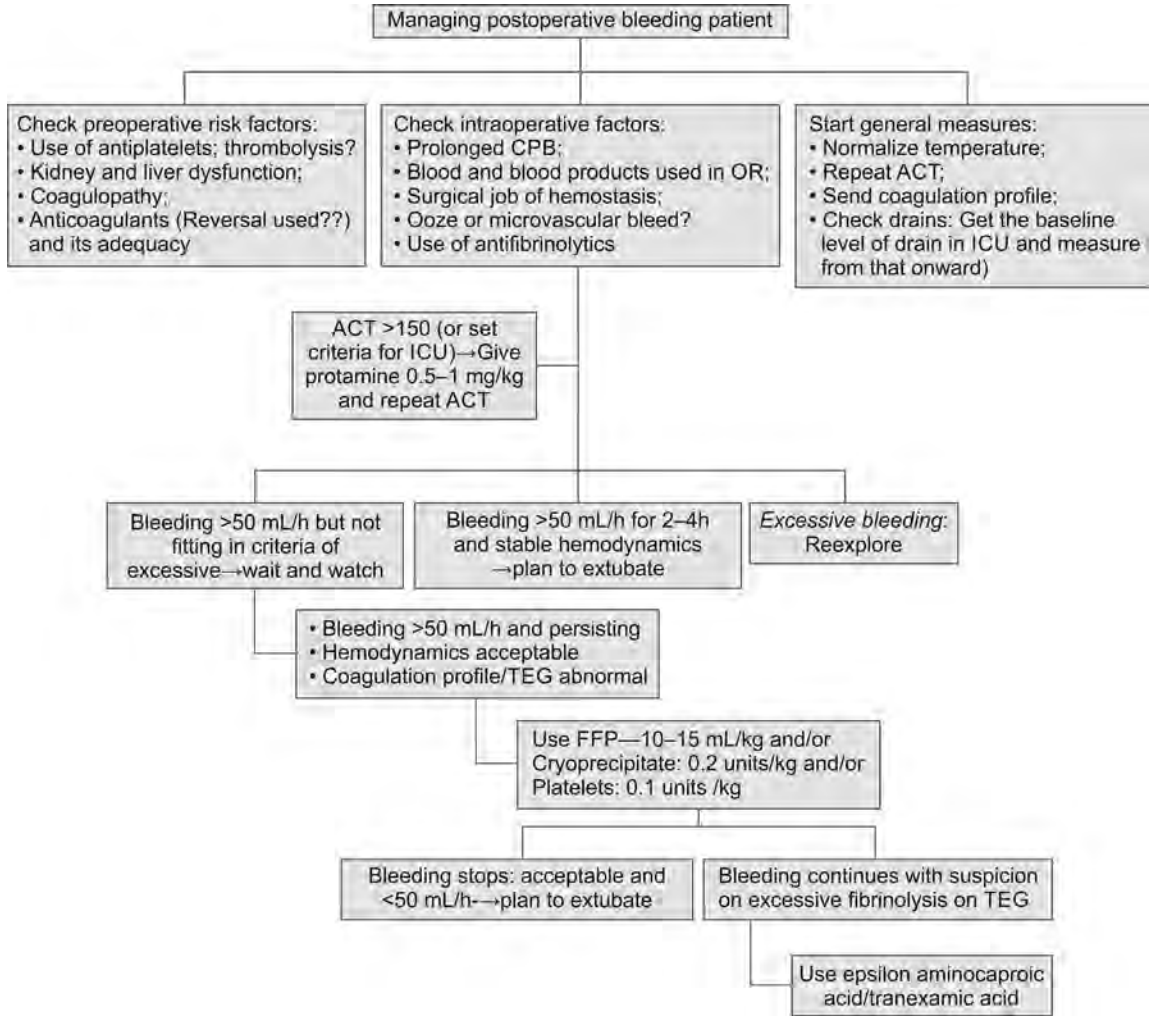
Ventricular fibrillation (VF) commonly occurs just while coming off CPB, which is acceptable at that moment (it is not a surprise at that moment). Defibrillation by internal cardiac defibrillation 10–20 j (1–4 j/kg in pediatrics) is sufficient. However, if it occurs late in the course like in postcardiac surgical ICU, it is treated as any witnessed arrest with a VF and treated on the same lines. The only difference is that there can be internal cardiac massage after opening the chest if the need so arises. The dose for external defibrillation is 150–200 j biphasic.

Ventricular Tachycardia

Stable or unstable ventricular tachycardia (VT); stable VT may be given a trial of medical treatment, however, if unstable, the treatment is defibrillation. Other arrhythmias are not very common in postcardiac surgery barring pediatric surgery where they may occur.

Prophylaxis for Arrhythmias

Though not proven with certainty to have a predictable antiarrhythmic, anti-ischemic effect, magnesium in the dose of 2 g slow intravenous dose and lignocaine 100 mg bolus followed by an infusion at the rate of 2 mg/min are used. A universal drug



Managing postoperative bleeding patient
Check preoperative risk factors:
• Use of antiplatelets; thrombolysis?
• Kidney and liver dysfunction;
• Coagulopathy;
• Anticoagulants (Reversal used??) and its adequacy
Check intraoperative factors:
• Prolonged CPB;
• Blood and blood products used in OR;
• Surgical job of hemostasis;
• Ooze or microvascular bleed?
• Use of antifibrinolytics
Start general measures:
• Normalize temperature;
• Repeat ACT;
• Send coagulation profile;
• Check drains: Get the baseline level of drain in ICU and measure from that onward)
ACT >150 (or set criteria for ICU)→Give protamine 0.5–1 mg/kg and repeat ACT
Bleeding >50 mL/h but not fitting in criteria of excessive→wait and watch
Bleeding >50 mL/h for 2–4h and stable hemodynamics →plan to extubate
Excessive bleeding: Reexplore
• Bleeding >50 mL/h and persisting
• Hemodynamics acceptable
• Coagulation profile/TEG abnormal
Use FFP—10–15 mL/kg and/or Cryoprecipitate: 0.2 units/kg and/or Platelets: 0.1 units /kg
Bleeding stops: acceptable and <50 mL/h-→plan to extubate
Bleeding continues with suspicion on excessive fibrinolysis on TEG
Use epsilon aminocaproic acid/tranexamic acid

(ACT: activated clotting time; ICU: intensive care unit; FFP: fresh frozen plasma; TEG: thromboelastography)

FLOWCHART 1: Algorithm for management of bleeding.

for all kind of arrhythmias is amiodarone—though there is no scientific evidence to support its use, magnesium in a dose of 2 g is frequently given prior to CABG in many institutes. The multidisciplinary team will have to come to a rationale-based use of such drugs as a prophylaxis.

Bradycardias

Bradycardias especially complete heart block (CHB) is most commonly seen either in aortic valve replacement (AVR) on adults or in ventricular septal repairs in children because of the unintended damage to the conduction system. For the same reason, the pacing wires are left in AVR for 72 hours and for nearly 48 hours in CABG or mitral valve replacement (MVR). At the completion of the open heart procedure/or CABG and before closing the chest, pacing wires are normally placed epicardially at the end of the surgery as a prophylactic measure, so that whenever the need arises, the wires can be attached to the external pacemaker to tide over the crisis. Later, if the patient is pacing dependent, the patient may be given a permanent pacemaker in the cardiac catheterization laboratory. The most common mode used in the postoperative period is DDD. A cautionary note here is never to leave the patient with DOO or VOO because it is just a sensing mode.

TENSION PNEUMOTHORAX

Normally in the immediate postsurgical time, this emergency is not seen because mediastinal and chest tubes are in place (unless the tubes are blocked with blood or kinked); however, it may occur on the side where the chest tube is not placed. It may also occur later in postoperative period when the chest tube is removed. Most of the times, if it is tension pneumothorax, it is diagnosed clinically and confirmed on CXR or while putting the chest drain on mere clinical suspicion. If the hemodynamics suddenly gets deranged, differential diagnosis of tension pneumothorax should be kept in mind along with other causes. Check the chest tube or any blockade with blood, or crimping. And if found so, then release the blockade or crimping. If it does not get resolved, then place wide-bore angiography catheter in the anterolateral part of chest above T4 level. Consider placing intercostal drain on ipsilateral side (with pneumothorax).

CARDIAC TAMPONADE

Cardiac tamponade is a common but largely unrecognized cause of the Low cardiac output syndrome (LCOS) after cardiac surgery. It happens when the heart gets compressed

by blood and/or clots and/or fluid accumulating in the mediastinum. Hemodynamic derangement due to tamponade is seen in nearly 3–6% of the patients requiring massive/multiple blood/blood products for bleeding after surgery. Postoperative cardiac tamponade is called acute when it is within 24 hours of surgery. Delayed pericardial tamponade on the contrary develops after 10–14 days after surgery. Delayed tamponade is known to occur in patients on preoperative anticoagulants.

Reduced filling of the heart because of tamponade causes hemodynamic collapse. As the collection or tamponade increases, pressure inside heart increases in order to compensate. However, if the pressure because of tamponade is more than pressure because of filling inside the heart, diastolic collapse of ventricle (right ventricle first) happens leading to severe deterioration of hemodynamic. Reduced venous return leads to reduced filling (lesser end diastolic volume) which in turn leads to reduced end systolic volume. This explains the LCOS in cardiac tamponade. Low cardiac out, reduced atrial natriuretic factor (because of decreased atrial size because of tamponade), and increased adrenergic discharge in turn lead to reduced urine output.

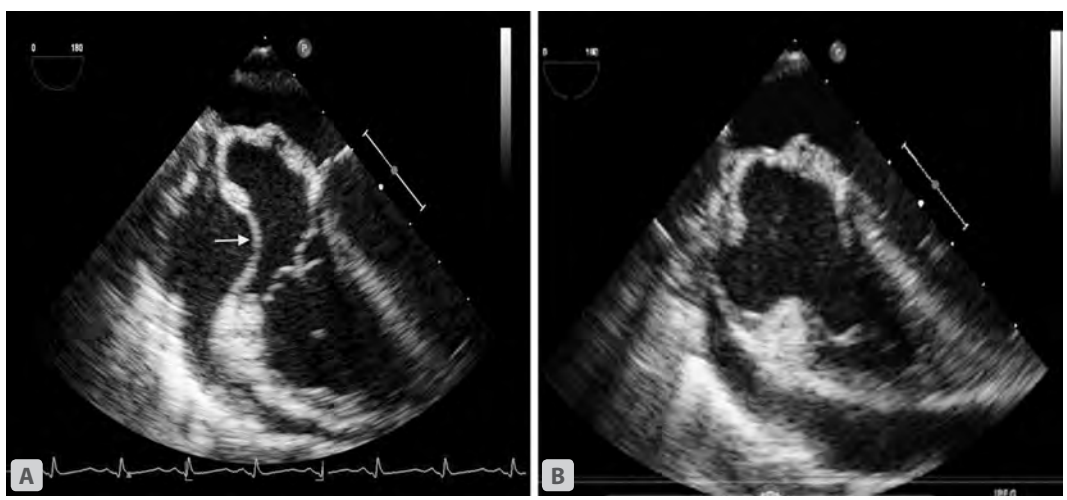
The tamponade that happens postoperatively is very different from tamponade arising of medical reasons (which happen slowly and is therefore well tolerated) because postoperative pericardial tamponade can be regional as well global, clotted and unclotted, pericardium open, and communicating with the pleural cavity. In a slowly increasing pericardial collection (especially medical), compensatory changes occurring over a period do not allow hemodynamic collapse even in presence of a major collection in the pericardial cavity (>1,000 mL). Many surgeons leave the pericardial cavity open and in communication with pleural cavity, so, at times it may be well tolerated even with large volumes.

A very high degree of suspicion should be kept for this diagnosis. If the hemodynamic suddenly deteriorates, it is advisable to open the chest and not wait for the diagnosis. Diagnosis of tamponade is considered in a postcardiac surgery patient whose hemodynamic deteriorate along with (or without) a classical triad of lower blood pressure, increased heart rate and increased filling pressures, and/or low cardiac output. However, it may also present as slowly increased requirement of inotropes and pressers. The classic findings of elevated central venous pressure or equalization of intracavity pressures (in all chambers of heart) may or may not occur. Similar clinical picture is seen in postoperative biventricular failure. invasive positive pressure ventilation (IPPV) deteriorates, it further because of excessive additional pressure on the heart leading to further reduction of filling. Increased pulse pressure variation and stroke volume variation with IPPV when seen with increased central venous pressure and reduced cardiac output should be sufficient to ring the bell toward tamponade.

With a widened cardiac shadow in chest X-ray (CXR), significant pericardial collection on echocardiography, reduced drainage, and deranged hemodynamics—the patient is a candidate for urgent exploration of the chest for relieving tamponade. Similarly, if you have a patient who is not maintaining hemodynamic despite two inotropes, and good amount of intravenous fluids, you must consider tamponade.

Echocardiographic features of tamponade (**Figs. 1** to **3**) include systolic collapse of right atrium and left atrium (atrial diastole) and diastolic collapse of RV (LV collapse does not occur, but occasionally it may occur) along with fluid all around the heart. However, these may not necessarily be seen in a postcardiac surgery patient. However, if the fluid is present all around the heart, more the fluid moves anterior, more is the severity.

Management includes intravenous fluids and inotropes but not those alone; the exploration of chest for removing clots and relieving tamponade is the definitive treatment. It may happen that the tamponade is acute and severe, in that case it may need to be explored as an emergency in postcardiac surgery unit only. If tamponade occurs later than 2 weeks, it is justified to proceed with pericardiocentesis. While the preparations are made to explore the chest, it is advisable to go liberal with intravenous fluids and increasing inotropic doses. Both these measures manage to improve cardiac output till definitive measures are taken. Ventilation should be managed with lowest tidal volume and positive end-expiratory pressure (PEEP) which allows acceptable gas exchange as the mechanical ventilation causes increased pressure on the already compromised heart and its venous return. Sedation should be used with utmost caution as the innate sympathetic discharge may be compromised which is required to maintain hemodynamic.



FIGS. 1A AND B: Systolic collapse of RA in pericardial tamponade; (B) Diastolic collapse of RV in pericardial tamponade.

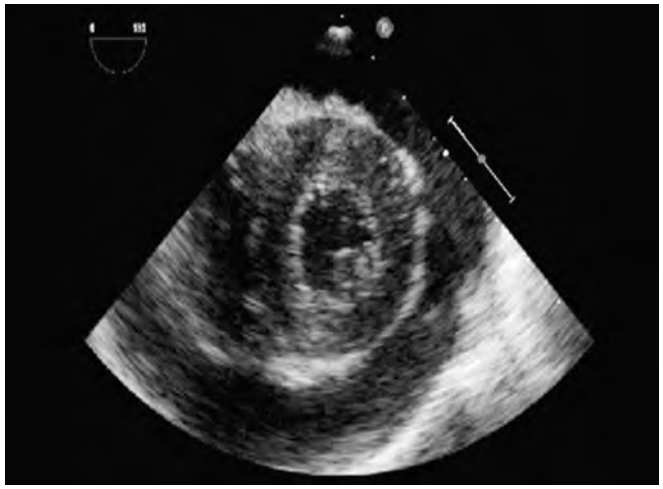


FIG. 2: Fluid all around the heart in pericardial tamponade (fluid is even around the anterior most part of heart indicating that it is severe).

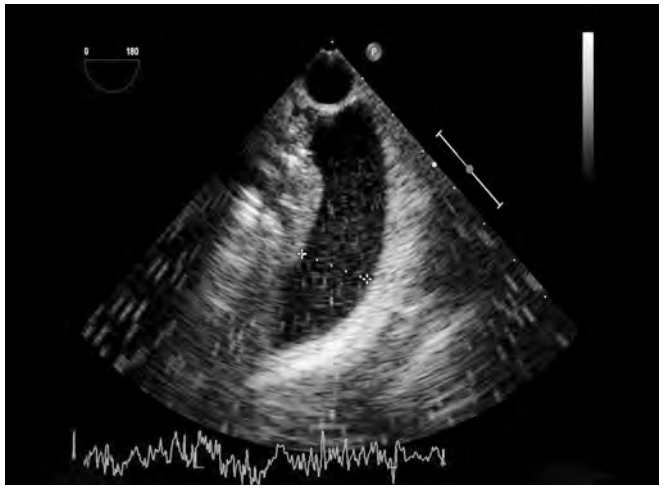

FIG. 3: Associated pleural collection in a c/o pericardial tamponade (tiger claw sign depicting the left pleural collection—claw tip on left side).

ACUTE CORONARY SYNDROME FOLLOWING CARDIAC SURGERY

Myocardial ischemia in postoperative period is not as uncommon as thought. It occurs in nearly 30–45% of patients who underwent CABG. It is detectable in the form of electrocardiogram (ECG) and echocardiographic changes in the form regional wall motion abnormalities (RWMAs). Significant RWMAs are associated with worse outcomes.

Causes

Though there is revascularization of the heart but during the procedure itself, plaques can rupture; later in postoperative period grafts can clot or the lie of the grafts may make them prone to kinking and occlusion, air bubbles (especially in the immediate postoperative period while coming off CPB), stunning, tachycardia, and excessive use of inotropes all can lead to acute myocardial infarction. During valvular repair, coronary artery may get occluded accidentally and may lead to fresh hemodynamic instability, most of the times immediately going back on CPB, if recognized then and correcting the cause. The notorious amongst these is the left circumflex artery getting included while doing MVR.

The handling of the tissues during cardiac surgery leads to troponin I levels getting elevated even without MI. The acceptable limit of troponin levels in postoperative period is 10 times the normal. However, if it exceeds 20 times the normal, it probably indicates ischemia and is associated with increased morbidity and mortality in postoperative period.

Postoperative ischemia is probably caused by the arterial grafts (left internal mammary artery graft and radial graft) or the native diseased vessels going in spasm. The reason for spasm is the endothelial dysfunction because of handling during surgery and preexisting atherosclerosis. Apart from the endothelial dysfunction, it can be the use of vasoconstrictors, calcium, preoperative withdrawal of calcium channel blockers, and probably thromboxane released by platelets causing the spasm. The treatment for the vasospasm of the arterial grafts and native vessels is the use of glyceryl trinitrate (GTN) and/or calcium channel blockers (diltiazem) and/or phosphodiesterase inhibitors.

Intra-aortic balloon pulsation (IABP) can be a great help in alleviating the crisis both by increasing flow to coronaries by diastolic pressure augmentation (inflation of balloon during diastole) and reduced afterload (deflation of balloon in systole), thereby reducing cardiac work and increasing oxygen supply to heart.

INTRACTABLE HYPOTENSION

Intractable hypotension is also commonly seen during postoperative period because of the CPB and because of the drugs such as angiotensin-converting enzyme (ACE) inhibitors being used in preoperative period. It requires vasoconstrictors and if not corrected with that, one may have to proceed with the use of methylene blue. It may not be amenable to even intravascular volume and vasoconstrictors such as selective alpha-agonists or vasopressin. Administration of vasoconstrictors must be guided by objective assessment of cardiac function on pulmonary artery catheters/echocardiography/other monitoring**,** because optimization of blood pressure by vasoconstrictors may make us miss a LCOS state.

GASTROINTESTINAL EMERGENCIES

Gastrointestinal (GI) emergencies that require emergent surgical or medical care are rare after cardiac surgery but these do occur in nearly 1% of patients undergoing cardiac surgery. The most common complication among these is *upper GI bleeding* from duodenal or gastric ulceration or varices. For this reason, the stress ulcer prophylaxis is important.

Mesenteric ischemia is another dreaded complication that has a very high mortality. It may occur because of hypoperfusion that may happen during CPB or because of embolization to the splanchnic vessels during aortic manipulation. The embolization can be treated in catheterization laboratory by interventional radiologist, if a removable thrombus is localized. Mortality remains high.

STROKE AND OTHER NEUROSURGICAL/ NEUROLOGICAL COMPLICATIONS

Neurosurgical Complications

The complications such as subdural hematoma (SDH)/extradural hematoma (EDH) may happen inside operation theatre and present in postoperative period. SDH may happen because of a heparinized patient (for putting in CPB) having poor venous drainage from brain (venous cannula malposition). EDH also happens partially because of heparinization (for CPB) having undiagnosed cerebral aneurysms or very high blood pressure during the perioperative period.

Not all patients with the SDH/EDH require neurosurgical intervention for drainage. Only those with significant midline shifts on CT scan need to be operated as emergency. Transferring these patients to CT suites itself is a very tedious and risky cause they may be on life support systems such as ventilatory and inotropic support, although with the advent of portable CT at bedside has become easier.

Neurological Complications

The treatment of perioperative stroke is actually preventive**.** The reason being that by the time it presents in the postoperative period as a deficit, the irreversible damage is already done. Neurologic events happening in the postoperative period have a strong association with increased mortality, increased length of stay in ICU and hospital, and reduced life span. Neurological complication not only includes stroke but cognitive dysfunction, visual deficits, coma as well. In fact, cognitive dysfunction has an incidence of nearly 80% in the perioperative period. All these lead to a poor quality of life, even though the cardiac issue may be resolved.

The incidence of these neurological emergencies postcardiac surgery is not very high but its occurrence is ominous. With the improved preventive and therapeutic techniques, there is improved survival rate and lifespan. Still therapies are tried with mixed benefits both in digital subtraction angiography (DSA) catheterization laboratories and as a neurosurgical procedure.

Because of rising population in general and geriatric population surviving more, the requirement of cardiac surgeries is increasing. Once cerebral injury is diagnosed, the main measures to be taken in the ICU are:

- Glucose control
- Prevention of hypertension
- Prevention of seizures
- Maintenance of normal oxygenation and normocarbia
- Prevention of raised intracranial pressure (ICP)

Neurological injuries are more common after heart surgery in the geriatric age group. Though the mortality rate because of cardiac surgeries has gone down, but the rate of neurological complications has remained nearly the same. The neurological injuries in the perioperative period leads to nearly 20% increased mortality in comparison to those without neurological dysfunction. The morbidity also increases in the population with neurological deficits in the perioperative period. The mechanism of neurological injuries is cerebral embolism, hypoperfusion because of low perfusion pressure, inflammatory mediators because of CPB, and preexisting neurological deficits/problems.

CARDIAC SURGERY ASSOCIATED ACUTE KIDNEY INJURY

Cardiac surgery associated acute kidney injury (CSA-AKI) as the name indicates is AKI associated with cardiac surgery. It has a huge impact on the quality of life in perioperative period and even in later life after surgery. The etiology of this complication is governed by multiple factors especially related to perioperative management and use of pharmacological agents. Significant implications for short- and long-term outcomes are:

- Increased infections
- Increased stay in hospital and increased ICU stay
- Later, dependency on dialysis
- Greater mortality

Risk Factors of CSA-AKI

Advanced age, female gender, severe left ventricle dysfunction congestive heart failure (CHF), DM, peripheral vascular disease, chronic obstructive pulmonary disease (COPD), valve surgery emergency surgery, prolonged CPB time excessive and prolonged hemodilution on CPB, combined procedures and severe LV dysfunction, use of IABP, and preoperatively elevated serum creatinine.

It is seen in up to 30% of subjects after CPB. Fortunately, only up to 5% require dialysis, but in that 5%, the mortality rate is very high AKI is the strongest independent risk factor for death after CPB. The risk is least in CABG alone, but increases exponentially for valve replacement and is greatest after combined procedures. Unfortunately, this complication and its effect on mortality have not reduced despite better understanding of pathophysiology, pharmacotherapeutics, and the advances in renal replacement therapy (RRT).

Diagnosis

Acute kidney injury is a complex diagnosis. Many diagnostic criteria have been applied for the AKI (example, percentage change in serum creatinine and requirement for hemodialysis).

There are two classifications, which need special mention—(1) the *RIFLE* (GFR, creatinine and urine output) and (2) *AKIN classification* (creatinine and urine output). Even these well-validated criteria-based classifications are not completely reliable as these do not guide about the actual site of kidney injury whether tubular or glomerular. Also, both these depend more on change in serum creatinine. *Society of Thoracic Surgeons (STS) bedside risk tool* and many other such models are used to predict the kidney dysfunction or need for dialysis in advance. Newer biomarkers are also being studies to help in the early detection of AKI. Early detection of AKI leads to early institution of RRT and better outcomes.

Serum Creatinine

It is not sensitive and not consistent in diagnosis. It has a significant time lag in the diagnosis of AKI as well as its recovery. Multiple factors apart from AKI govern the increase and decrease of serum creatinine. Also, it does not guide about the nature of kidney injury whether ischemic or prerenal. The risk of AKI requiring dialysis—10–20% with baseline creatinine of 2.0–4.0 mg/dL and 25% if >4.0 mg/dL. Other newer markers,

which were found to have a better association with AKI, are *NGAL, KIM-1, IL-18, and L-FABP.*

What Fluids to Use ?

A good preload is important for prevention of AKI, but we are unclear as to what fluids are better for kidney. Recent studies have shown that balanced solution is better than saline in reducing the risk of AKI in perioperative period. The chloride restriction reduces AKI as well as the need for RRT. The chloride is detrimental because of its thromboxane release, renal vasoconstrictive effect, and decreased GFR. Dexmedetomidine also may be beneficial.

Ultrafiltration (UF) has been studies a lot for its benefit for AKI. It is safe and reduces perioperative morbidity. The optimal use of UF is combined use of conventional UF and modified UF. More studies in larger trials are required for using UF in a better way. There is still no consensus on best timing of initiation of RRT.

Measures to prevent and managing the CSA-AKI are summarized in **Box 3** and **Flowchart 2**.

ACUTE DECOMPENSATED HEART FAILURE

In postcardiac surgery decompensated heart failure may be encountered pretty often.

The causes may be preoperative LV dysfunction, poor myocardial protection during CPB, prolonged CPB, and cross clamp time; chronic regurgitant lesions with LV dysfunction, graft failure, and involvement of coronaries in valve surgery. It is one of the most common conditions requiring active management in the perioperative period. Postoperatively, decompensated heart failure is seen as an early occurrence of classical signs and symptoms of heart failure secondary to suboptimal heart function, often in those with preexisting heart failure. However, it does not mean that the acute decompensated heart failure (ADCHF) is an entity not seen in previously healthy subjects. It means that the clinicians should have a high index of suspicion for this condition in the perioperative period and the required skill in managing it.

Management of ADCHF in the perioperative period is very demanding and requires the in-depth knowledge of the pathophysiology behind ADCHF in perioperative period. The myocardial stunning causes injury to heart which happens during CPB and it sometimes takes quite a long time to recover. During this time of recovery, we need to support heart by pharmacological means and support devices.

Pharmacological Therapy

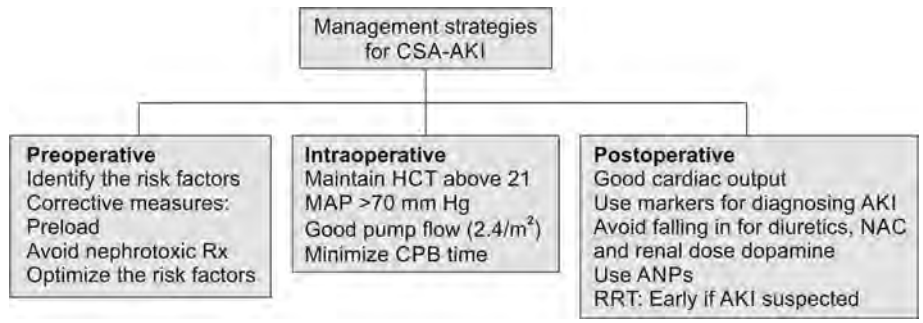
The intended purpose behind the pharmacological means is to support or improve the contractility while reducing the afterload/systemic vascular resistance (SVR) at the same time.

The choice between the inotropes rests between drugs such as adrenaline (0.05–0.2 μg/kg/min), milrinone (0.3–0.7 μg/kg/min), and dopamine (5–20 μg/kg/min) (not much preferred because of the arrhythmogenic nature and the unwanted tachycardia), dobutamine (5–20 μg/kg/min). While all these drugs increase the contractility, *only milrinone and dobutamine decrease the SVR as well and that way seem more suitable.* The disadvantage with milrinone is that it cannot be used for a longer period produces thrombocytopenia, and that it reduces the SVR exponentially, at times so severe as to require a vasopressor to counter the effect and hence nullifying the purpose.

BOX 3: Measure to prevent or treat the CSA-AKI.

- To maintain and replete intravascular volume
- Optimizing cardiac output/treating LV failure
- Avoid nephrotoxic agents whenever possible
- Discontinue of ACE inhibitors/ARB's though its benefit is doubtful; in fact, in diabetic nephropathy it has been shown to be beneficial
- Maintaining adequate tissue perfusion primary goal
- Reasonable glycemic control and outcomes (<180 mg/dL, avoid fluctuations)
- Nesiritide/recombinant atrial natriuretic peptide has shown good results but larger trials are needed
- Avoid anemia (especially on CPB) but at the same time avoid excessive transfusion, because anemia decreases the renal DO_2, increases oxidative stress, and impaired hemostasis and transfused stored RBCs decrease tissue DO_2, is proinflammatory, increases oxidative stress, and activates leukocytes and coagulation cascade
- Fenoldopam (D1 receptor agonist) also has shown positive results in smaller trials. Preoperative RRT as a prophylaxis in preoperative period for optimization is another option
- Be meticulous in closing and hemostasis as any reexploration is an added insult and the combination of insults including associated anemia and blood transfusion contribute to AKI

(ACE: angiotensin-converting enzyme; ARB: angiotensin II receptor blocker; CPB: cardiopulmonary bypass; CSA-AKI: cardiac surgery associated acute kidney injury; RRT: renal replacement therapy)



(ANP: atrial natriuretic peptide; CPB: cardiopulmonary bypass; CSA-AKI: cardiac surgery associated acute kidney injury; HCT: haematocrit; MAP: mean arterial pressure; NAC: N-acetylcysteine; RRT: renal replacement therapy)

FLOWCHART 2: Strategies for prevention and treatment of CSA-AKI.

The devices that help the heart tide over the crisis are suitably called assist devices. The most common amongst these is the intra-aortic balloon counterpulsation which improves the coronary flow during diastole by getting inflated during diastole and reducing the afterload in systole by getting deflated during systole. Use of the intra-aortic balloon counterpulsation has been discussed earlier.

PERIOPERATIVE RESPIRATORY FAILURE

Postcardiac surgery respiratory failure is seen as ventilator dependency and may or may not be a direct complication of the cardiac surgery. The reason being, it may be a preexisting COPD/asthma leading to a type 2 respiratory failure, i.e., lack of drive leading to CO_2 retention and accompanying hypoxemia. In this case, however, the hypoxemia is very responsive to simple measures such as increasing FiO_2 by a minimal proportion. As a direct complication of the cardiac surgery, it occurs as type 1 respiratory failure which means a failure of exchange of gases, because of decompensated ADCHF or preexisting/new onset chest infection may not even respond to a FiO_2 of 100%, if not accompanied by other measures. So, type 1 respiratory failure requires not just raising the FiO_2 but also raising the PEEP, antibiotics, chest physiotherapy, frequent suctioning, and other supportive measures. Both these two classic types of RF have distinctly different abnormalities in the mechanics of breathing, but they share the mechanisms finally leading to respiratory muscle dysfunction, fatigue, and hence ventilator dependence.

Treatment of any type of respiratory failure includes these key elements other than the chest supportive measures:

- Improvement of cardiac function
- Achieving improved oxygen carrying capacity by improving hemoglobin
- Improving arterial saturation
- Reducing oxygen requirement

The endpoint of each therapy is individualized. Early freedom from ventilator dependency is done by prompt identification and correction of multiple factors which had been the cause of increased work load and/or compromised neuromuscular functions.

Aggressive early resuscitation is very important to avoid the vicious cycle of ventilator dependence. Acute management such patients follow airway, breathing, and circulation (ABC) of resuscitation and not CAB of the recent guidelines of CPCR, because here the concern is respiratory failure. This means these patients need airway, ventilator management, and optimal management of circulation. However, at the same time, open-minded approach is kept for prompt diagnosis and treatment plan for the cause of such condition early in course. It is guided by not just by the clinical examination and laboratory evaluation but also supplemented by the results of focused intensive care interventions.

It is very optimistic to know and say that amongst all other surgical fields, the outcomes of cardiac surgery have become excellent, reason being it is driven by very strict protocols. Also, the postcardiac surgical emergencies are getting rarer because of *precardiac surgery evaluation and advanced monitoring of vital parameters*. In the coming times, point-of-care monitoring for excessive bleeding and the liberal use of TEE for any hemodynamic instability in postoperative period will actually reduce the two common complications, i.e., bleeding and tamponade apart from other complications getting diagnosed early like paravalvular regurgitation.

PREVENTION OF POSTCARDIAC SURGERY COMPLICATIONS

Precardiac Surgery Evaluation

Cardiac surgical patients are one of the most extensively investigated. However, evidence from studies using intraoperative TEE suggests that as many as 5% of patients have additional undocumented pathology (e.g., valvular heart disease and patent foramen ovale). Therefore, thorough preoperative evaluation is essential to identify the risk factors, asses the risk of surgery, optimize medical condition if necessary and take written informed consent, is necessary.

History

In majority of cases, the diagnosis would have already been established. So, preoperative assessment invariably begins with a review of the patient's medical record. The presence of risk factors known to be associated with increased perioperative mortality and morbidity like age >60 years, arterial and pulmonary hypertension, BMI <20 or >35, CHF, peripheral vascular disease, DM, renal insufficiency, acute coronary syndromes, chronic pulmonary obstructive disease, neurological disease, and previous cardiac surgery should be sought. Drug history is very important.

Patient on medications such as steroids, bronchodilators, antihypertensive, anticoagulants, antiplatelet, antibiotics, antidiabetics, immunosuppressants, etc., should be noted. Some medication may need discontinuation before cardiac surgery such as anticoagulant, potent antiplatelets, oral antidiabetics, ACE inhibitors, etc. If the patient is on anticoagulation warfarin should be stopped 3–7 days before surgery and INR should be generally <1.5 for surgery. Heparin should be discontinued 6 hours before cardiac surgery.

History of allergy to any drug or food should be noted, especially fish allergy as there are higher chances of protamine reaction in these patients. Signs and symptoms of cardiorespiratory disease [e.g., angina, dyspnea, orthopnea, impaired exercise tolerance, and (pre)syncope] should be actively looked for. The severity of symptoms and effort tolerance should be documented using conventional indices; for example, the Canadian Cardiovascular Society angina score, the New York Heart Association (NYHA) classification of functional capacity and the Duke activity status index. A short systematic examination should be conducted to exclude any gastrointestinal, renal, hepatic, neurological, metabolic, or hematological disease. A symptom suggestive of gastroesophageal reflux necessitates the use of strategies to reduce the risk of regurgitation and pulmonary aspiration during anesthesia. Furthermore, a history suggestive of upper gastrointestinal tract pathology, such as hiatus hernia, may contraindicate the use of TEE intraoperatively.

Physical Examination

Physical examination should be focused on the cardiovascular and respiratory systems. Examination should include heart rate, blood pressure measurement in supine and sitting

position, respiratory rate; characterization of the heart rhythm, gentle palpation of the carotid, femoral and peripheral arteries, and auscultation of the precordium, carotid arteries, and lung fields. Allen's test although not specific but should be performed to confirm the presence of an adequate collateral (ulnar) circulation in patient who are likely to undergo radial artery cannulation. Assessment of dentition, mouth opening, and cervical mobility should be done to predict difficult airway.

Investigations

A blood count, coagulation profile, blood group, serum electrolytes, urea, creatinine and liver function test, a 12-lead ECG, and a left heart catheter should be regarded as routine preoperative investigations in virtually all cardiac surgical patients. A plain posteroanterior CXR provides information about heart size, pulmonary vasculature, lungs size of trachea sings of cardiac failure, and bony cage of the chest. Left heart catheterization typically comprises coronary angiography (useful in coronary artery patients), aortography, left ventriculography (ventricular function), and manometry. This provides information about the sites and severity of coronary artery stenoses, mitral and aortic valve function, and LV morphology and function. ECG is done to detect arrhythmias, conduction changes, myocardial injury, and myocardial infarction. Exercise stress testing is a noninvasive test. It is useful in patient with chest pain of unknown etiology, and for quantification and prognosis in patients with known coronary artery disease (CAD). Currently many treadmill protocols are available of which Bruce protocol is most familiar. Pharmacological stress testing, e.g., dobutamine stress echocardiography is suitable for patient who are unable to exercise adequately. Transthoracic echocardiography is frequently used to define cardiac anatomy and assess ventricular and valvular function. Regional wall motion abnormality can be seen and it is helpful in deciding optimum preoperative management and perioperative monitoring and care. Additional investigations such as respiratory function tests, arterial blood gas analysis, carotid ultrasonography and angiography, creatinine clearance, and evaluation of a permanent pacemaker or cardiodefibrillator should be conducted, as appropriate.

Risk Assessment and Stratification

Cardiac surgeries still have a certain risk of death and serious complications despite advances in surgical techniques, anesthesia and critical cardiac care. It is essential that the cardiac anesthesiologist understands how risk is assessed and that the patient and his/her relatives are adequately informed about the risk of surgery. In the late 1980s, Parsonnet and colleagues identified 14 independent risk factors for death after cardiac surgery. The so-called Parsonnet score was adopted by many centers worldwide and is still in use today. The European System for Cardiac Operative Risk Evaluation (EuroSCORE) was developed in the late 1990s, across 128 centers in eight European states in 19,030 patients undergoing cardiac surgery. Based on the EuroSCORE, the patients were categorized as, patients with low risk (EuroSCORE 0-2), moderate risk (EuroSCORE 3–5), and high risk (EuroSCORE >6) of in-hospital mortality following cardiac surgery. The model has not been validated till date in India and Australia. The study involved assessment of 17 risk factors identified in EuroSCORE model. The additive EuroSCORE can be satisfactorily applied to low- and moderate-risk Indian patients but is less accurate for high-risk Indian patients undergoing cardiac surgery. For high-risk patients, the logistic EuroSCORE[10] provides a more accurate prediction than the simple additive score.

SUMMARY

In patient undergoing cardiac surgery extensive cardiac evaluation, preoperative cardiac risk assessment and stratification is a part of routine workup. The main goal is to provide risk adjusted mortality rates for the preoperative patient and adequate patient and family counseling. Various complex or simplified models are available and can serve as a tool for risk assessment and stratification for perioperative mortality and morbidity.

Systemic Hypertension

Au Kin Heng Constantine, Quintin Kwok

INTRODUCTION

Systemic hypertension, or simply "hypertension", is a common condition affecting about 1.5 billion adults in the world. Untreated hypertension leads to cardiovascular diseases such as heart attacks and strokes.

Hypertension does not traditionally belong to the realm of emergency medicine. It is, by and large, a chronic condition managed by general practitioners. It does, however, cross paths with emergency physicians in several ways. First of all, as all patients have their vital signs checked at the emergency department (ED), many previously undiagnosed cases are identified. Secondly, patients who are taking antihypertensive drugs may attend ED when their blood pressures (BPs) are not well controlled or due to the side effects of the antihypertensives. Last but not least, hypertension can sometimes be life-threatening. Such instances are called hypertensive emergencies. They are not common but are truly medical emergencies. There are different categories, treatment protocols, and even definitions for systemic hypertension. This manuscript serves as a general reference. Please refer to your local guidelines.

DEFINITION CLASSIFICATION GRADING

In adults, hypertension is defined as a systolic blood pressure (BP) equal to or over 140 mm Hg, or a diastolic BP equal to or over 90 mm Hg according to European, Indian, and UK standards. The American Heart Association uses a definition of BP > 130/80 mm Hg instead (**Table 1**).

ETIOLOGY AND PATHOPHYSIOLOGY

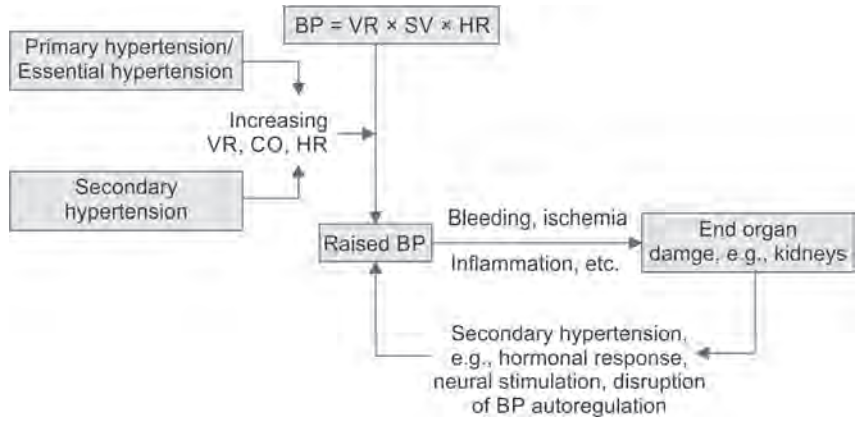
A majority (90%) of adult patients with high BP have primary hypertension (also called essential hypertension), which means the condition is not caused by another disease. Genetic and environmental factors such as diet and lifestyle are believed to be the underlying causative factors. Secondary hypertension is high BP caused by certain underlying, often undiagnosed diseases or drugs (**Table 2**). Some of these diseases are rare. Emergency physicians must have a high index of suspicion to diagnose these conditions. **Flowchart 1** summarizes the

TABLE 1: Grading of hypertension in adults.

Grading	*Systolic (mm Hg)*		*Diastolic (mm Hg)*
Mild	140–159	and/or	90–99
Moderate	160–179	and/or	100–109
Severe	≥180	and/or	≥110
Hypertensive urgency	Severe hypertension without acute organ failure		
Hypertensive emergency	Severe hypertension with evidence of acute target organ failure		
For a child, refer to standardized tables of blood pressure for diagnosis			

TABLE 2: Secondary causes of systemic hypertension.

Secondary cause	*Features suggesting*
Acromegaly	Enlargement of forehead, jaw, and nose
Drugs/food/herbs	Oral contraceptives, amphetamine, ephedra, and poor antihypertensive drugs compliance
Coarctation of aorta	Radiofemoral delay, murmur
Cushing syndrome	Cushingoid features
Genetic causes	Rare (e.g., Geller syndrome)
Hyperaldosteronism	Hypokalemia, metabolic alkalosis
Hyperparathyroidism	Hypercalcemia and hypophosphatemia
Obstructive sleep apnea	Snoring, daytime somnolence
Pheochromocytoma	Episodic attacks: Flushing, headache, and palpitation
Primary aldosteronism	Muscle weakness
Renal artery stenosis	Renal bruit, kidneys of unequal size on ultrasound (the smaller one on the side with the stenosed renal artery)
Renal parenchyma	Raised creatinine, proteinuria
Hyper-/hypothyroidism	Goiter, abnormal thyroid tests



(BP: blood pressure; HR: heart rate; SV: stroke volume; VR: vascular resistance)

FLOWCHART 1: Etiology and pathophysiology of hypertension.

etiology and pathophysiology of hypertension. A patient may have both primary and secondary hypertension together.

CLINICAL PRESENTATION

Patients with essential hypertension may have no symptoms at all. Some may complain of mild headache or dizziness only. In secondary hypertension, there may be features of the underlying diseases noted on history taking, physical examination, or basic investigation. One should be alert if the patient is young (<40), or the BP is very high or difficult to control with medications.

In hypertensive emergencies, the BP will be in the severe range; patients may have signs and symptoms of acute target organ failure (**Table 3**). The organs affected most often are the brain, eyes, heart, and kidneys. Added to this list is preeclampsia in pregnancy. These target organs may, in turn, raise the BP via hormonal, neuronal response, or disruption of autoregulation.

Red flags (concerning features) look for the features of hypertensive emergencies and secondary hypertension as summarized in **Tables 1** to **3**. Hypertension itself and antihypertensive drugs may complicate the patient's presentation in a trauma setting. Beware of the Cushing's triad in trauma patients. With regards to treatment, lowering the BP too rapidly may be harmful. Drug history such as amphetamine or missing antihypertensive drugs must be checked.

TABLE 3: Acute target organs damaged involved in severe hypertension.

Target organs	*Pathophysiology*	*Features*
Brain	• Ischemia • Bleeding	Confusion due to hypertensive encephalopathy or intracerebral hemorrhage
Eyes	• Retinal hemorrhages • Microaneurysms • Papilledema	Papilledema on fundoscopy
Heart/chest	Overloading of the left ventricles	Arrhythmia, acute coronary syndrome, aortic dissection, and pulmonary edema
Kidneys	Endothelial dysfunction and damage	Hematuria, proteinuria, and raised creatinine/potassium/acidosis
Lungs	Increased hydrostatic pressure in lungs, or increased permeability	Pulmonary edema
Preeclampsia	Abnormal vascular changes	Proteinuria, peripheral edema, and hyperreflexia

Measurement of Blood Pressure in Emergency Department

Blood pressure is a dynamic physiological parameter which fluctuates over the course of the day and is affected by a wide range of factors from pain to emotion. Common presentation at the A and E is headache or vertigo. Their BPs may be very high at presentation, but once the symptoms are palliated, the BP returns to normal. These patients may be misdiagnosed as having hypertension. ED is not the ideal place to diagnose hypertension because of white-coat hypertension (raised BP at emergency but normal in the community) and masked hypertension (normal BP emergency but raised in the community). There are many factors affecting the BP measurement and some tips are used during measurement of the accurate BP (**Table 4**).

Ideally, hypertension should be diagnosed in the community when the patient is not acutely unwell, is relaxed and the reading is repeated on different days. Only if the BP is persistently high under these circumstances should one commit to the diagnosis. Home BP monitoring (HBPM) or 24-hour ambulatory BP monitoring (ABPM) may be helpful in uncertain cases.

For all these reasons, unless a hypertensive emergency with acute organ failure occurs, the emergency physician often refers patients with high BPs to their colleagues in the community for follow-up. Two important aspects of managing essential hypertension are risk factor identification and modification of lifestyle. These do not affect the immediate well-being of patients and should not be added to the workload of emergency.

TABLE 4: Factors affecting the blood pressure measurement and some tips for measurement.

Tip	*Remarks*
Environment	Relaxed
Position	Ideally, BP is measured with patient sitting on a chair with back support and upper arm positioned at the level of the heart
Cuff bladder size	• The length should be about 80–100% of the girth of the mid-arm; a bladder too short will overestimate the BP • The width should be about 40% of the girth of the mid arm
If irregular pulse	Use a manual sphygmomanometer
If BP different between left and right arms	• If difference is persistently >20 mm Hg systolic or 10 mm Hg diastolic, consider investigation of underlying cause • For documentation purposes, use the higher reading
Repeat and confirm	Never diagnose hypertension with one abnormal reading; consider HBPM or ABPM

(ABPM: ambulatory blood pressure monitoring; HBPM: home blood pressure monitoring)

EVALUATION OF HYPERTENSION

In the Acute Setting

Follow the adage of "ABCD" (airway, breathing, circulation, and disability). If the BP is in the severe range, ensure airway and breathing are adequate. The emergency physician should then determine whether a hypertensive emergency exists—are there any features of acute target organ failure as in **Table 3**? If so, a rapid reduction of the BP by 20–25% is suggested, together with treatments for the corresponding organ failures. This is usually accomplished by repeated doses of intravenous labetalol or nicardipine in adults. Reducing the BP too quickly or too much may cause ischemia and do more harm than good. Disability means acute organ failure.

The *choice of investigation* depends on which organ failure is suspected. Heart and brain failure may be obvious when the patient presents with acute coronary syndrome, acute pulmonary edema, or is confused or comatose. Consider 12-lead electrocardiogram, chest X-ray, echocardiogram, troponin I test, CT-angiogram, and CT-brain. Involvement of the eye and the kidneys, however, may be subtle. Fundoscopy, urine analysis for blood and protein, blood tests for creatinine, potassium, and bicarbonate must be done in this kind of patients. Thoracic CT (for aortic dissection) or drug/toxicology screening may be needed. Admit patients with hypertensive emergency after stabilization.

In hypertensive urgency where there is no acute target organ failure, BP should be lowered within 24 hours using oral antihypertensive agents such as an angiotensin-converting enzyme (ACE) inhibitor, angiotensin II receptor blocker (ARB), calcium channel blockers (CCBs), or beta-blockers. Patients should be admitted or have a follow-up within a week with an internal medicine specialist.

In the Chronic Setting

In the longer term, for patients with essential hypertension and for those who have recovered from their acute crises, managing hypertension is not only BP reduction. It includes cardiovascular risk assessments and modifications, patient education, lifestyle changes, drug treatment and long-term monitoring of BP control, and target organs' status. The ultimate aim is to reduce the risk of heart attacks, strokes, and other end organ damage.

Chronic Target Organ Damage Assessment

The organs affected acutely by hypertensive emergencies can also be damaged slowly by a chronically elevated BP. The well-being of these organs should be assessed regularly. If organ damage is suspected, further evaluations and treatments by relevant specialists should be instituted.

Risk Factor Identification and Modification

There are risk assessment tools such as Systematic Coronary Risk Evaluation (SCORE) to estimate the risk of cardiovascular events. There are many risk factors for cardiovascular diseases. Some of these are modifiable are given in **Table 5**.

STEPWISE APPROACH TO SYSTEMIC HYPERTENSION

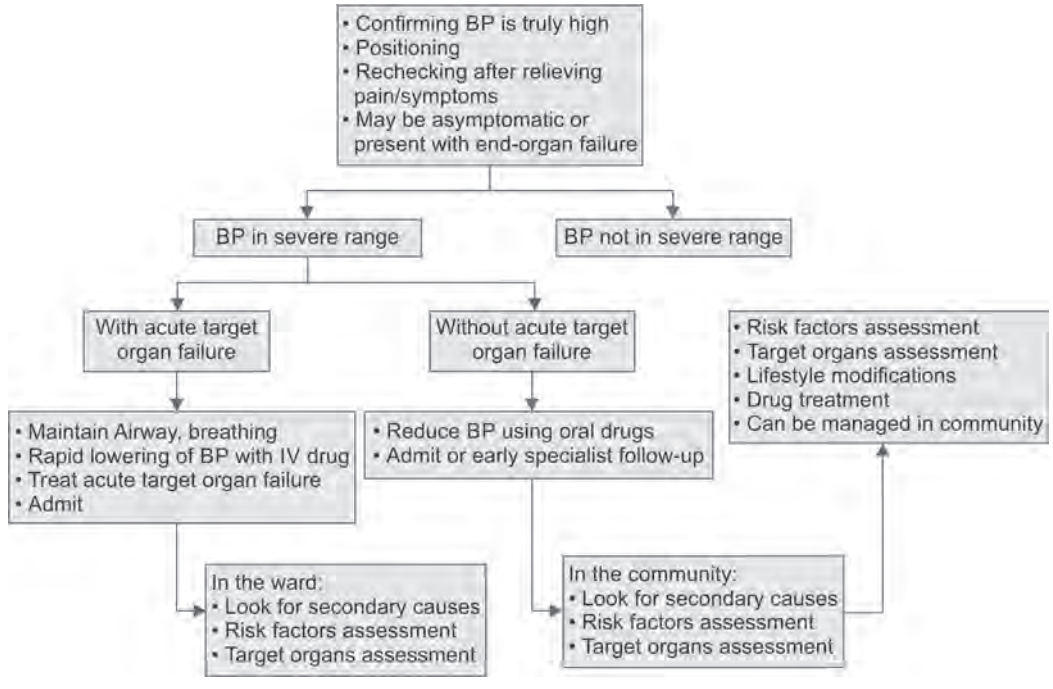
There are well-established evidence-based guidelines for choosing oral antihypertensive agents. The rule of thumb is to keep BP < 130/80 mm Hg. Other target BPs may be applied in subgroup patients. Always check for drug compliance and adverse drug reactions. Stepwise approach is considered while managing the hypertension and also selecting the appropriate antihypertensive agents (**Table 6**). Monitoring the BP at the observation ward may be needed before starting or changing the antihypertensive drugs. With newly diagnosed mild or moderate hypertension, an antihypertensive may be better started by a community physician after detailed assessment and lifestyle modification. Among the elderly, treatment target may be more relaxed so as to avoid the side effects of antihypertensives such as postural hypotension. **Flowchart 2** will helpful emergency physician in managing the systemic hypertension.

TABLE 5: Risk factors for cardiovascular diseases.

Nonmodifiable	*Modifiable*
• Early onset of menopause • Family history of cardiovascular disease • Increasing age • Male gender	• Diabetes mellitus (DM) • Diet • Drug-iatrogenic symptoms, drug abuse or missing dosages • Exercise • Hyperlipidemia • Hypertension • Obesity • Psychosocial factors • Smoking

TABLE 6: Drug choice in systemic hypertension.		
Step 0	Lifestyle modification such as weight loss, low-salt diet, exercise, avoidance of smoking and excessive alcohol	
	All ages with diabetes mellitus (DM)	No DM and > 55 years old
Step 1	ACE inhibitor or ARB	Calcium channel blocker (CCB)
	Check drug compliance	
Step 2	Add a thiazide diuretic or a CCB	Prefer adding an ACE inhibitor or ARB rather than a thiazide (not much synergy between thiazide diuretics and CCBs)
	Check drug compliance	
Step 3	ACE inhibitor or ARB plus a thiazide diuretic plus a CCB	
	Check drug compliance	
Step 4	• Known as resistant hypertension • Consider beta-blocker • Look for secondary causes • Refer to a specialist	
Choice of antihypertensives: • ACE inhibitor and ARB are preferred in diabetes and heart failure • β-blockers are preferred choice for Ischemic heart disease and heart failure • CCBs and diuretics are preferred in elderly • Pregnancy always demands special consideration; consider labetalol and hydralazine		
Remarks: • ACE inhibitors are contraindicated in hyperkalemia, bilateral renal artery stenosis produces cough • ARBs are contraindicated in hyperkalemia, bilateral renal artery stenosis • β-blockers are contraindicated asthma/COPD, pheochromocytoma 2° and 3° heart blocks • CCBs are contraindicated in 2° and 3° heart blocks • Renin–angiotensin levels are lower in patients >55; ACE inhibitors/ARBs are less effective on them • ACE inhibitors and ARBs are not usually used together		

(ACE: angiotensin-converting enzyme; ARB: angiotensin II receptor blocker)



• Confirming BP is truly high
• Positioning
• Rechecking after relieving pain/symptoms
• May be asymptomatic or present with end-organ failure
BP in severe range
BP not in severe range
With acute target organ failure
Without acute target organ failure
• Risk factors assessment
• Target organs assessment
• Lifestyle modifications
• Drug treatment
• Can be managed in community
• Maintain Airway, breathing
• Rapid lowering of BP with IV drug
• Treat acute target organ failure
• Admit
• Reduce BP using oral drugs
• Admit or early specialist follow-up
In the ward:
• Look for secondary causes
• Risk factors assessment
• Target organs assessment
In the community:
• Look for secondary causes
• Risk factors assessment
• Target organs assessment

FLOWCHART 2: Approach to systemic hypertension in emergency department.

THERAPEUTIC APPROACH TO HYPERTENSIVE EMERGENCIES AND URGENCIES

Clinical presentation of hypertensive emergencies in ED is associated with different diseases and they manifest in various form such as pulmonary edema myocardial ischemia, aortic dissection, and preeclampsia hypertensive encephalopathy. So, in each subset of presentation, the choice of antihypertensive agent is different (**Table 7**). The target BP goals in hypertensive emergencies of varied etiology are also different (**Table 8**). Controlled BP reduction to target goals should be achieved in order to prevent organ damage. Care should be taken to not lower BP rapidly and to normal levels. The therapeutic approach should be to refrain from a rapid reduction in BP as this approach has been found to be associated with considerable morbidity. Clinical presentation guides the choice of antihypertensive agents in hypertensive emergencies. In patients presenting with *hypertensive urgencies, oral medications* are used to gradually lower the BP over a period of 24–48 hours (**Table 9**).

TABLE 7: Choice of pharmacological agent in hypertensive emergency according to presentation.

Condition	*Preferred drugs*	*Drugs to avoid*
Acute pulmonary edema/ heart failure	Fenoldopam/nitroprusside + nitroglycerin (up to 60 µg/min) + loop diuretic	Hydralazine and β-blockers
Myocardial ischemia and infarction	Labetalol/esmolol + nitroglycerin (up to 200 µg/min) +/- nicardipine/fenoldopam if BP uncontrolled or poorly controlled	Hydralazine, minoxidil, diazoxide, and nitroprusside
Hypertensive encephalopathy	Labetalol/nicardipine/fenoldopam	β-blockers, methyldopa, clonidine, diazoxide, hydralazine, and nitroglycerin
Acute aortic dissection	Labetalol or nicardipine + esmolol or nitroprusside + esmolol/ IV metoprolol	Hydralazine, minoxidil
Preeclampsia and eclampsia	Labetalol/nicardipine	Diuretics and ACE inhibitors
Acute renal failure, Microangiopathic anemia	Fenoldopam/nicardipine	
Intracerebral hemorrhage	Nimodipine (oral)/nicardipine/labetalol/nitroprusside/ enalaprilat	β-blockers, methyldopa, clonidine, diazoxide, hydralazine, and nitroglycerin
Hyperadrenergic states/ Sympathetic overdrive	Phentolamine/nitroprusside/labetalol/nicardipine/verapamil. Alternatively, Fenoldopam +/– a benzodiazepine (in cocaine overdose)	β-blockers (in cocaine overdose)

TABLE 8: Target blood pressure (BP) goals for specific emergencies.

Conditions	*Target BP Goal*
Hypertensive encephalopathy	MAP lowered by maximum 20% or to DBP 100–110 mm Hg within 1st hour then gradual reduction in BP to normal range over 48–72 h
Ischemic stroke	MAP lowered no >15–20%, DBP not <100–110 mm Hg in first 24 h (thrombolytic protocols in stroke may allow slightly more aggressive management)
Intracerebral hemorrhage	MAP lowered by 20–25%
Hypertensive retinopathy	MAP lowered by 20–25%
Left ventricular failure	MAP to 60–100 mm Hg
Aortic dissection	SBP 100–120 mm Hg
Acute renal insufficiency	MAP lowered by 20–25%
Pregnancy-induced hypertension	SBP 130–150 mm Hg, DBP 80–100 mm Hg

(MAP: mean arterial pressure; SBP: systolic blood pressure)

TABLE 9: Oral antihypertensive agents for hypertensive urgencies.

Agent	*Dose*	*Onset of action*	*Duration of action*	*Precautions*
Captopril	25 mg	15–30 min	2–6 h	Can cause renal failure in bilateral renal artery stenosis
Clonidine	0.1–0.2 mg, can be repeated hourly to a total dose of 0.6 mg	30–60 min	8–16 h	Drowsiness and dry mouth
Labetalol	200–400 mg, repeated every 2–3 h	0.5–2 h	2–12 h	Bronchoconstriction, heart block, and orthostatic hypotension
Prazosin	1–2 mg, repeated hourly as needed	1–2 h	8–12 h	First dose syncope, palpitation, and orthostatic hypotension

SUMMARY

Systemic hypertension is common. The incidence and prevalence of people living with hypertension are growing in India every day. As a result, the number of hospital visits in our country due to hypertensive emergencies also is on the rise. It is imperative for the emergency physicians and other medical personnel working in the ED to have a proper understanding of the pathophysiology and presentation of hypertensive crisis and distinguish urgency from an emergency. Prompt treatment based on correct diagnosis can prevent severe end-organ morbidity. As such, the treating physicians should also know the various treatments available and their dosing including adverse effects. Various *antihypertensive drugs used in hypertensive emergencies* are summarized in **Table 10** for the benefit of the reader. Many medications are available to treat hypertensive emergencies but none is universally recognized as being superior to the others. The appropriate therapeutic approach is specific to patients depending on their clinical presentation. With appropriate identification and management, hypertensive crisis can be halted and reversed.

ACKNOWLEDGMENT

The authors wish to thank Dr Chan Wai Kwong, Dr Chan Tsan Fai, and Dr Risa Ozaki for their valuable advice.

TABLE 10: Pharmacological agents used in hypertensive emergencies.

Drug	*Dose*	*Onset of action*	*Duration of action*	*Adverse effects*	*Indications*
Sodium nitroprusside	0.25–10 µg/kg/min IV infusion	Few seconds	1–2 min	Nausea, vomiting, and cyanide toxicity	Most hypertensive emergencies; use cautiously in patients with high intracranial pressure or azotemia
Nitroglycerine	5–100 µg/min IV infusion	1–5 min	5–30 min	Headache vomiting, methemoglobinemia caution in right ventricular infarct	Cardiac ischemia, flash pulmonary edema; use cautiously in right ventricular infarction or with recent use of phosphodiesterase inhibitors
Nicardipine	5–15 mg/h IV infusion	5–10 min	15–30 min, may last several hours	Tachycardia, headache, flushing, and local phlebitis	Most hypertensive emergencies; caution—causes coronary steal in cardiac ischemia
Fenoldopam	0.1–0.3 µg/kg/min IV infusion	5–10 min	30 min	Tachycardia, headache, nausea, and flushing	Best for renal hypertensive emergencies
Enalaprilat	1.25–5 mg IV every 6 h	15–30 min	6–12 h	Significant fall in BP in high renin states	Acute left ventricular failure, flash pulmonary edema; avoid in acute MI
Hydralazine	10–20 mg 10–40 mg IM	10–20 min IV 20–30 min IM	1–4 h IV 4–6 h IM	Tachycardia, flushing, headache, vomiting, and worsening angina	Eclampsia; caution—gives erratic response
Clevidipine	1–2 mg/h then titrate to maximum 16 mg/h IV infusion	2–4 min	5–15 min	Headache, nausea, vomiting, hypotension, rebound hypertension, and reflex tachycardia	Postoperative hypertension, hypertensive emergency in renal dysfunction, or acute heart failure
Esmolol	250–500 µg/kg/min IV bolus, then 50–100 µg/kg/min IV infusion; repeat bolus after 5 min or increase infusion to 300 µg/kg/min	1–2 min	10–30 min	Nausea, hypotension, bronchoconstriction, heart failure, and first-degree heart block	Aortic dissection and perioperative hypertension
Labetalol	20–80 mg IV bolus every 10 min; or 0.5-2 mg/min IV infusion	5–10 min	3–6 h	Vomiting, dizziness, nausea, orthostatic hypotension, bronchoconstriction, and heart block	Most hypertensive emergencies, ideal for preeclampsia; caution—with acute heart failure
Phentolamine	5–15 mg IV bolus	1–2 min	10–30 min	Tachycardia, flushing, and headache	Pheochromocytoma and other conditions with catecholamine excess

CHAPTER

Pulmonary Hypertension

Asaad S Shujaa, Marah Alatrash, Noor Bamohammed

INTRODUCTION

Pulmonary hypertension (PH), defined as a mean pulmonary arterial pressure >25 mm Hg at rest or >30 mm Hg during exercise, is often characterized by a progressive and sustained increase in pulmonary vascular resistance (PVR) that eventually may lead to right ventricular (RV) failure. The hemodynamic-based definition of pulmonary arterial hypertension (PAH) includes mean pulmonary artery pressure (mPAP) ≥ 25 mm Hg, pulmonary capillary wedge pressure (PCWP) < 15 mm Hg, and PVR ≥ 3 wood units. The incidence is estimated to be 2.5–7.1 cases/million and with a prevalence ranging from 5–52/million in studies from Scotland and France. The mean age ranged from 45 to 65 years. There is a female predominance noted with a female to male ratio ranging from 1.7:1 to 4.8:1 among different registries. The racial distribution reported by REVEAL (the Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management) registry shows |PAH most prevalent among Caucasian (72.8%) followed by African American (12.2%) then Hispanics (8.9%)]. It can be a life-threatening condition if untreated. Therapy for PH is targeted at the underlying cause and its effects on the cardiovascular system, with success rates varying according to the etiology. Novel therapeutic agents, such as prostacyclin and others undergoing clinical trials, have led to the possibility of specific therapies for these once untreatable disorders.

CLASSIFICATION

The World Health Organization (WHO) has divided PH into five groups on the basis of similarities in pathophysiology, clinical presentation, and therapeutic options (**Table 1**). The groups 1 and group 5 are further divided into subgroups also.

Pulmonary veno-occlusive disease (PVOD) and pulmonary capillary hemangiomatosis have been designated as 1' to reflect the fact that although related, they are clinico-pathologically and therapeutically distinct entities from PAH of note, while persistent PH of the newborn was previously classified under group 1 PAH, the 2013 classification schema removed this from group 1 to better reflect the differences

TABLE 1: Classification of pulmonary hypertension (WHO).

Group 1	Pulmonary arterial hypertension (PAH)
	Subgroup 1: Idiopathic PAH (IPAH)
	Subgroup 2: Heritable PAH, including those with BMPR2 and *ALK2* gene mutations
	Subgroup 3: Drug- and toxin-induced PAH (aminorex, fenfluramine derivatives, and toxic rapeseed oil have been identified as definite risk factors for PAH. Other drugs implicated as possible risk factors for PAH include amphetamine and amphetamine derivatives, cocaine, L-tryptophan, phenylpropanolamine, St John's wort, leflunomide, phentermine, mazindol, dasatinib, and interferon)
	Subgroup 4: Conditions with known localization of lesions in the small pulmonary arterioles, which include: (1) Collagen-vascular disease (scleroderma/CREST syndrome), (2) Congenital left-to-right shunts, (3) Portopulmonary hypertension, (4) HIV-associated pulmonary hypertension, and (5) Schistosomiasis
Group 2	Pulmonary hypertension due to left-sided heart disease
Group 3	Pulmonary hypertension due to lung diseases and/or hypoxia
Group 4	Chronic thromboembolic pulmonary hypertension (CTEPH)
Group 5	Pulmonary hypertension with unclear or multifactorial etiologies including: *Subgroup 1*—hematologic disorders (e.g., myeloproliferative disorders), *Subgroup 2*—Systemic disorders (e.g., sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, and vasculitis), *Subgroup 3*—metabolic disorders (e.g., glycogen storage disease, Gaucher disease, and thyroid disorders), and *Subgroup 4*—miscellaneous conditions (e.g., tumor obstruction, mediastinal fibrosis, and chronic renal failure on dialysis)

between this and other PAH subgroups. The updated schema also moved chronic hemolytic anemia from group 1 to group 5 PH.

On the basis of information adapted from the executive summary of the world symposium on primary PH in Evian, France, in 1998, PH may be divided into the following functional classes:

- *Class I*: These are patients with PH but without resulting limitation of physical activity; ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near-syncope.
- *Class II*: These are patients with pulmonary hypertension resulting in slight limitation of physical activity; they are comfortable at rest, but ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near-syncope.
- *Class III*: These are patients with PH resulting in marked limitation of physical activity; they are comfortable at rest, but even less than ordinary activity causes undue dyspnea or fatigue, chest pain, or near-syncope.
- *Class IV*: These are patients with PH who are unable to perform any physical activity without symptoms; these patients manifest signs of right-sided heart failure; dyspnea or fatigue may even be present at rest, and discomfort is increased by any physical activity.

PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION

Pulmonary hypertension is a result of an increase in resting mean mPAP ≥ 25 mm Hg as measured with right heart catheterization. This low pressure is due to low resistance which results in a large cross-sectional area of the pulmonary circulation. This can happen due to several etiologies or due to anatomical site and function. Regardless the etiology, anything increase the resistant will cause an increase PH.

The pathological pathway consistent of enhanced pulmonary arteriole contractility, endothelial dysfunction, remodeling and proliferation of both endothelial and smooth muscle cells, and in situ thrombi. The physiological outcome of these disturbances is the partial occlusion of small pulmonary arteries, eventuating in increased PVR leading to RV hypertrophy with eventual cor pulmonale. There are three mechanisms of chemical disturbance (signaling pathways) that happen in the pulmonary trunk that's lead to smooth muscle hypertrophy of pulmonary arteries, and intimal fibrosis these are:

1. *Nitric oxide (NO) pathway*: NO is produced in endothelial cells and follows sequence of reaction that results of pulmonary vasodilation. Additionally, NO inhibits pulmonary vascular smooth muscle cells proliferation, platelet aggregation and thrombosis, and collectively maintaining normal healthy pulmonary vasculature. In PH, there is decreased bioavailability of NO, causing vasoconstriction and increased smooth muscle cell proliferation, inflammation, and thrombosis.
2. *Prostacyclin-thromboxane A2 pathway*: Prostacyclin, produced in endothelial cells prostaglandin I2 (PGI2), binds to specific receptors in smooth muscle cells which leads to smooth muscle relaxation and subsequent vasodilation. Prostacyclin inhibits platelet aggregation, attenuates smooth muscle proliferation, and produces anti-inflammatory and antithrombotic effects. In PH, the pathway shifts toward an alternative product, thromboxane A2, leading to platelet aggregation, vasoconstriction, and proliferation.
3. *Endothelin-1 (ET-1) pathway*: ET-1 is a peptide that acts as a potent vasoconstrictor. ET-1 is produced on endothelial cell membranes from the precursor peptide big-ET-1 by endothelin-converting enzymes. ET-1 activates endothelin receptor A (ETA) and endothelin receptor A (ETB)—two G-protein coupled receptors. ETA is found on vascular smooth muscle cells, and promotes vasoconstriction, hypertrophy, proliferation, cell migration, and fibrosis when activated. ETB is located on both vascular smooth muscle and endothelial cell surfaces. On smooth muscle, activation of ETB causes vasoconstriction whilst on endothelial surfaces, ETB activates NO and prostacyclin production, causing vasodilation and anti-proliferation. In PH, there is an increase in expression of ETA and smooth muscle ETB, but reduced expression of endothelial ETB. In addition, patients exhibit increased ET-1 concentrations in their plasma and pulmonary vascular endothelial cells.

CLINICAL PRESENTATION

The clinical manifestations of PAH are frequently masked by the underlying disease entities. The PH presenting in ED setting is complex because of nature of disease and nonspecific symptoms because the majority of symptoms are subtle except is started worsening and presented clinical evidence of RV failure and the only way you can evaluate by looking for full symptoms and signs as in **Table 2**. Most of emergency presentation is going with worsening RV failure such as dyspnea on exertion and eventually at rest, fatigue, syncope at exertion anginal chest pain, and hemoptysis. There is no clear red flag for PH because the symptoms are subtle and nonspecific especially in emergency settings, however, the only important red flags are worsening short breath with known cases of PH and clinical evidence of RV failure can raise suspicion for PH and need further work-up and investigation of *nonspecific symptoms* secondary to PH. These may include the following—dyspnea upon exertion fatigue lethargy syncope with exertion, chest pain, anorexia, and right upper quadrant pain. *Less common symptoms* include—cough hemoptysis hoarseness (due to compression of the recurrent laryngeal nerve by the distended).

TABLE 2: Symptoms and signs of pulmonary hypertension.

Symptoms	***Signs***
Dyspnea on exertion	Jugular vein distention
Fatigue	Prominent right ventricular impulse
Syncope	Accentuated pulmonic valve component (P2)
Anginal chest pain	Right-sided third heart sound (S3)
Hemoptysis	Tricuspid insufficiency murmur
Raynaud's phenomenon	• Hepatomegaly • Peripheral edema

EVALUATION

Obtaining a careful history may help differentiate PAH from groups 2–5 PH. Important clues to a specific cause include the following:

- History of heart murmur
- Deep venous thrombosis (DVT) or pulmonary embolism (PE)
- Raynaud phenomenon
- Arthritis or arthralgias
- Rash
- Heavy alcohol consumption
- Hepatitis
- Heavy snoring
- Daytime hypersomnolence
- Morning headaches
- Morbid obesity
- Family history of PH
- Drug use, in particularly diet drugs and illicit drugs
- Medications

INVESTIGATIONS AND INTERPRETATION

The diagnosis of PH requires a clinical suspicion based on symptoms and physical examination and reviews of a comprehensive set of investigations to confirm that hemodynamic criteria are met and to describe the etiology and the functional and hemodynamic severity of the condition. The interpretation of these investigations requires, at the very least, expertise in cardiology, and imaging and respiratory medicine and may best be discussed at a multidisciplinary team meeting. Tests for PH may include:

- *Blood tests*: Blood tests determine the cause of PH or look for signs of complications.
- *Chest X-ray* is inferior to the electrocardiogram (ECG) in detecting PH, but it may show evidence of underlying lung disease.
- *Electrocardiogram* is may demonstrate signs of RV hypertrophy, such as tall right precordial R waves, right axis deviation, and RV strain.
- *Echocardiogram* is the most useful imaging modality for detecting PH.
- *Right heart catheterization* should be performed in patients with unexplained PH, and remains the gold standard for its diagnosis and quantification. Catheterization is particularly useful in diagnosing occult shunts, congenital heart disease, and distal pulmonary artery stenosis. Various heart pressures are measured (pressure inside the pulmonary arteries, coming from the left side of the heart), the rate at which the heart is able to pump blood, and finds any leaks between the right and left sides of the heart (**Fig. 1**).

TREATMENTS FOR PULMONARY HYPERTENSION

Treatment for PH is based on three parameters: (1) To correct the underlying cause, (2) Therapy to decrease the PVR; and (3) Measures to increase the cardiac output.

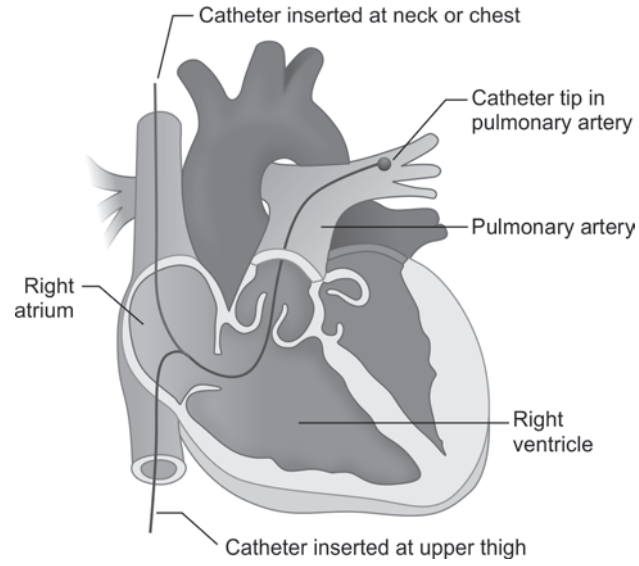

FIG. 1: Right heart catheterization.

Medical Therapy

Correct Underlying Cause

- Surgical treatment of mitral stenosis, left to right shunt, or accessible chronic thromboembolism.
- Afterload reduction, digoxin (Lanoxin), and diuretics for left ventricular dysfunction.
- Prevention and treatment of respiratory infection
- Avoidance of anorectic agents.

Decrease Pulmonary Vascular Resistance

- Vasodilators
- Oxygen
- Calcium channel blockers such as diltiazem (Cardizem) or nifedipine (Procardia)
- Nitric oxide (investigational)
- Anticoagulants for primary PH and chronic thromboembolism.
- Sildenafil and tadalafil relax pulmonary smooth muscle cells, which lead to dilation of the pulmonary arteries.
- Endothelin-receptor antagonists—bosentan and ambrisentan help block the action of endothelin, a substance that causes narrowing of lung blood vessels. These medications require monthly lab work to monitor liver function.

Increase Cardiac Output

- Short-term parenteral inotropes
- Digoxin
- Reduce volume overload
- Low-salt diet
- Diuretic

Surgical Therapies

- *Pulmonary thromboendarterectomy*: If present, a large clot in the pulmonary artery may be surgically removed to improve blood flow and lung function.

- *Lung transplantation*: Currently, this is the only cure for primary PH. Transplantation is reserved for advanced PH that is not responsive to medical therapy. The right side of the heart will generally return to normal after the lung/lungs have been transplanted.
- *Heart/lung transplantation*: This type of double organ transplant is very rare but is necessary for all patients who have combined lung and left heart failure.

DISPOSITION

Majority of above treatment will be started with specialized doctor as outpatient clinic, except if patient presented in pulmonary edema or instability in ED will treated according advanced cardiac life support (ACLS) protocol and to be consulted and admitted to the hospital.

SUMMARY

Pulmonary hypertension is a chronic, complex and challenging disease. Advances in treatment are for the subset of patients with pulmonary arterial hypertension. PH is classified into five groups based on WHO classification. Echocardiography remains the initial test of choice, and careful assessment of the right heart system aids in the diagnosis and prognosis of the disease. Right heart catheterization remains the gold standard of diagnosis and key guidance of treatment. Multidisciplinary approach is recommended for the care of patients with PH. Treatment selection is based on individual risk stratification of patients, and early referral to specialized centres improves outcomes of patients. Treating PH is complex and is best carried out in higher centres and with multidisciplinary approach. Early diagnosis and referral to those centres are key not to delay treatment.

76
CHAPTER

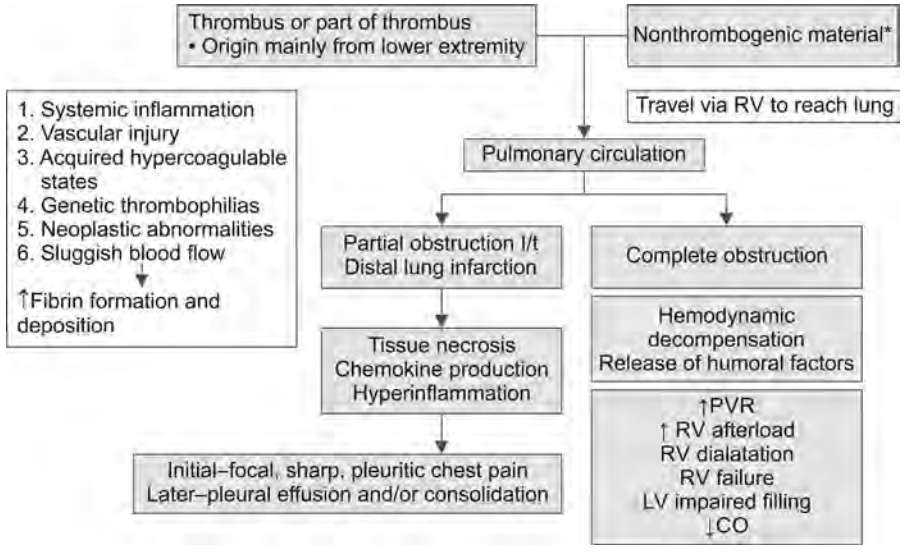
Pulmonary Embolism

Ashima Sharma

INTRODUCTION

Pulmonary embolism (PE) is a common emergency presenting to Indian emergency departments which frequently goes undiagnosed or misdiagnosed. PE is a condition when blood clots enter in to the pulmonary arterial circulation. Deep vein thrombosis (DVT) of the legs, arm pelvis jugular, or inferior vena cava is the common cause. PE and DVT are collectively known as *venous thromboembolism*. The symptomology can overlap with various cardiorespiratory illnesses such as acute coronary syndrome, pneumonias, chronic obstructive pulmonary disease (COPD) exacerbations, pericardial effusions, etc. It is a potentially life-threatening diagnosis that is seen in patients with dyspnea and/or chest pain, but can span the entire clinical spectrum of medical presentations from asymptomatic to cardiovascular collapse. It does not have any particular historical feature, physical examination finding, laboratory test, or diagnostic modality that can independently and confidently excludes its possibility.

The role of the emergency physician is to identify potentially life-threatened patients, who would benefit from early intervention and treatment, and to stabilize and treat accordingly. Although the treatment of PE is straightforward and algorithmic, the diagnostic approach is subject to significant debate and variability. Incidence in India, Overall, the annual incidence of PE ranges between 23 and 69 cases per 100,000 population, with an average case fatality rate within 2 weeks of diagnosis of approximately 11% roughly accounting for at least 100,000 deaths each year. **Flowchart 1** shall illustrate the pathophysiology of the disease. In severe cases, the disease



*Adipocytes, hematopoietic, amniotic, trophoblatic, or tumor cells, bacteria, fungi, parasites, foreign material (e.g., central venous catheters), or gas.

(PVR: pulmonary vascular resistance; RV: right ventricular)

FLOWCHART 1: Pathophysiology of pulmonary embolism.

progresses to pulmonary hypertension and post-thrombotic syndrome to cause significant morbidity.

RISK FACTORS

- Trauma to lower extremity and pelvis during the past 3 months
- Travel ≥4 hours in the past month, air travel for 3,000 miles for ≥6 hours
- Originally, the increased risk was attributed to the high estrogen content of the early oral contraceptive pill (OCP); however, low estrogen plus progesterone OCP has also been associated with thrombogenicity.
- Surgery within the last 3 months—neurosurgical, oncologic, and orthopedic are high-risk procedures. 15% of postoperative deaths are due to PE.
- Pancreatic carcinoma has the highest incidence, whereas bladder tumors have the lowest incidence. Patients with lung, brain, or ovarian tumors are also particularly prone to the development of DVT and PE.
- Sickness like congestive heart failure (CHF), stroke, sepsis/infection, hyperviscosity syndromes—polycythemia, multiple myeloma, nephrotic syndrome, human immunodeficiency virus, and Behçet's disease. Classic and inherited risk factors of PE are summarized in **Table 1**.

CLINICAL PRESENTATION

The combination of classic findings of chest pain, dyspnea, and hemoptysis is present in less than 20% of patients. Any complaints related to pain, shortness of breath, nonspecific malaise or functional deterioration, extremity discomfort, weakness, dizziness, or syncope could be a presentation of PE. One should always keep a high degree of suspicion for PE, if a patient presents with rapid onset of symptoms, which can be a combination of any of the ones listed above. The elderly patients are known to present atypically. 20% of patients will have no identifiable risk factors at the time of ED presentation. Varicose veins are prone to develop clots, the smaller ones, however, seldom embolize. *Symptoms according to the descending order of appearance are*: dyspnea—90%, pleuritic chest pain—75%, tachycardia—<50%, nonpleuritic chest pain—20%, hemoptysis—<20%, and reproducible chest pain—<20% but we should know that even MI pain can be reproducible, uncommon symptoms are <5%—low grade fever, change in pattern of breathing, altered mental status, syncope, vomiting, abdominal pain, back pain, atrial fibrillation, syncope, hiccoughs, and reactive airways disease. No symptoms—<3%.

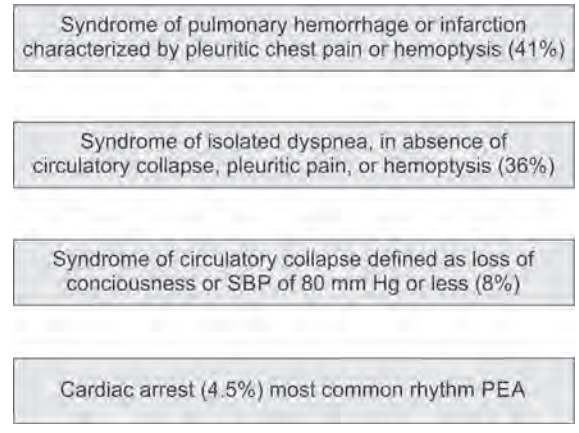
No physical examination finding is sensitive or specific for PE. Physical examination may fail to reveal any clues in 28–58% of patients. However, it may help to rule out other causes of dyspnea like presence of pallor (acute decompensated anemia), raised jugular venous pressure (JVP) (pericardial tamponade), Kussmaul breathing (metabolic acidosis) third heart sound and/or a new onset murmur (acute coronary event) and wheeze, and crepitations (acute COPD exacerbation and pneumonia). A systolic blood pressure (SBP) <90 mm Hg, tachycardia (>94/min), or sometimes bradycardia in patients on AV nodal blockers or beta-blockers and a low SpO_2 (<95%) are most commonly found. A shock index of >1.0, unilateral leg swelling, RR > 24/min, and fever >100.4°F are the classical physical findings but rare. **Figure 1** illustrates the different presentation syndromes. It is important to understand these because the pretest possibility of the disease is strongly associated with a clinical gestalt judgment by an experienced physician. However, it is argued that increased clinical experience may result in reduced comfort clinically excluding PE.

TABLE 1: Classic risk factors for PE can be memorized by a mnemonic "THROMBOSIS".

T	Trauma/travel
H	Hypercoagulable states/hormonal replacement therapy
R	Recreational drug use
O	Older
M	Malignancy
B	Birth control
O	Obesity/obstetrical (risk highest from second week of pregnancy to first 6 weeks postpartum)
S	Surgery
I	Immobilization
S	Sickness
Inherited risk factors: Factor V Leiden mutation, antiphospholipid antibody syndrome, antithrombin III deficiency, protein C deficiency, protein S deficiency, prothrombin gene mutation, Increased factor VIII activity, activated protein C (APC) resistance, and dysfibrinogenemia hyperhomocysteinemia	

PRETEST PROBABILITY, SCORING SYSTEM AND PERC

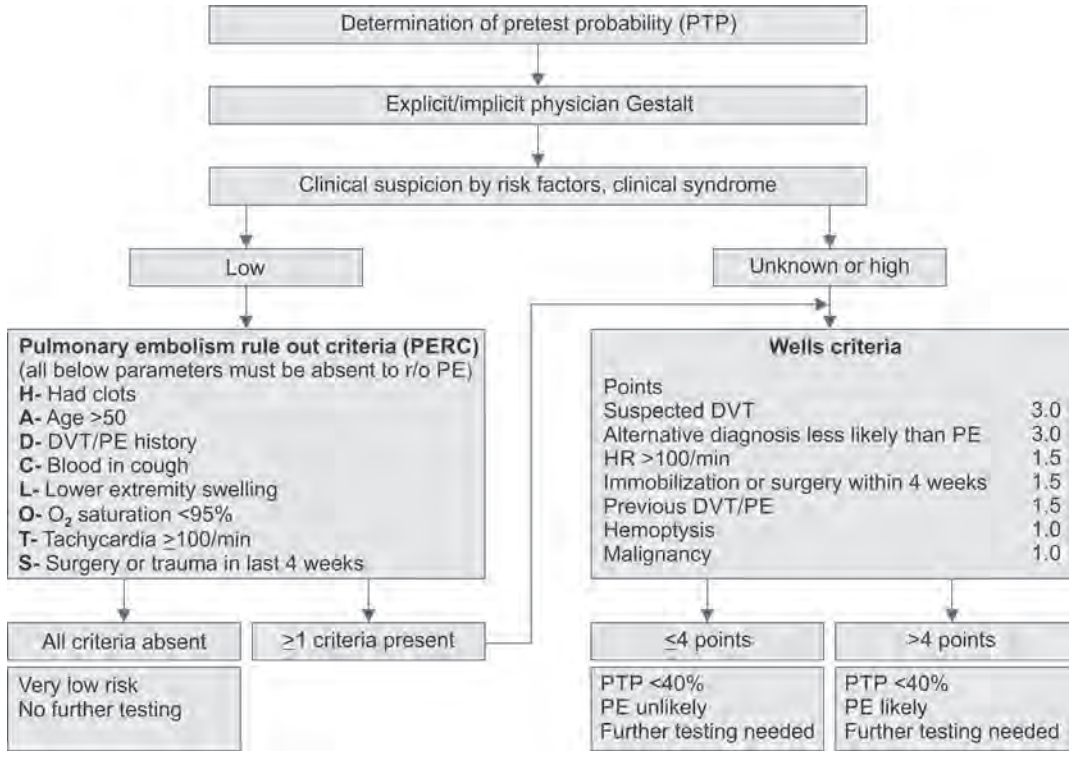
Determining the pretest probability (PTP) identifies high-risk patients who may benefit from treatment prior to the completion of investigation, and low-risk patients in whom few, if any, investigations are required (**Flowchart 2**). Explicit assessment of PTP relies on the use of evidence-based clinical decision rules or scoring systems to categorize the PTP. *Three scoring systems have been prospectively tested* and validated in large clinical trials: (1) *The Wells score (**Table 2**), (2) the Geneva*



Syndrome of pulmonary hemorrhage or infarction characterized by pleuritic chest pain or hemoptysis (41%)
Syndrome of isolated dyspnea, in absence of circulatory collapse, pleuritic pain, or hemoptysis (36%)
Syndrome of circulatory collapse defined as loss of conciousness or SBP of 80 mm Hg or less (8%)
Cardiac arrest (4.5%) most common rhythm PEA

(PEA: pulseless electrical activity)

FIG. 1: Different presenting syndrome of pulmonary embolism.



(DVT: deep vein thrombosis; PE: pulmonary embolism)

FLOWCHART 2: Determining pretest probability.

TABLE 2: Assessing probability Of PE and DVT using Well's score.

Well's score for pulmonary embolism (PE)		***Well's score for deep vein thrombosis (DVT)***	
Factor	Points	Factors	Points
Suspected DVT	3	Active malignancy	1
Alternative diagnosis is less likely	3	Immobilization (paralysis and fracture)	1
Heart rate	1.5	Bedridden within 12 weeks for >3 days	1
Previous PE/DVT	1.5	Whole leg swelling	1
Surgery/immobilization last 1 month	1.5	Tenderness along deep vein distribution	1
Active malignancy	1	Calf swelling unilateral	1
Hemoptysis	1	Superficial vein collaterals	1
Interpretation of risk score: Probability of PE <2 points—low risk, 2–6 points—moderate risk, >6 points—high risk		Alternative diagnosis is more likely	–2
		H/O PE or DVT	1
		Interpretation of risk score: Probability of DVT ≥3 score high risk, 1–2 points moderate risk, <1 point low risk	

(DVT: deep vein thrombosis; PE: pulmonary embolism)

*score (**Table 3**), and (3) the Pisa score. The Pisa score is more appropriately used for hospitalized patients, whereas the Wells and Geneva scores were developed for use in the emergency department.*

Pulmonary Embolism Rule out Criteria (PERC) rule (**Box 1**) should be applied only in population with very low prevalence of PE. There are few more contraindications to apply the *PERC* rule. These are as follows—concurrent β-blocker use (may blunt tachycardia), transient tachycardia, thrombophilia, strong family history of thrombosis, patients with amputations, massively obese patients (may be difficult to clinical assess leg swelling), and patients with baseline hypoxemia.

DIAGNOSTIC WORKUP

Most routine investigations, including basic blood work, chest radiograph, ECG, cardiac troponins, brain natriuretic peptide (BNP), and arterial blood gas (ABG), are of limited value.

TABLE 3: Revised Geneva score for assessing probability of pulmonary embolism.

Clinical variables	*Points*
>65 years of age	1
h/o venous thromboembolism	1
Lower limb fracture (in previous month) or surgery requiring anesthesia	1
Malignancy (active)	1
Leg pain (unilateral)	1
Hemoptysis	1
Unilateral limb edema or pain	1
Heart rate >95	1
Interpretation of score 0–3 indicates low probability, 4–10 moderate probability, >10 high probability of PE	

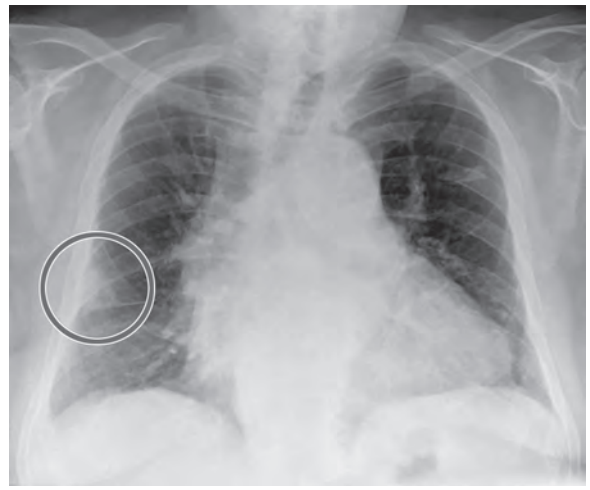


FIG. 2: Chest X-ray showing Hampton hump.

BOX 1: Pulmonary Embolism Rule out Criteria (PERC).

- Age <50 years
- Pulse <100 bpm
- Oxygen saturation >94%
- No hemoptysis
- No history of PE/DVT
- No surgery/trauma (no requirement of endotracheal intubation and anesthesia)
- No unilateral limb swelling, tenderness
- No h/o hormone replacement (estrogen) therapy
- Low clinical probability (<15% by Gestalt assessment)
- All clinical factors must be present to rule out pulmonary embolism

(DVT: deep vein thrombosis; PE: pulmonary embolism)

Electrocardiograph

It is neither sensitive nor specific. A normal ECG can be seen in 30% of patients with PE, whereas the classic S1Q3T3 occurs in only 20% of patients with angiographically proven PE, and has a sensitivity and specificity of 54% and 62%, respectively. The most common ECG change is T-wave inversion in the precordial leads, found in 68% of patients with PE. T-wave inversions may mimic an ischemic event, which is seen in 11% of patients without prior history of cardiopulmonary disease. Sinus tachycardia is the most frequent rhythm seen in patients with PE, occurring in 36%. Other ECG findings include changes suggestive for acute cor pulmonale—right bundle branch block, P-wave pulmonale, right axis deviation, and new-onset atrial fibrillation.

Chest Radiograph

It is typically nonspecific and nondiagnostic. It is reported to be normal in 12–24% of patients. Cardiomegaly, elevated hemidiaphragm, atelectasis, pleural effusion, parenchymal infiltrates, and PA enlargement are among the most common abnormalities. Patients without cardiopulmonary disease had only blunting of the costophrenic angles, and none had an effusion more than one-third of the hemithorax. The flip side of chest infiltrates is that those which are not fitting in clinical diagnosis of pneumonia, these patients can be having PE.

Hampton hump (**Fig. 2**) is a wedge-shaped, pleural-based, apex central pulmonary opacity that is uncommon and has a sensitivity and specificity of 22% and 82%. *Westermark* sign (**Fig. 3**) is relative oligemia usually in the presence of an ipsilateral dilated PA. It is also uncommon and has a sensitivity and specificity of 12% and 97%.

Arterial Blood Gas

In patients with normal lungs, a PCO_2 >36 mm Hg and normal alveolar arterial oxygen (A-a) gradient had a 98% negative predictive value for PE. The unexplained presence of hypoxemia or any sudden change in the A-a gradient increases the likelihood of PE. An elevated lactate generally reflects aerobic hyperlactatemia due to endogenous epinephrine production. This reveals that the patient is under occult hemodynamic stress, and is trying to compensate for that stress through increased sympathetic outflow.

Neutrophil/Lymphocyte Ratio

It is affected by occult physiologic stress (because endogenous cortisol will increase the neutrophil count and reduce the lymphocyte count, thereby increasing the ratio). Neutrophil/lymphocyte ratio (NLR) may be interpreted in the context of acute PE as follows—NLR <5.5 suggests low mortality risk (~2.7%), NLR 5.5–9.2 is a gray zone (NLR in this range is nonspecific and adds no useful information) and NLR >9.2 suggests high mortality risk (~26%).

Troponin and Brain Natriuretic Peptide

Troponin value may be helpful to clinicians in risk stratification of those patients found to have acute PE. Troponin can be increased in patients with massive acute PE and may be related to acute right ventricular strain or failure. BNP is not specific for PE and may be increased secondary to acute right ventricular strain with CHF, or other causes of pulmonary hypertension.

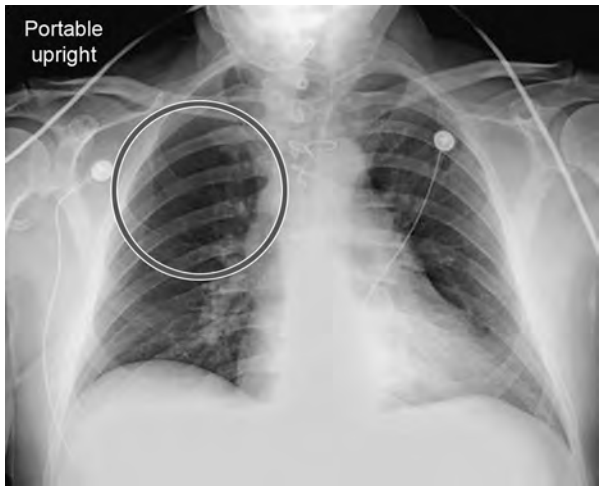

FIG. 3: Chest X-ray showing Westermark signs.

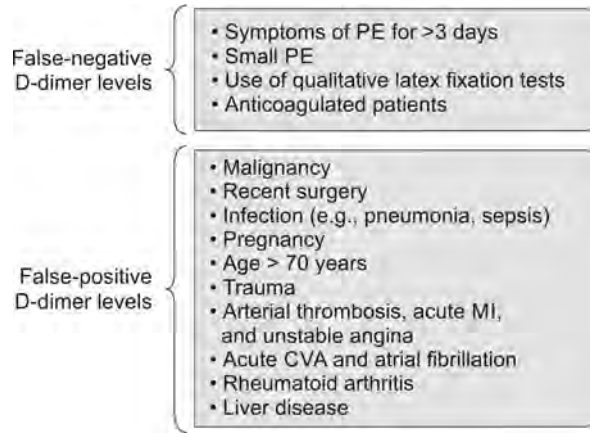

False-negative D-dimer levels
• Symptoms of PE for >3 days
• Small PE
• Use of qualitative latex fixation tests
• Anticoagulated patients
False-positive D-dimer levels
• Malignancy
• Recent surgery
• Infection (e.g., pneumonia, sepsis)
• Pregnancy
• Age > 70 years
• Trauma
• Arterial thrombosis, acute MI, and unstable angina
• Acute CVA and atrial fibrillation
• Rheumatoid arthritis
• Liver disease

(MI: myocardial infarction; PE: pulmonary embolism)

FIG. 4: Clinical conditions affecting the D-dimer level from expected values.

D-dimer

It is a fibrin degradation product that indicates the presence of intravascular fibrin deposition and is usually increased in thromboembolic disease. It was initially applied to patients already scheduled for imaging in an effort to reduce the number of pulmonary angiograms performed. With increasing use, the D-dimer became applied to manage patients even prior to the decision to perform diagnostic imaging. *The tips for using the D-dimer test wisely are* (1) Use a high sensitivity assay, (2) test low-risk patients, (3) test if you expect a negative result, and (4) Do not test if you have already scheduled the patient for computed tomography pulmonary angiography (CTPA). The quantitative D-dimer assays, ELISA and turbidimetric tests, have reported sensitivities of >93% and specificities of 39–55% (at a cutoff of 500 ng/mL; varies by institution) and are thus recommended for use to rule out the possibility of PE. It is important to learn how to decipher D-dimer result especially in elderly where normal D dimer level = Age in years × 10. Pregnant females increase their level by two times in second trimester and three times in third trimester, increase starting from end of first trimester. There is always a possibility to get normal value of D-dimer in presence of clinical PE and vice versa. In **Figure 4,** causes of false negative and false positive D-dimer value are given.

Echocardiographic

These abnormalities are present in approximately 30–40% of patients with PE. Transthoracic echocardiography (TTE) is noninvasive and rapidly available at the bedside, but lacks the sensitivity of TEE. Transesophageal echocardiogram (TEE) has greater sensitivity and diagnostic ability than TTE, but is invasive, of limited availability, often requires procedural sedation, and is unable to accurately detect peripheral PE. Echocardiography is most useful in patients with contraindications to other imaging modalities, hemodynamically unstable patients who cannot be transported outside the ED, or in patients with suspected massive PE to justify thrombolytics. Echocardiographic findings of PE are shown in **Figures 5A** to **H**.

Computed Tomography Pulmonary Angiography and V/Q Scan

- *The rule for computed tomography angiography (CTA)*—sensitivity for central clots is 100% and 90% for peripheral clots. It is 91% specific. If the PTP is high, but the CTA is negative, still one should order Doppler USG legs to look for VTE. The only good point here is that one can wait for initiating anticoagulation. The subsegmental PEs are more often recognized these days with advancement in CT scanners. 3–30% scans have isolated subsegmental clots with unclear clinical importance.
- *The rule for V/Q scan*—a young patient with no known lung disease [normal chest X-ray (CXR)] and normal V/Q scan, PE can be ruled out with very high predictive value. A normal V/Q scan essentially rules out PE with an NPV of 97%. A high-probability scan has a positive predictive value of 85–90% with a sensitivity and specificity of 41% and 97%, respectively. A low-probability interpretation is controversial, and many investigators advocate for additional testing. Indeterminate rates are more common among patients with significant cardiopulmonary disease, including acute and chronic airway disease, patients with abnormal chest radiography, and the elderly. A comparative analysis of both modalities is presented in tabular form in **Table 4**.

Other Modalities such as Compression Ultrasonography, MRI, and Pulmonary Angiography

- *Compression ultrasonography (CUS)* can be used at various points in the investigation of PE—(1) as an initial imaging modality; (2) after a negative or inconclusive CTPA; or (3) after a nondiagnostic V/Q scan. In patients with suspected PE, CUS as an initial investigation only detects 10% of DVTs. Two negative CUS examinations following a nondiagnostic or indeterminate V/Q scan result in a 3-month risk of PE of >1%. Early studies with single-slice or four-slice multidetector CTPA showed that CUS

TABLE 4: Comparative analysis of computed tomography pulmonary angiography (CTPA) and V/Q scan.

CT pulmonary angiography	*V/Q scan*
Advantages: • Readily available at most centers • Short acquisition time • Ability to detect alternative diagnosis • Retrospective reconstruction • High sensitivity/specificity • Dichotomous interpretation • Sole diagnostic test (multidetector CT) • Age does not influence result *Disadvantages*: • High maternal breast radiation dose • Reader expertise required • Expensive • Nephrotoxic iodinated contrast injection • Not portable • Physiological changes in pregnancy may cause non diagnostic result • Contraindicated in patients with contrast allergy and renal insufficiency	*Advantages*: • Radionuclide poses minimal risk and is safe in pregnancy • Safe in patients with contrast allergy and renal insufficiency • Low maternal breast radiation (0.28–0.9 mSv) • Dose can be further decreased by perfusion only scan *Disadvantages*: • Inability to provide alternative diagnosis • Long acquisition time • Potentially significant rate of nondiagnostic results • Limited access and availability

diagnosed an additional 3.1–6% of DVTs in patients with negative CT.

- *Magnetic resonance angiography (MRA)* advantages include safer contrast material, the absence of ionizing radiation, and similar sensitivity and specificity to CTPA. The combination of MRA and magnetic resonance (MR) venography had a sensitivity and specificity of 92% and 96%, respectively. MRI should only be considered in centers in which it is routinely performed.
- *Pulmonary angiography* has long been considered the gold standard for the diagnosis of PE. It is less helpful in visualization of subsegmental pulmonary arteries and greater interobserver disagreement.

TREATMENT

Systemic anticoagulation is the mainstay of the treatment for venous thromboembolism (DVT + PE). Unfractionated heparin and low molecular weight heparin (LMWH) are the two most common options. LMWH is preferred over unfractionated heparin as per recent data. Early administration of heparin is recommended but no study found morbidity or mortality benefit if heparin administers early and prior to imaging. Other measures such as placing the affected limb at neutral level, removal of tight clothing, dressing, and cast are equally important. Vascular consultation and catheter-directed thrombolysis should be arranged. Systemic thrombolysis is another option with Alteplase 50–100 mg infusion over 4 hours. The management of PE will be dealt under following headings. The initial management starts with resuscitation of PE patient (**Box 2**).

Anticoagulation

The treatment of acute PE is systemic anticoagulation with or without thrombolysis. Anticoagulation halts clot progression and allows endogenous fibrinolysis to occur. Clot resolution occurs over weeks to months, and may be incomplete in some individuals. Typically, an initial short-term therapy using unfractionated heparin, LMWH (e.g., enoxaparin and dalteparin), or fondaparinux is used and bridges the transition to the vitamin K antagonist warfarin.

Initial anticoagulation should be administered for 5 days and until the INR is in the therapeutic range of 2–3 for 2 days. In patients with a high clinical probability of PE, this treatment should begin before diagnostic imaging. In patients with low clinical PTP, it is considered safe to await confirmatory tests before initiating systemic anticoagulation. In general, empiric treatment confers more benefit than harm when, PTP exceeds 30%, imaging would delay anticoagulation for >24 hours, and the patient has no major contraindications. Available choices and the indications are discussed below (**Table 5**).

Thrombolysis in Pulmonary Embolism

Thrombolysis of a massive PE reduces the risk of cardiovascular collapse.

- Thrombolysis with alteplase is safer than is usually thought, available studies are underpowered to clearly define the risk of intracranial hemorrhage, but it seems to be low (1%) for reduced-dose regimens of alteplase (e.g., 50 mg). There is no need of complete resolution of clot. The goal should be to normalize the pulmonary pressures, but rather merely to cut back pressure sufficiently to prevent sudden cardiac death. Hence, a small dose 12–50 mg of alteplase can be recommended with lower risk of hemorrhage, thereby

BOX 2: Important points to remember during resuscitation of pulmonary embolism patient.

- Use high-flow nasal cannula for hypoxemic failure
- Add inhaled pulmonary vasodilators, whenever possible
- First thrombolytics, then intubation
- Define criteria of intubation—depressed mental status or respiratory exhaustion
- Intubation pearls:
  - Before intubation, try to increase the SBP = 130–140 mm Hg, usually with an epinephrine infusion
  - Be prepared with push-dose epinephrine to support the blood pressure after intubation. Have a low threshold for using this for hypotension or worsening bradycardia
  - Consider getting inhaled pulmonary vasopressors at the bedside and ready to be given through the ventilator circuit as soon as the patient is intubated. Administration of a milrinone dose through the endotracheal tube may also be utilized, if this is available.
  - Use meticulous preoxygenation and apneic oxygenation, paired with intubation by the most experienced operator present
  - Use sedatives that are hemodynamically stable (e.g., ketamine)
  - Avoid overvigorous bag ventilation, which will cause excessive intrathoracic pressures
  - Pay extreme attention to the patient's hemodynamics and oxygenation in the first 10 minutes after intubation, as this is when they are most likely to arrest
- Epinephrine due to its beta-agonist action is the first-line vasopressor. Helps in pulmonary vasodilatations as well. Vasopressin as second-line drug—systemic vasoconstriction with pulmonary vasodilatation
- Nitric oxide and epoprostenol—comparable results. High FiO_2 is a poor man's pulmonary vasodilator
- Try to limit ABG punctures. These may be the sites of bleeding when urgent thrombolysis is done
- Similar caution has to be taken for central venous cannulation—single puncture, experienced physician
- Intubation and positive pressure ventilation increases peripheral vascular resistance. Avoid or delay intubation
- Fluid boluses—very small, guided by US massive PE is not a fluid depleted state. Expect the IVC to be full. If not, suspect another diagnosis

(ABG: arterial blood gas; FiO_2: fraction of inspired oxygen; IVC: inferior vena cava; PE: pulmonary embolism; SBP: systolic blood pressure)

TABLE 5: Antithrombotic agents for pulmonary embolism (PE) and deep vein thrombosis

Drugs	*Indications and doses*	*Comments*
Heparin	Submassive PE bolus dose of 5,000 IU or 80 IU/kg, followed by a continuous 18 IU/kg/h nomogram-adjusted infusion to an APTT of 1.5–2.5 times the normal value	It can be stopped if any indication of bleeding. It can be paused or down-titrated in anticipation of thrombolysis or procedures
Low molecular weight heparin (LMWH)	Dalteparin is dosed at 200 U/kg once daily Enoxaparin administered at 1 mg/kg twice daily Tinzaparin is given at 175 U/kg once daily Fondaparinux patients weighing <50 kg, 50–100 kg, and >100 kg = doses of 5 mg, 7.5 mg, and 10 mg, s/c per day, respectively	The LMWHs and fondaparinux are preferable to unfractionated heparin because they are easier to administer, do not require intravenous infusions, and do not require monitoring of INR or Xa levels

TABLE 6: Identifying risk of Intracranial hemorrhage with thrombolysis by PECH score.

	Criteria	*Points*
P	Peripheral vascular disease	1
E	Elderly age >65 years	1
C	Prior CVA with residual deficit	5
H	Heart—prior myocardial infarction	1
Risk = 0 points = 1.2%, 1 point = 2.9%, 2 points = 3.4%, 5 points or more = 18%		

improving the overall risk/benefit ratio. *PECH score* can help to predetermine the risk of ICH with thrombolysis (**Table 6**).

- Ideally, heparin will be stopped and allowed to clear from the patient prior to systemic thrombolysis. This may be possible for hemodynamically stable patients with submassive PE, but not for patients with massive PE. On the other hand, a patient who is anticoagulated (e.g., with enoxaparin) and develops hemodynamic instability can receive thrombolysis.
- It is equally important to know when to resume heparin. The traditional approach is to resume heparin (without a bolus) when the PTT is below 1.5–2 times normal. The newer approach is to avoid resumption until fibrinogen is over approximately 100–150 mg/dL.
- Tenecteplase is a bit easier to reconstitute, so it is possible that tenecteplase might have an advantage in PE-induced cardiac arrest if it were quicker to access.
- The most common dose of tPA for catheter-based thrombolysis (both PA cannulated) has been 0.5–1 mg/h per catheter for a total dose of 12–24 mg delivered over a 24-hour period.

Percutaneous Mechanical Thrombectomy by Interventional Radiology

Potential indications are: (1) Patients with high-risk submassive or massive PE with contraindication to thrombolysis; and (2) Patients in whom thrombolysis has failed to be effective. The devices used are Angiojet, Angiovac, Penumbra Indigo embolectomy system, etc.

Surgical Thrombectomy

Indications are: (1) Clot-in-transit which is lying across a patent foramen ovale. This situation carries a risk of immediate stroke if the clot breaks up and parts of it enter the systemic circulation. (2) Massive PE in a patient with absolute contraindication to thrombolysis. (3) Massive PE with failure of other interventions—10% of clots which have become chronic and have organized will not respond to thrombolysis.

Venous Arterial Extracorporeal Membrane Oxygenation

Potential indications in emergency department are (1) Massive PE in a patient with absolute contraindication to thrombolysis. (2) Stabilization of a patient with massive PE prior to intubation, and (3) patient with massive PE and persistent instability despite thrombolysis. Potential roles for venous arterial extracorporeal membrane oxygenation (VA-ECMO) may include bridge to anticoagulation efficacy, controlled thrombolysis—ECMO could be used to support a patient while undergoing gradual thrombolysis and intervention, e.g., catheter-directed thrombolysis or cardiothoracic surgery.

Inferior Vena Cava Filter

The role of placing IVC filter has been debated to do more harm than good. On one hand, it might intercept clots traveling to the lungs (thereby avoiding PE) and on the other hand, stasis of blood increases in lower extremity, veins get thrombosed and there is a major risk of procedural complications like IVC tear, filter embolization or bleeding. Inability to receive anticoagulation, (sub)massive PE with a low hemodynamic reserve and known DVT with large clot burden (especially large, free-floating, and proximal DVT) are the indications for IVC filter.

SUMMARY

The presentation of PE ranges from incidentally discovered asymptomatic emboli to massive embolism causing an immediate threat to life. The EP job is to recognize, resuscitate, investigate, and refer the patient to cardiologist, interventional radiologist, or cardiac surgeon. The introduction of PERT (pulmonary embolism response teams) including members from every department involved in the treatment of PE shall be a good move in future. Approach to treatment of PE is summarized in **Box 3**.

BOX 3: Summary of approach to pulmonary embolism

- Step 1—keep a high degree of suspicion of the disease
- Step 2—make an implicit and/or explicit determination of pretest probability (PTP)
- Step 3—decide on doing D dimer and CTPA or perfusion scan
- Step 4—categorize pulmonary embolism into:
  - *Low-risk PE*: Patients at the lowest risk of dying. Some may be able to be discharged home.
  - *Low-risk submassive PE*: Patients with RV dilation, but who are at low risk of dying and do not require intensive care
  - *High-risk submassive PE*: Hemodynamically stable patients who nonetheless have elevated mortality. They merit ICU admission and consideration for advanced therapies
  - *Noncrashing massive PE*: Patients with hypotension who stabilize well on low-dose vasopressor. These patients need ICU admission and advanced therapies
  - *Crashing massive PE*: Patients with hypotension and persistent features of instability, who are at the greatest risk for immediate death
- Step 5—start treatment

(CTPA: computed tomography pulmonary angiography; ICU: intensive care unit; PE: pulmonary embolism)

CHAPTER

Acute Aortic Dissection

Devendra Richhariya

INTRODUCTION

Acute aortic dissection (AAD) is one of the catastrophic diseases seen in emergency department (ED), which is rare, difficult to diagnose, and also carries high mortality even if diagnosed early and properly. Delay in diagnosing the AAD in ED can be devastating for patient and also stressful for the emergency physician. AAD is responsible for 40% of the immediate death and 20% of the perioperative death. Although 50–70% survival rate is reported after initial surgery depending upon patient age and cause of the AAD.

EPIDEMIOLOGY

Acute aortic dissection can be instantly fatal in prehospital setting (cause of death may be attributed to other cause) so true incidence is difficult to define. Also missed diagnosis or delay in diagnosis leads to misclassification of disease. According to various studies prevalence ranges between 2.5 and 3 cases (United States) per 100,000 person/year to 16 cases (Sweden) per 100,000 person/year. Higher incidence (>60%) is noted in men with increasing age group. AADs have 75% mortality rate within 2 weeks if left untreated while in surgically repaired AAD 5-year survival rate is about 75% and 10-year survival rate is 40–60%.

Missed diagnosis of the AAD attracts the significant medicolegal issues also. Canadian Medical Protection Agency (CMPA) reviewed the litigations related to AAD and found complete lack of typical and atypical findings in these patients and about 56% of cases were dismissed. CMPA also cautioned the physician to consider the diagnosis in case of sudden severe chest pain with visceral symptoms such as nausea, vomiting pallor, diaphoresis, normal, or minimal changes of electrocardiography (ECG) findings. It is also suggested to avoid too much reliance on classic features like tearing chest pain, blood pressure/pulse discrepancies, new cardiac murmurs, mediastinal widening on chest radiograph, as these are potentially misleading.

PATHOGENESIS AND RISK FACTORS OF AORTIC DISSECTION

The aortic wall is consisting of three layers: (1) Intima the inner most layer, (2) media (made up of elastic connective tissue and smooth muscle), and (3) adventitia the outer most layer.

Normally, cardiac contractions give swinging movement of the heart within pericardium and give slight flexion movement of ascending and descending part of aorta. This multiple swinging movement (37 million beats/year) of the heart put stresses on the aortic layers. Prolonged hypertension is also hemodynamic stressors to aortic wall. Disease like Ehlers–Danlos syndrome where aortic walls are inherently weakened and laminar flow toward aortic wall is also altered in bicuspid aortic valve. So degenerative changes during normal aging process or any other pathological process and pulsatile blood flow create tear in the aortic intima resulting in the separation between the aortic intima and aortic media (**Fig. 1**). Blood travels into this false lumen and resulting in various clinical presentations. False lumen can extent distally or proximally and can lead to obstruction of other arterial origins from the aortic trunk, rupture back into the true vascular lumen, or into the pericardial sac or pleural cavity. Most aortic dissections occur with an initial transverse tear along the greater curvature of the aorta. The next most common site is the descending thoracic aorta immediately distal to the origin of the left subclavian artery.

Risk Factors

There are various reported risk factors (described in **Table 1**) that affect and weaken the aortic wall layers and create false lumen. Common risk factors are uncontrolled hypertension, history of cardiac surgery, or catheterization. Congenital and connective tissues disorder also risk factors for aortic dissection. Cocaine and other stimulant use are also associated with the aortic dissection. Positive family history is also associated with aortic dissection even in absence of any genetic syndrome.

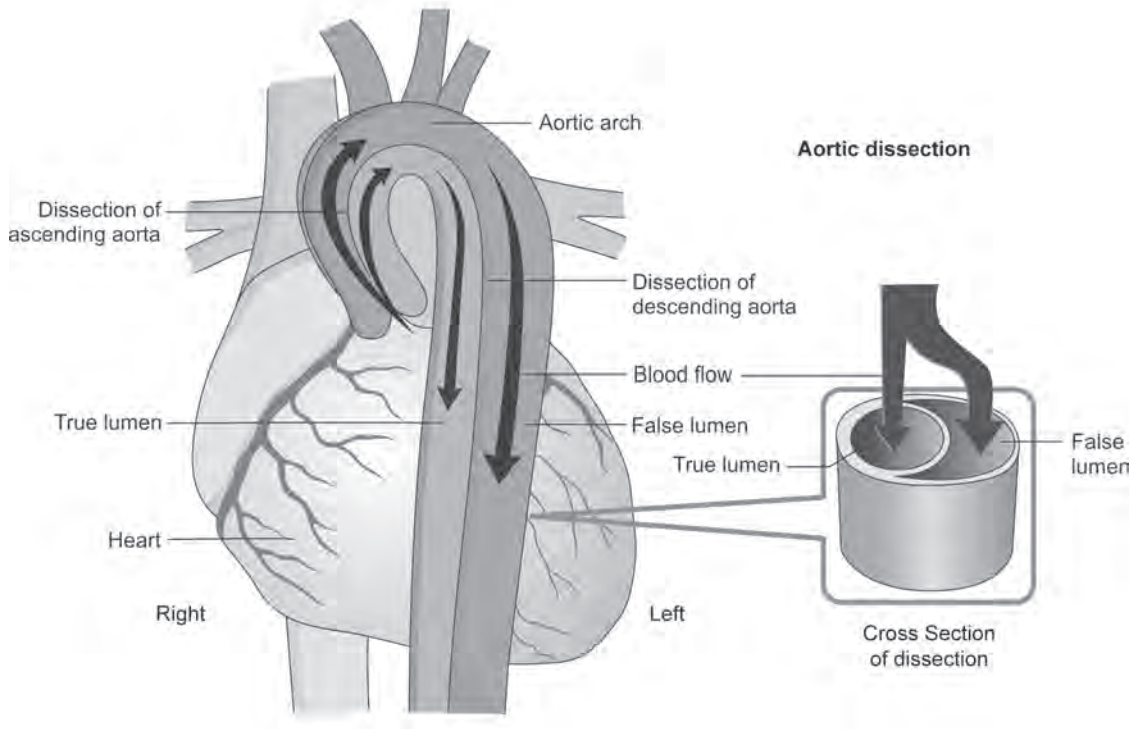

FIG. 1: Pathophysiology of aortic dissection (false lumen between intima and media due to various disease process).

TABLE 1: Risk factors for acute aortic dissection.

Disorders	***Impact***
Uncontrolled hypertension Pheochromocytoma Cocaine use Valsalva situation (weight lifting) Blunt trauma Coarctation of aorta	Aortic wall stressors
Genetic disorders: Ehlers–Danlos syndrome, congenital bicuspid aortic valve *Inflammatory vasculitis*: Takayasu, giant cell granulomatous arteritis	Affecting medial layers
Cardiac or valvular surgery intra-aortic balloon pump (IABP) insertion	Iatrogenic
Male: • Age > 50 years • Pregnancy • Polycystic kidney disease • Immunocompromised state	Other

Aortic dissection is also reported in pregnancy and certain infectious disease such as tuberculous aortitis.

CLASSIFICATION OF ACUTE AORTIC DISSECTION

Classification of AAD is based on anatomical location. This is very important to recognize the location of the dissection to ascertain the prognosis and treatment (**Fig. 2**). The Stanford (type A and type B) and DeBakey (type I, II, and III), two different anatomical classifications are commonly used described in **Table 2**.

As far as emergency physician is concern classification is may not be very useful as compare to vascular surgeons for surgical management planning. Aortic dissection is categorized in another way as acute (if diagnosis within 2 weeks of pain onset) subacute (2–6 weeks) and chronic (>6 weeks after onset of pain).

CLINICAL PRESENTATION OF ACUTE AORTIC DISSECTION

Diagnosing the AAD in ED is always challenging due to its catastrophic nature. Sudden onset chest pain, excruciating, severe at onset (sharp, tearing, in nature), is usually typical feature of aortic dissection. But aortic dissection may not present always with this typical feature. Sometime it is possible to localize the origin of dissection on the basis of pain, anteriorly situated pain (ascending aorta), neck or jaw (arch of aorta), interscapular pain (descending aorta), and intensity of pain may decrease over the time depending upon extension of dissection or involvement of other organ system. Chest pain is the prominent symptoms for type A dissection while back pain for type B dissection. Typical symptoms may accompany with visceral symptoms such as nausea, vomiting, diaphoresis apprehension, and light-headedness. Painless presentation of aortic dissection may be noted in patient of older age group, chronic steroid user, and Marfan's syndrome. These groups may present with syncope stroke or congestive heart failure.

Physical findings are usually absent but unreliable. We may get important clues by examination of upper extremities pulses

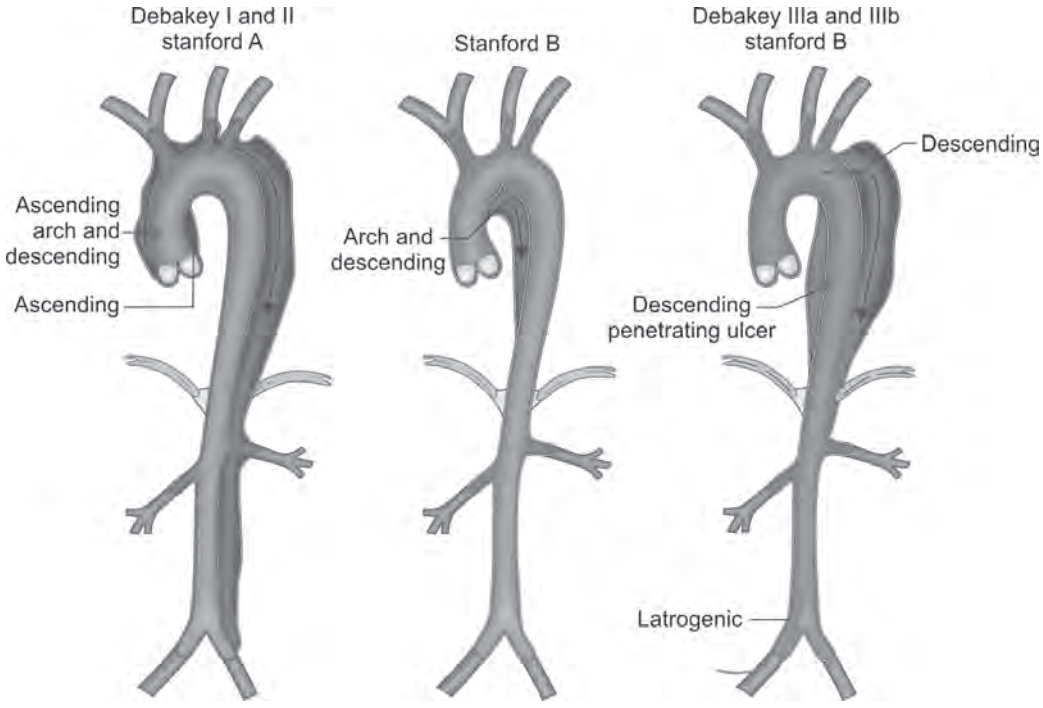

FIG. 2: Anatomical classification of aortic dissection (Stanford and DeBakey).

TABLE 2: Classification of acute aortic dissection (AAD).

Stanford classification of AAD		***DeBakey classification of AAD***		
Type A	**Type B**	**Type I**	**Type II**	**Type III**
Any dissection involving the ascending aorta (proximal to brachiocephalic artery)	Only descending aorta is involved (distal to subclavian artery)	Intimal tear originates from ascending aorta, involving arch and then extend even beyond descending aorta	Only ascending aorta is involved	Only descending aorta is involved

and blood pressure differential (in one study 20–30 mm Hg blood pressure differential reported as significant in cases of AD), while other study revealed that 20% of normal patient may have pulse differential. Newly developed aortic regurgitation is present in about 30–70% patient. Aortic regurgitation may present with severe complications such as life-threatening congestive heart failure or cardiogenic shock. Aortic dissection may give rise to mass effect on adjacent structure presenting with superior vena cava syndrome, Horner syndrome, hoarseness (recurrent laryngeal nerve), dyspnea (pressure on tracheobronchial tree), and dysphagia (pressure on esophagus).

Wide variety of presentation of AAD is noted ranging from painless presentation to life-threatening complications such as congestive heart failure and cardiogenic shock. Diagnosing the AAD remains a challenge for the emergency physician in this situation. Hence during triaging and initial assessment the triaging nursing staff/emergency physician should be aware of *"Red flags"* (**Table 3**). Clinical presentation helps them in implementing the lifesaving interventions in early stage. Apart from these presentations, AAD presents with symptoms of end organ damage described in **Table 4** (Complications of AAD).

DIAGNOSTIC STRATEGIES FOR ACUTE AORTIC DISSECTION IN THE EMERGENCY DEPARTMENT

Emergency physician must make the proper diagnosis if possibility of aortic dissection is considered. Routine initial test such as electrocardiogram chest radiograph, laboratory markers are available in every ED with variable reliability and thus further advanced imaging modalities are also required (**Box 1**).

TREATMENT

Early lifesaving management in AAD starts with high index of suspicion with targeted history, physical examination, and timely diagnosis. Once diagnosis is established, medical management is instituted as soon as possible to aggressively control the blood pressure and heart rate (target systolic blood pressure is 100–120 mm Hg and heart rate 60 beats/min. Several classes of drugs are used to achieve these goals. By controlling the BP and heart rate, the stressors which are acting on aorta (described in pathophysiology section) are diminished.

TABLE 3: Red flags (concerning features) for acute aortic dissection.

On the basis of history	*On the basis of pain*	*On the basis of examination*
• Family history	• Sudden onset	• Peripheral pulse difference
• Known aortic valve disease	• Excruciating	• Blood pressure difference
• Known aortic aneurysm	• Tearing	• Syncope
• Known Marfan's or other connective tissue disease	• Interscapular pain	• New aortic regurgitation murmur
• History of cardiac surgery		• Hypotension and shock

Alert for aortic dissection if patient presentation is chest pain + abnormal pulse or low blood pressure, or high blood pressure, or neuronal symptoms or chest pain poorly responds to medications

TABLE 4: Complications of acute aortic dissection (AAD).

Cardiovascular complications	• Aortic regurgitation • Pulse deficit • Blood pressure differential • Syncope (as a result of acute cardiac dysfunction, vascular outflow obstruction, and vasovagal pain response) • Myocardial infarction • Congestive heart failure • Shock
Neurological complications	• Focal neurological deficit (can be due to hypotension, decreased perfusion, thromboembolism, or nerve compression from mass effect) • Intracranial or brainstem involvement, e.g., cerebral ischemia and stroke syndrome (proximal arch dissection) • Spinal cord and lower extremities involvements (distal arch dissection) • Sudden coma (basilar artery occlusion) • Transient locked in syndrome described in painless AAD
Respiratory complications	• Dyspnea (mass effect) • Hemorrhage into lung tissues and pleural space pleural effusion
GI complications	• Mesenteric ischemia (type B) • Catastrophic GI bleed (rare)
Ear/Nose/Throat complications	Dyspnea, stridor, dysphagia, hoarseness of voice, and ipsilateral Horner syndrome
Atypical presentations	Chronic aortic dissection may present with fever of unknown origin, mesenteric ischemia, and renal colic

BOX 1: Diagnostic tests for acute aortic dissection.

Basic routine tests:

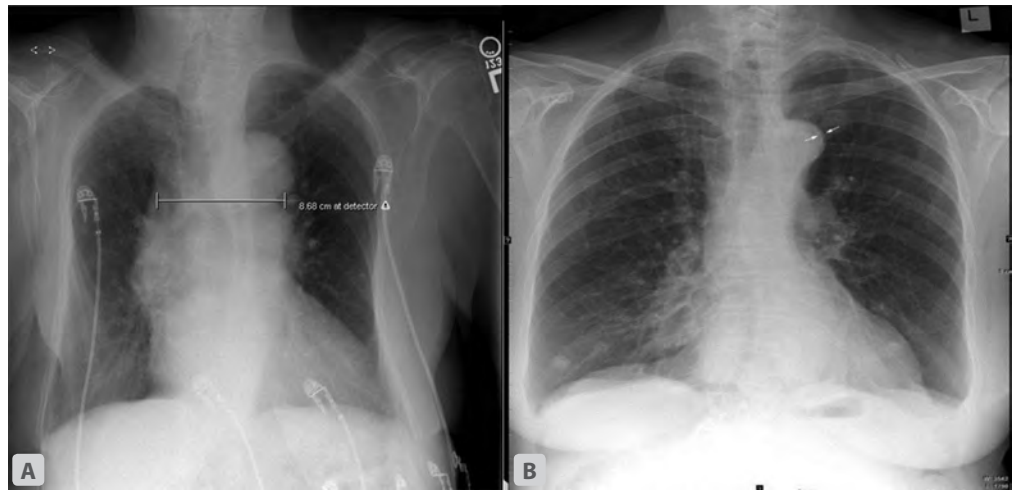
- *Electrocardiography (ECG)*:
  - Normal or nonspecific while left ventricular hypertrophy seen in hypertensive patients
  - ECG is primarily useful to rule out alternative diagnosis
- *Chest radiography*: 90% of patients with aortic dissection have abnormal aortic contour and mediastinal widening on chest radiograph (**Fig. 3A**). Other radiographic changes are displaced aortic calcification especially in elderly (**Fig. 3B**), pleural effusion, and abnormalities of aortic arch displacement of trachea. Normal chest X-ray narrows down the differential diagnosis
- *Laboratory markers*: (D-dimers and other biomarkers) Initial studies showed D-dimer as a highly useful marker (sensitivity 94–99%). In spite of that not recommended for screening and diagnosis because lack of large prospective studies. Similarly, further investigations are required for other biomarkers such as serum smooth muscle myosin heavy chain and calponin (smooth muscle troponin such as protein)

Advanced imaging modalities:

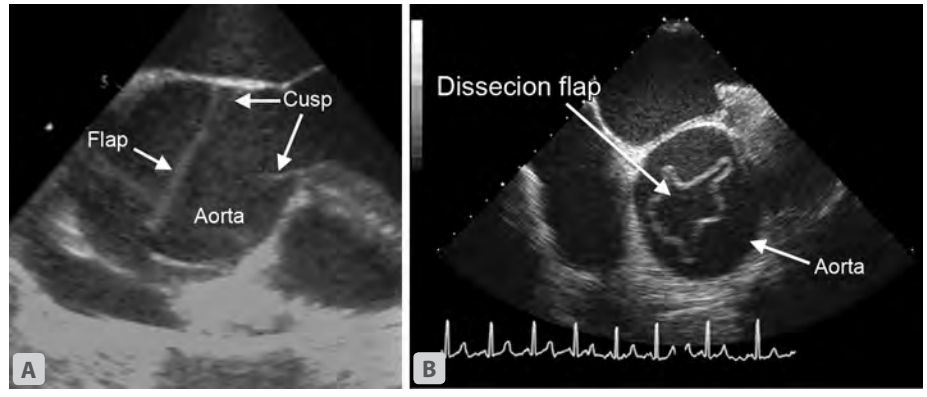
- *Transesophageal echocardiography (TEE)*: Important role in diagnosing the AAD rapidly noninvasively particularly in hemodynamically unstable patient (**Figs. 4A** and **B**). TEE also able to diagnose aortic regurgitation and pericardial effusion
- *Transthoracic echocardiography (TTE)*: TTE able to visualize aortic dissection but should not be used as isolated test to diagnose AAD. TTE can be used with TEE as there is a blind spot in the distal portion of the aortic arch on TEE
- *Computed tomography imaging (CT)*: CT with angiography is now imaging modality of choice for stable AAD (**Figs. 5A** to **C**). CT scan can locate dissection flap and helpful in operative planning for ascending aortic dissection. CTA requires contrast bolus which is inappropriate for renal insufficiency patient. Also, hemodynamically unstable patient cannot leave the ED for CT angiography for AAD
- *Magnetic resonance imaging (MRI)*: MRI provide much more detail evaluation of location and extension of dissection with lack of radiation but less often used due to variable availability and many patients with AAD are not stable enough for MRI

Medical Management

- *Pain management*: Opioid analgesics can be used in titratable dose to relieve pain and decreasing the sympathetic tone, also augmenting the rate control and vasodilatation.
- *Beta-blockers*: Lowers blood pressure and heart both so beta-blockers are used as first-line therapy in aortic dissection.
  - Esmolol—first agent of choice in beta-blockers class, short-acting agent starting with 500 μg/kg bolus followed by infusion at 50–200 μg/kg/min titrated to its effect, rebolus also can be given.
  - *Labetalol*: Labetalol is alternative choice if esmolol is not available bolus 20 mg every 5–10 minutes up to 80–300 mg total dose infusion rate 1–2 mg/min.
- *Calcium channel blockers (CCBs)*: CCBs such as verapamil or diltiazem are not routinely used for AAD. This class of drug alternative to β-blockers if patient has contraindications.



FIGS. 3A AND B: (A) Widening of mediastinum on chest X-ray; (B) Medially displaced aortic calcification on chest X-ray.



FIGS. 4A AND B: (A) Transesophageal echocardiography (TEE) image showing presence of an intimal flap in the ascending aorta. (B) TEE image showing circumferential intimal flap in ascending aorta on.

FIGS. 5A TO C: (A) Aortic root dilatation; (B) CT angiographic image showing dissection flap in the arch of aorta; (C) CT angiogram in aortic dissection. ***(For color version, see plate 9)***

- *Nitroprusside*: Nitroprusside reduces preload and also afterload, once the heart rate is controlled and additional blood pressure control is required, nitroprusside vasodilator can be added. Nitroprusside should be added after β-blocker because independently, it causes reflex tachycardia (increases the aortic stress and worsening dissection).

Surgical Management

Surgical intervention is gold standard for type A dissection involving the ascending aorta. The main aim of the surgery is to prevent aortic rupture, cardiac tamponade, and relief from aortic regurgitation. Surgical procedure also improves the blood flow in the branches affected by the false lumen**.** Surgery is reserved in type B dissection for the patient who is having ongoing pain, refractory hypertension, major arterial occlusion, and leaking or rupture. Surgical management reduces the in-hospital mortality to 27% in comparison to 56% in medically treated type A dissection so patient should be transferred to tertiary care center if cardiac surgery is not available in particular center and aggressive medical management to continue.

Newer Interventions

Endovascular stenting is the newer intervention and alternative to surgery for patient with type B dissection with evidence of limb or visceral ischemia. Aortic fenestration is also used as alternative to endovascular stenting to restore the perfusion in patient with end organ damage. Aortic fenestration is a procedure where communication is created between false and true lumen of the aorta and this communication helps in flowing the blood toward the arteries which are originating from false lumen.

Pitfalls in Aortic Dissection Management

Acute chest pain is very common in ED. Aortic dissection as a cause of chest pain is infrequent as comparison to other causes such as acute coronary syndrome pulmonary embolism, pneumothorax, and esophageal rupture. This is usually noticed that emergency physician has less awareness about aortic dissection incidence risk factors and AAD evaluation. Even most of the institute have care pathways specific to more common chest pain presentation such as acute coronary syndrome and pulmonary embolism but not for the most dangerous and devastating AAD. Emergency physician is much more trained to give loading dose of antiplatelet and anticoagulant to acute onset chest pain suspecting acute coronary syndrome. Consider AAD evaluation in acute chest pain patient if risk factors, clinical features are as described earlier in this chapter or lack of response to chest pain management before jumping to potentially irreversible fibrinolytic therapy.

ACUTE AORTIC DISSECTION IN PREGNANCY

Several hemodynamic and physiologic changes occur in pregnant women. Hemodynamic changes in intravascular volume, compensatory cardiac output demand, and intimal wall connective tissue changes work as stressors. Pregnant women are at risk of expansion of aortic dissection and rupture in third trimester. Specialized vascular surgeon obstetric team is required for maintaining fetal viability. Emergency caesarean section delivery can also be performed with strict monitoring of maternal and fetal hemodynamic.

SUMMARY

Assessment of acute undifferentiated chest pain and diagnosis of AAD in the ED are one of the challenging things for emergency physician. AAD not always present with typical clinical feature. There are numerous and misleading clinical features related to cardiovascular, abdominal, neurologic, and other system. Emergency physician should have knowledge about typical and atypical presentation, able to carry out thorough physical examination, and routine/advanced imaging techniques, if high index of suspicion for AAD. Once AAD is diagnosed, pain, heart rate, and blood pressure control are priority followed by definitive surgical consultation can be taken. Consider AAD in given situation to avoid adverse outcome for patient and medicolegal liability for emergency physician.

CHAPTER

Antithrombotic Therapy

Santosh Pandey

INTRODUCTION

Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhage. Alteration in balance in favor of coagulation results in thrombosis. Antithrombotic therapy is used to treat arterial and venous thromboembolic conditions. They also help to prevent occlusive vascular events in patients who are at risk of thrombosis. Antithrombotic drugs used to treat thrombosis are classified by their mechanism of action (**Fig. 1**). Antithrombotic drugs are used to treat acute coronary syndrome, acute venous thromboembolism, and arterial thrombosis, summarized in **Box 1** and also used to treat various stage of ischemic stroke (**Box 2**). This chapter reviews the agent commonly used for controlling fluidity, including:

- Coumarin anticoagulants that block multiple steps in coagulation cascade
- Direct oral anticoagulants, which inhibit factor Xa or thrombin
- Parenteral anticoagulants heparin and its derivative, which activate antithrombin, a natural inhibitor of coagulant proteases
- Fibrinolytic agents, which degrade fibrin
- Antiplatelets agents which attenuate platelet activation or aggregation
- Reversal agents for antithrombotic drugs

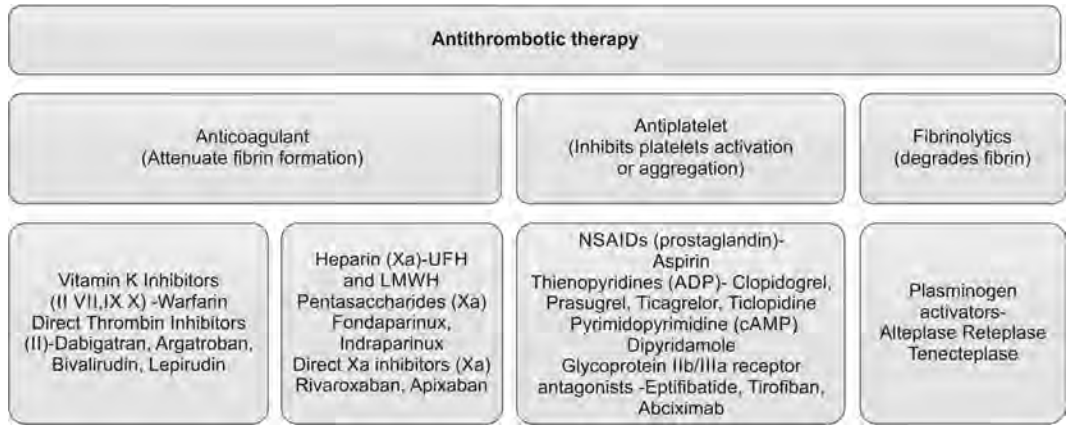
OVERVIEW OF HEMOSTASIS

The normal hemostatic system consists of a complex process that limits blood loss through the formation of a platelet (primary hemostatic) and the production of cross-linked fibrin (secondary hemostasis), which strengthens the platelet plug. These reactions are counter regulated by the fibrinolytic system (**Flowchart 1**).

ORAL ANTICOAGULANTS

Warfarin (Vitamin K Antagonists—VKAs)

A hydroxycoumarin derivative, which is commonly used as oral anticoagulant. Warfarin has both antithrombotic effect by inhibiting the synthesis of factors II, VII , IX, and X and a prothrombotic effect through inhibition of protein C and S production, but during maintenance therapy, the overwhelming effect is one of the anticoagulation. It is suggested to add



(ADP: adenosine diphosphate; NSAID: nonsteroidal anti-inflammatory drug; LMWH: low-molecular weight heparin; UFH: unfractionated heparin)

FIG. 1: Basic classification of antithrombotic agents.

BOX 1: Indications for antithrombotic therapy.

***Prophylaxis for deep vein thrombosis and pulmonary embolism*:**

- Unfractionated heparin 500-unit SC every 8–12 h:
  - Dalteparin 2,500–5,000 IU SC once a day
  - Enoxaparin 40 mg SC once daily in normal renal function 30 mg SC twice daily for trauma patient
  - Rivaroxaban 10 mg PO once daily
  - Apixaban 2.5 mg PO twice daily
  - Fondaparinux 2.5 mg SC once daily

***Treatment for deep vein thrombosis and pulmonary embolism*:**

- Unfractionated Heparin: 80 units/kg IV bolus followed by 18 units/kg/h, continuous infusion, with aPTT checked after 6 hours and infusion adjusted to maintain aPTT 1.5–2.5 times the standard
- *Enoxaparin*: 1 mg/kg SC every 12 h or 1.5 mg/kg daily
- *Dalteparin*: 200 units/kg SC once daily
- *Tinzaparin*: 175 mg/kg once daily
- *Fondaparinux*: <50 kg: 5 mg SC once daily 50–100 kg: 7.5 mg SC once daily >100 kg: 10 mg SC once daily
- *Warfarin*: 2–5 mg/day for 2–4 days , followed by 1–10 mg/day as indicated by INR
- *Dabigatran*: 150 mg PO twice daily (after 5–10 day of parenteral anticoagulation)
- *Apixaban*: 10 mg PO twice daily for 7 days, then 5 mg twice daily
- *Rivaroxaban*: 15 mg PO twice daily for 21 days, then 20 mg once daily
- Streptokinase 250,000 unit IV bolus followed by 100,000 unit/h continuous infusion for 1–3 days or alteplase 100 mg IV infused over 2 h or tenecteplase weight-tiered single IV bolus (<60 kg: 30 mg) (60–70 kg: 35 mg) (70–80 kg: 40 mg) (80–90 kg: 45 mg (>90 kg: 50 mg)

ST-Segment elevation myocardial infarction

Aspirin 150–300 mg PO once an day plus clopidogrel 300 mg PO loading dose and 600 mg if PCI is planned followed by 75 mg PO once daily

Or

Ticagrelor 180 mg PO loading dose followed by 90 mg PO twice daily

Or

Prasugrel 60 mg PO loading dose followed by 10 mg PO once day contraindicated in previous stroke patient and age >75 years

Unfractionated heparin 60 unit/kg (5,000-unit bolus followed by 12 unit/kg/h—max 1,000 unit) maintain aPTT 1.5–2.5 times of reference range

Or

Enoxaparin 30 mg IV bolus followed by 1 mg /kg SC every 12 h

Streptokinase 1.5 million units IV over 60 min

Or

Alteplase 15 mg IV bolus over 2 min, then 0.75 mg/kg IV OVER 30 min (max 50 mg), then 0.50 mg/kg IV over 60 min (max 35 mg)

Or

Reteplase 10 units IV bolus, then repeat 10 doses at 30 min

Or

Tenecteplase weight-tiered single IV bolus (<60 kg: 30 mg) (60–70 kg: 35 mg) (70–80 kg: 40 mg) (80–90 kg: 45 mg (>90 kg: 50 mg)

BOX 2: Antithrombotic therapy in stroke.

Acute ischemic stroke:

- Alteplase 0.9 mg/kg (max 90 mg) with 10% of the total dose given as an IV bolus over 1 min, then remainder as infusion over 60 min
- Tenecteplase 0.25 mg/kg IV bolus

Postischemic stroke:

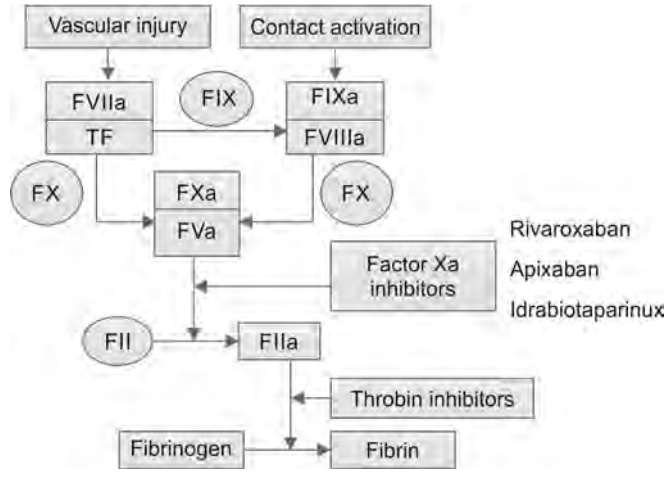
- Aspirin 75 mg PO once a day
- Clopidogrel 75 mg PO once a day (if patient allergic to aspirin)
- Dipyridamole 200 mg ER PO twice daily (usually combined with aspirin)

Transient ischemic stroke:

- Aspirin 75 mg PO once a day
- Clopidogrel 75 mg PO once a day (if patient allergic to aspirin)

Atrial fibrillation (stroke prevention):

- Warfarin dose adjusted to maintain INR 2.0–3.0
- Dabigatran: 150 mg PO twice daily
- Apixaban: 5 mg PO twice daily
- Rivaroxaban: 20 mg PO twice daily with evening meal



FLOWCHART 1: Hemostasis mechanism.

parenteral anticoagulant during the first 3–5 days of warfarin treatment. Its dosing is guided by desired therapeutic range, if INR of 2–3 in most of cases. Drug interaction with warfarin is numerous and complex. Bleeding and skin necrosis are two major complication. The risk is clinically significant when the INR is >4.5–5. Major limitations of vitamin K antagonist lead to development of various new direct thrombin inhibitors (DTIs) (**Table 1**).

Novel Oral Anticoagulants/Direct Thrombin Inhibitors (Nonvitamin K Antagonist)

Direct thrombin inhibitors were developed to overcome the limitations of vitamin K antagonist. Used in high-risk patient including stroke and with atrial fibrillation. Currently, five direct acting oral anticoagulants are available. Mechanism of action of novel oral anticoagulant (NOAC) is shown in **Figure 2**.

- *Dabigatran*: Oral direct thrombin inhibitor, which is used to reduce the risk of stroke and systemic embolism with nonvalvular atrial fibrillation. It has more predictable pharmacology activity than warfarin and broad therapeutic window. It is safer than warfarin, with notable exception of higher risk of major GI bleeding. For practical purposes, a normal thrombin clotting time excludes a significant coagulopathy due to dabigatran.
- *Apixaban, rivaroxaban, betrixaban, and edoxaban*: These oral direct factor Xa inhibitors have predictable pharmacological properties that do not require routine laboratory monitoring. Currently, used for prevention of thromboembolism in patients undergoing hip or knee replacement surgery and reduction of systemic embolism in nonvalvular atrial fibrillation. Currently, available antifactor Xa activity assay can be used specifically for their activity.

TABLE 1: Limitation and consequences of vitamin K antagonists (warfarin).

Limitations	*Consequences*
Slow onset of action	Necessitates overlap with rapidly acting parenteral anticoagulants when treating patients with thrombosis
Genetic polymorphism affects metabolism	Variable dose requirements
Multiple food and drug interactions	Coagulation monitoring required
Narrow therapeutic window	Coagulation monitoring required

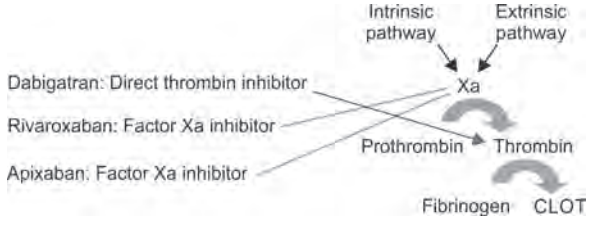


FIG. 2: Mechanism of action of novel oral anticoagulants (NOAC).

HEPARIN

Heparin derivatives have no intrinsic anticoagulant activity; rather these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Antithrombin inhibits activated coagulation factors, particularly thrombin and factor Xa, by serving as "suicide substrate." Bleeding and HIT (heparin-induced thrombocytopenia) are major complication. Comparative features [unfractionated heparin and low-molecular weight heparins (UFH and LMWH)] are summarized in **Table 2**.

- *Unfractionated Heparin (UFH)*: It is a heterogeneous mixture of polysaccharides. It has unpredictable anticoagulant effects, which is generally monitored by aPTT.
- *Low-molecular weight heparins*: They are polysaccharide chains with commercial preparations (enoxaparin, dalteparin, and tinzaparin), LMWH possesses many clinical advantages compared to UFH.
- *Fondaparinux*: Synthetic pentasaccharide that binds to antithrombin and enhances its affinity for factor Xa, but not thrombin.

ANTIPLATELET AGENTS

Antiplatelet agents can be subclassified, on the basis of their site of action (**Flowchart 2**), into those that inhibit (1) adhesion, (2) activation, (3) aggregation, or (4) platelet-mediated links with inflammation. Of currently available agents, aspirin, clopidogrel, dipyridamole, and cilostazol inhibit platelet activation, whereas GPIIb/IIIa antagonist blocks platelet aggregation (**Table 3**). Bleeding secondary to antiplatelet therapy should be treated with supportive therapy, platelet transfusion, and possibly desmopressin.

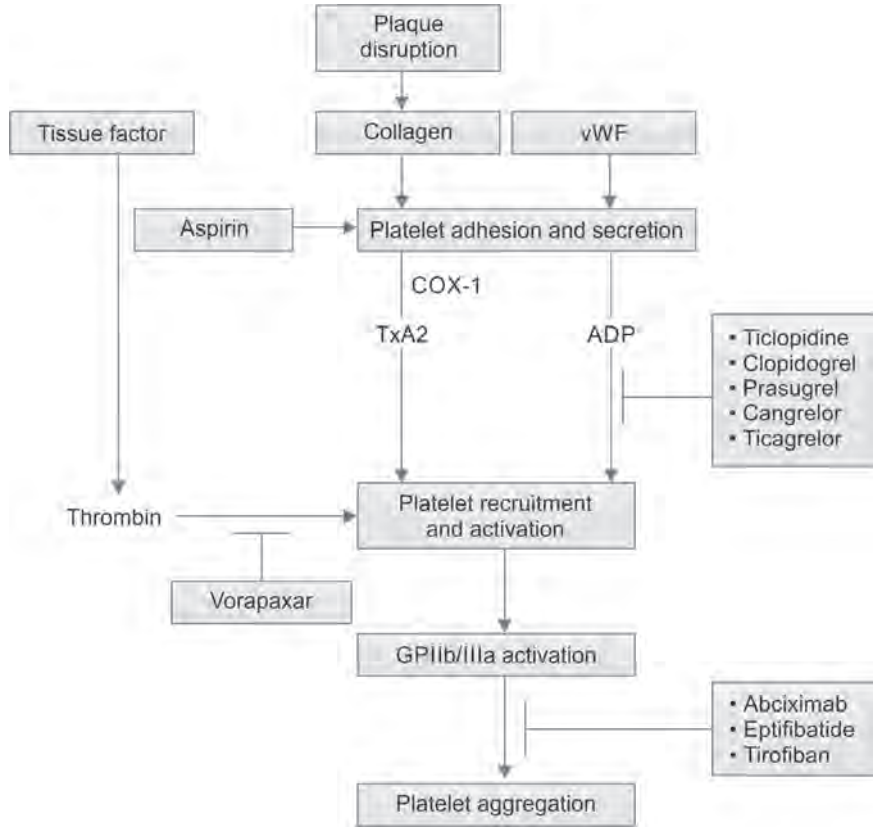
FIBRINOLYTIC DRUGS

Fibrinolytic drugs initiate the fibrinolytic pathway. Fibrinolytic agents stimulate conversion of plasminogen to plasmin. Approved fibrinolytic agents are included streptokinase, anistreplase, alteplase, reteplase, and tenecteplase.

- First generation—streptokinase and anistreplase
- Second generation—alteplase tissue plasminogen activator
- Third generation—reteplase and tenecteplase

TABLE 2: Comparison of features of subcutaneous heparin, LMWH, and fondaparinux.

Features	*Heparin*	*LMWH*	*Fondaparinux*
Sources	Biological	Biological	Biological
MMW (Da)	15,000	5,000	1,500
Target	Xa and IIa	Xa and IIa	Xa
Bioavailability (%)	30 (at low doses)	90	100
t1/2 (hour)	1–8	4	17
Renal excretion	No	Yes	Yes
Thrombocytopenia	<5%	<1%	<0.1%
Monitoring	More frequent	Unnecessary Antifactor Xa assay	Unnecessary Antifactor Xa assay
Antidote	Complete	Partial	None



FLOWCHART 2: Classification of antiplatelet drugs on the basis of sites of action.

TABLE 3: Antiplatelets agents.

Drugs	*Mechanism of action*	*Type of inhibition*	*Time to peak effect*	*Half life*	*Duration of effect*	*Typical dose*
Aspirin	Nonselective cyclooxygenase inhibitor	Irreversible	20–40 min	3–4 h	Up to 7 days	162–325 mg PO once per day
Clopidogrel	ADP receptor inhibitor	Irreversible	2–4 h	7–8 h	Up to 7 days	300 mg PO loading dose, then 75 mg PO per day
Prasugrel	ADP receptor inhibitor	Irreversible	1–2 h	7–8 h	5–7 days	60 mg PO loading dose, then 10 mg PO once a day
Ticagrelor	ADP receptor inhibitor	Reversible	2–3 h	7–9 h	3–5 days	180 mg PO loading dose 90 mg PO twice per day
Dipyridamole	Reduces platelet aggregation, vasodilator, weak phosphodiesterase	Reversible	N/A	Biphasic 40 min and 10 h	1–2 days	200 mg extended- release PO twice per day
Cilostazol	Phosphodiesterase inhibitor; reduces platelet aggregation, vasodilator	Reversible	N/A	11–13 h	3–4 h	100 mg PO twice per day
Abciximab	Glycoprotein IIb/IIIa antagonist	Non-competitive inhibition	–	10 min	24–48 h	0.25 mg/kg IV bolus, then 0.125 µg/kg/min infusion IV
Eptifibatide	Glycoprotein IIb/IIIa antagonist	Competitive inhibition	–	2.5 h	3–5 h	180 µg/kg IV bolus, then 2 µg/kg/min infusion IV
Tirofiban	Glycoprotein IIb/IIIa antagonist	Competitive inhibition	–	2 h	3–5 h	25 µg/kg /min IV for 30 min then 015 µg/kg/min infusion

TABLE 4: Contraindication to fibrinolytic therapy.	
Absolute	***Relative***
• Prior intracranial hemorrhage • Known structural cerebral vascular lesion • Known malignant intracranial neoplasm • Ischemic stroke within 3 months • Suspected aortic dissection • Active bleeding or bleeding diathesis (excluding menses) • Significant closed-head trauma or facial trauma within 3 months	• Uncontrolled hypertension (SBP > 180 mm Hg or DBP > 110 mm Hg) • Traumatic or prolonged CPR or major surgery within 3 weeks • Recent (within 2–4 weeks) internal bleeding • Noncompressible vascular punctures • For streptokinase, prior allergic reaction • Pregnancy • Active peptic ulcer • Current use of warfarin and INR >1.7

All fibrinolytic agents are associated with bleeding and which can be minor, major, or catastrophic in nature. Concomitant use of certain drugs can also enhance the risk of bleeding. Risk of bleeding can be reduced by applying the knowledge of contraindication of fibrinolytic therapy as summarized in **Table 4**.

ADVERSE EFFECTS

The major toxicity of all thrombolytic agents is hemorrhage. If heparin is used concurrently with tPA, serious hemorrhage will occur in 2–4% of patients. Intracranial hemorrhage is most serious problem. For this region, mechanical reperfusion is preferred in acute ST-segment elevation myocardial infarction (STEMI). In acute ischemic stroke also, current standard of care is mechanical thrombus extraction, with or without adjunctive tPA or tenecteplase. Anaphylaxis can occur at times with streptokinase and anistreplase. Fresh frozen plasma (FFP) and factor replacement with cryoprecipitate can be used in unstable patients. Antifibrinolytic agents (tranexamic acid or aminocaproic acid) with or without platelets can also be used.

SUMMARY

Thromboembolic disorders are a major cause of death and disability worldwide. Antithrombotic therapy is used to treat arterial and venous thromboembolic conditions and also to prevent occlusive vascular events in patients with increased risk of thrombosis. However, being emergency physicians, we need to know these agents can cause life-threatening complications. Consequently, there is an ongoing search for new antithrombotic drugs, particularly novel antiplatelet agents and anticoagulants. Therefore, a better understanding of the biochemical pathways involved in platelet activation and coagulation and of the links between these systems and the impact of thrombosis on inflammation is necessary. A larger number of new antithrombotic drugs are under development. With new targets and new drugs, antithrombotic therapy is evolving and our armamentarium of agents to combat thromboembolic disorders is rapidly expanding.

79
CHAPTER

Antithrombotic Reversal Agents

Devendra Richhariya

INTRODUCTION

Antithrombotic therapy is indicated for the prophylaxis and treatment of thromboembolic disorders. Commonly used oral antithrombotic therapies (**Box 1**) are vitamin K antagonists, heparin, low-molecular-weight heparins (LMWHs), direct thrombin inhibitors (DTIs), and factor Xa inhibitors. Warfarin, novel oral anticoagulants, is commonly prescribes oral anticoagulants while heparin LMWH is important part of in hospital therapy. Antiplatelet agent is also important part of prescription for diseases such as coronary artery disease stroke. So the emergency physician must be able to manage the most common complication of antithrombotic/anticoagulant therapies—bleeding.

THE CLOTTING/COAGULATION CASCADE

Before learning about the reversal of anticoagulation, we need to understand the clotting cascade, a complex physiologic process used to maintain homeostasis between clot formation and degradation. In the setting of vascular endothelial injury, clot formation begins with primary hemostasis.

BOX 1: Common antithrombotic medications.

Anticoagulants:

- *Vitamin K antagonists (II, VII, IX, X)*: Warfarin
- *Heparins (Xa, others)*: UFH and LMWH
- *Pentasaccharides (Xa)*: Fondaparinux and idraparinux
- *Direct Xa inhibitors (Xa)*: Rivaroxaban and apixaban
- *Direct thrombin inhibitors (II)*: Dabigatran, argatroban, bivalirudin, and lepirudin

Antiplatelet agents:

- *NSAIDs (prostaglandin)*: Aspirin
- *Thienopyridines (ADP)*: Clopidogrel, prasugrel, ticagrelor, and ticlopidine
- *Pyridopyrimidine (cAMP)*: Dipyridamole
- *Glycoprotein IIb/IIIa receptor antagonists*: Eptifibatide, tirofiban, and abciximab

Fibrinolytics:

- *Plasminogen activators*: Alteplase, reteplase, and tenecteplase

Primary Hemostasis

It is binding of platelets with the damaged endothelium via an interaction between a glycoprotein (GP IIb-IIIa) and von Willebrand factor. With the process of platelet activation and degranulation, more and more platelets are recruited to the site of injury, thereby forming a platelet plug. The efficacy of the platelet plugs in achieving hemostasis is a function of platelet quantity and quality. These platelet qualities may depend on patient comorbidities (bleeding diathesis, advanced renal disease, etc.) and pharmaceutical therapy (e.g., nonsteroidal anti-inflammatory drugs or aspirin). After primary hemostasis (**Fig. 1**), secondary hemostasis (**Fig. 2**) begins with activation of the clotting/coagulation cascade (**Fig. 3**).

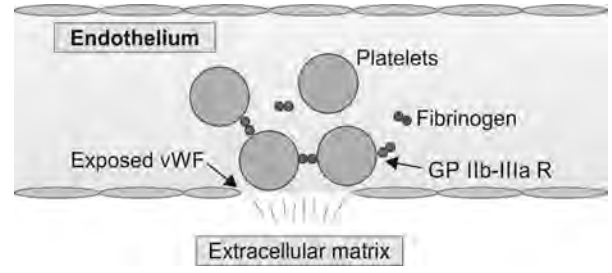

FIG. 1: *Primary hemostasis*. Platelets organize into a platelet plug at the site of endothelial injury by binding subendothelial von Willebrand factor (vWF) and circulating fibrinogen.

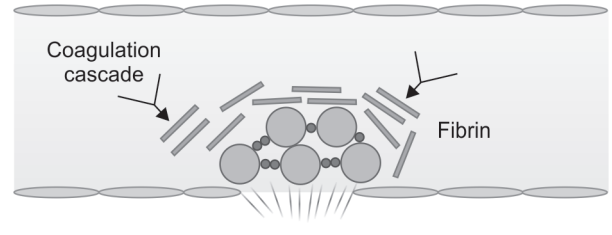

FIG. 2: *Secondary hemostasis*. Cross-linked fibrin cements and stabilizes the platelet plug formed at the site of endothelial injury.

Secondary Hemostasis

During secondary hemostasis, activated factor Xa catalyzes the conversion of prothrombin to thrombin (factor IIa). Thrombin, in turn, catalyzes the conversion of fibrinogen to fibrin. Ultimately, fibrin is responsible for cross-linking and strengthening the platelet plug. Secondary hemostasis process depends on the quantity of functional clotting factors, and their successful activation.

How to measure primary and secondary hemostasis?
Platelet function tests and platelet aggregation assays may be useful to assess primary hemostasis; however, many of these studies are time consuming and poorly standardized, limiting their clinical usefulness in the emergency setting. Bleeding time is no longer used clinically. The process of secondary hemostasis is measured using prothrombin time (PT), International Normalized Ratio (INR—extrinsic and common pathways; factors II, VII, and X), and activated partial thromboplastin time (aPTT—intrinsic and common pathways—all factors except factor VII).

REVERSAL OF WARFARIN

Warfarin is a vitamin K antagonist, inhibiting the hepatic enzyme vitamin K epoxide reductase, thereby limiting the synthesis of factors II, VII, IX, and X, and the anticoagulant proteins C and S. Warfarin is indicated for the prophylaxis and treatment of venous thromboembolism, pulmonary embolism (PE), thromboembolic complications associated with atrial fibrillation or cardiac valve replacement, and in myocardial infarctions (MIs) and cerebrovascular accidents for reduction of mortality risk secondary to emboli after.

Therapeutic doses of warfarin decrease the total amount of each active vitamin K–dependent clotting factor by approximately 30–50%. As mentioned before, anticoagulant effect of warfarin is measured by PT and INR (measures the extrinsic pathway of the coagulation cascade). The reversal of warfarin needs immediate and sustained therapy. Immediate reversal is achieved by the therapy of prothrombin complex concentrates (PCCs) and fresh frozen plasma (FFP), and sustained reversal is achieved through vitamin K administration (**Tables 1** and **2**).

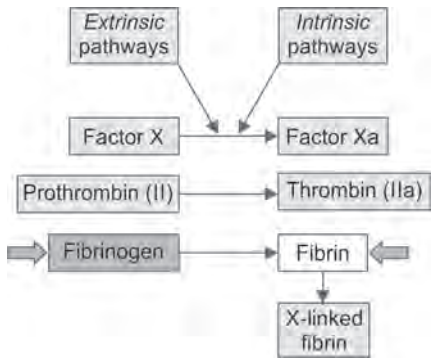

FIG. 3: *Coagulation cascades.* The plasma coagulation cascade funnels down to the conversion of soluble fibrinogen to insoluble fibrin.

Prothrombin Complex Concentrates

Prothrombin complex concentrates are available in three- and four-factor preparations. Three-factor concentrates contain factors II, IX, X, and minimal amounts of factor VII are approved by the US Food and Drug Administration (FDA) for the treatment of bleeding in hemophilia B (factor IX deficiency). In 2009, Holland and colleagues published data regarding three-factor PCC alone [25 international units per kilogram (IU/kg) and 50 IU/kg doses] satisfactorily decrease supratherapeutic INRs owing to the low factor VII content.

In 2013, the FDA approved a four-factor PCC, for the reversal of warfarin-related coagulopathy. Four-factor PCC contains factors II, VII, IX, and X, in addition to proteins C and S (heparin and antithrombin III are added to maintain factors in the inactivated form). Four-factor PCC is administered intravenously with recommended doses based on the patient's baseline INR (the initial dose is 25–50 IU/kg for significant bleeding).

Factor VIII inhibitor-bypassing activity (FEIBA) is activated PCC (aPCC), is useful for the treatment of bleeding episodes due to coagulation factors VIII or IX deficiencies. FEIBA contains primarily activated factor VII and smaller quantities of activated factors II, IX, and X. In 2009, Wójcik

TABLE 1: Management of vitamin K antagonists-induced high INRs and bleeding.

Condition	*Interventions*
Raised INR but <5; absent significant bleeding	Lower/omit dose, increase frequency of monitoring, resume therapy at a lower dose if INR more than minimally supratherapeutic
INR ≥ 5.0 but ≤ 10.0; absent significant bleeding	Omit 1–2 doses. Increase frequency of monitoring. Resume therapy when INR therapeutic Or Omit dose. Give 1.0–2.5 mg oral vitamin K. If the patient is at increased risk of bleeding, If requires more rapid reversal for a surgical procedure, give 2–4 mg oral vitamin K; the INR should decrease within 24 h If the INR remains elevated, additional vitamin K (1–2 mg orally) may be given
INR >10; absent significant bleeding	Hold warfarin therapy. Give 5–10 mg oral vitamin K; the INR should decrease within 24–48 h. Increase frequency of monitoring. Administer additional vitamin K if necessary. Resume therapy when INR within therapeutic range
Serious or life-threatening bleeding	Hold warfarin therapy. Give 10 mg vitamin K by slow IV infusion, in addition to four-factor PCC or FFP. Vitamin K may be given every 12 h

(FFP: fresh frozen plasma; INR: International Normalized Ratio; PCC: prothrombin complex concentrate)

TABLE 2: Reversal agents for warfarin.		
Vitamin K	1.25–10 mg orally or IV	Subcutaneous and intramuscular delivery not advised
PCC (Profilnine and Kcentra)	Strategy 1: INR and weight-based dosing • INR 2–4: 25 IU/kg IV push • INR 4–6: 35 IU/kg IV push • INR > 6: 50 IU/kg IV push Strategy 2: INR-based dosing • INR < 5: 500 IU • INR > 5 :1,000 IU Strategy 3: Fixed dose:1,500 IU	INR-based dosing is most effective with Profilnine (three-factor PCC). Fixed dosing should not be used with Profilnine. Any of the strategies may be used with Kcentra (four-factor PCC)
aPCC (FEIBA)	50–100 U/kg (U/kg)	Given the risk of thromboembolic events, use should be considered only when PCC is not available

(aPCC: activated prothrombin complex concentrate; INR: International Normalized Ratio; PCC: prothrombin complex concentrate; a: approved by the US Food and Drug Administration for warfarin-associated coagulopathy)

and colleagues 15 performed a retrospective chart review of patients who received FEIBA in the setting of life-threatening hemorrhage secondary to warfarin-induced coagulopathy. In this study, patients receiving FEIBA normalized the INR 12 times faster than those who received FFP. PCCs are contraindicated in persons with a history of anaphylaxis to PCCs or any of their components, or those with a history of disseminated intravascular coagulation, MI, and PE (increased risk of thrombosis). As far as thrombotic risk is concern, studies demonstrate that no statistically significant difference in the incidence of thromboembolic events in patients treated with three- and four-factor PCC versus FFP. FEIBA administration as associated with a thrombotic incidence of 8–9 per 100,000 infusions (the majority of data are from hemophiliacs). Sarode and colleagues have conducted the only clinical trial that directly compares four-factor PCC with FFP. There was no difference in the incidence of thrombotic events (8% PCC; 6% FFP). PCC should be considered superior to FFP. Each 500 IU (25 mL) vial of four-factor PCC is equivalent to 2 U (250 mL/U) of FFP. For treating the patient of with an INR of 10 kg and 80 kg weight (using reversal doses of 50 IU/kg of PCC and 15 mL/kg FFP) would require 8 vials (200 mL) of PCC or 16 U (4 L) of FFP.

Fresh Frozen Plasma

Fresh frozen plasma contains all of the coagulation factors. Although it is type specific, Rh compatibility is not required with individuals of the AB blood type being universal donors. Risks associated with transfusion of FFP include blood-borne infections and allergic reactions. The majority of resources advise the initial administration of 2 U of FFP for isolated intracranial bleeds and 4 U for extracranial bleeds (based on the generally accepted idea that one unit of FFP corrects clotting factors by 2–3% in a 70-kg individual); however, a volume of 10–15 mL/kg may be required to address life-threatening hemorrhage. The use of FFP in the reversal of anticoagulation for persons suffering from atrial fibrillation, cardiac valvular disease, and ventricular dysfunction, may be not ideal because significant increases in intravascular volume may result in decompensated heart failure or transfusion associated lung injury. Because the INR of FFP is 1.5, it is impossible to achieve an INR of <1.5 after FFP administration alone. The delivery of FFP is limited secondary to the product's frozen storage, requiring 15–20 minutes to thaw.

Vitamin K

Vitamin K is available in both oral and IV forms and an essential cofactor in the synthesis of factors II, VII, IX, and X, and proteins C and S. Vitamin K is not recommended by subcutaneous and intramuscular route due to unpredictable absorption and risk of hematomas formation. Time to onset of action of oral vitamin K starts in 6–10 hours, reaches to peak in 24–48 hours. Slow IV infusion (over 20 min) 5–10 mg of vitamin K should be given to actively bleeding patient. Intravenous route of vitamin K has rapid onset of action in 1– 2 hours, with peak effect in 12–24 hours. Parenteral vitamin K administration is associated with anaphylactic reactions. Of note, after vitamin K administration, therapeutic anticoagulation cannot be achieved for nearly 2 weeks. This consideration is important for providers to appreciate.

Recombinant Factor VIIa

Recombinant factor VII (rFVIIa; NoVo Seven) was developed for the treatment of bleeding episodes in individuals with factor VIII deficiency (hemophilia A), factor IX (hemophilia B), and congenital factor VII deficiency. The off-label use of rFVIIa in studies of nonhemophiliac trauma patients has demonstrated no benefit as compared with placebo. The administration of rFVIIa is not recommended as an adjunct for the reversal of warfarin due to increased risk of thromboembolic events.

REVERSAL OF DIRECT ORAL ANTICOAGULANTS

Direct Thrombin Inhibitors

Dabigatran etexilate mesylate (Pradaxa) is an oral DTI indicated for the reduction of stroke and systemic embolism in nonvalvular atrial fibrillation, for the treatment of DVT and PE, and for the prophylaxis of DVT and PE in patients who have undergone hip arthroplasty.

After hepatic metabolism, dabigatran binds the active site of free and clot-bound thrombin, inhibiting the conversion of fibrinogen to fibrin, and the feedback activation of factors VII, XI, and V. Laboratory monitoring of dabigatran's anticoagulant effect is rarely performed due to its reliable dose-proportional pharmacokinetics, INR response to DTIs is variable, and offers poor correlation to anticoagulation effect. Ecarin clotting time, diluted thrombin time, and aPTT are prolonged at the therapeutic levels of dabigatran prolong.

An elevated aPTT suggests at least therapeutic dabigatran effect, but a normal aPTT does not rule out dabigatran effect. A normal dilute thrombin time effectively excludes dabigatran effect. In 2015, the FDA approved idarucizumab (Praxbind), a humanized monoclonal antibody fragment, for the reversal of dabigatran in the setting of emergent/urgent surgical procedures, and life-threatening or uncontrolled bleeding. The recommended dose of idarucizumab is 5 g, provided as 2 separate vials containing 2.5 g/50 mL, administered no >15 minutes apart (data available for recommendation regarding repeat dosing is limited). Although a preexisting IV line may be used, per the manufacturer's guidelines, the line must be flushed with sterile sodium chloride before infusion, and no other infusion should be administered in parallel via the same.

In situations where idarucizumab is not available, hemodialysis should be performed because dabigatran predominately excreted through kidneys. The American Society of Hematology also recommends consideration of the administration of PCC or aPCC for life-threatening bleeds; however, this practice is supported by limited, poor-quality evidence, and is associated with thrombotic risk. **Table 3** contains a summary of reversal agents for DTIs.

Factor Xa Inhibitors

Factor Xa inhibitors include rivaroxaban (Xarelto), apixaban (Eliquis), edoxaban (Savaysa), and betrixaban (Bevyxxa). The factor Xa inhibitors are used to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. In addition, rivaroxaban is indicated for DVT and PE prophylaxis in patients undergoing hip or knee arthroplasty, edoxaban is approved for the treatment of DVT/PE after initial parenteral therapy, and betrixaban is approved for venous thromboembolism prophylaxis in hospitalized patients.

Rivaroxaban, apixaban, edoxaban, and betrixaban act by selectively blocking the active site of factor Xa, when free or bound to the prothrombinase complex. By inhibiting factor Xa, these novel anticoagulants indirectly inhibit platelet aggregation-induced by thrombin. Within 2 hours of administration of rivaroxaban, apixaban, and edoxaban, and within 4 hours of betrixaban dosing peak plasma concentrations are achieved. After oral administration, in patients with normal renal function, elimination half-lives of the novel anticoagulants are >12 hours. At therapeutic doses, all factor Xa inhibitors prolong clotting time tests (PT, INR, and aPTT); however, responses are variable, and are not useful in monitoring anticoagulation effects.

Rivaroxaban and inhibition of factor Xa can be correlated very closely (a normal PT/INR or normal antifactor Xa suggests normal range of rivaroxaban levels). Standardized kits using rivaroxaban callipers and controls are preferred, but may not be widely available. Antifactor Xa activity, calibrated with apixaban controls, is recommended to assess the anticoagulation effect of apixaban, (normal antifactor Xa suggests normal range of apixaban levels). The recommended assay for an assessment of the extent of edoxaban anticoagulation is antifactor Xa activity, calibrated with heparin or edoxaban. Andexanet alfa (Annexa) was designed as a reversal agent for all factor Xa inhibitors. Further research and data are required before recommending the use of andexanet alfa. Reversal agents for factor Xa inhibitors are summarized in **Table 4**.

Antifibrinolytic Agents

Antifibrinolytic agents such as tranexamic acid and aminocaproic acid are relatively inexpensive and possess favorable safety profiles, experts recommend that they be considered in the setting of life-threatening bleeding, though their efficacy in direct oral anticoagulant-associated bleeding is unknown (**Table 5**).

TABLE 3: Reversal agents for direct thrombin inhibitors.

Reversal agents	*Doses*
Idarucizumab	• 5 g, provided by the manufacturer as 2 vials containing 2.5 g/50 mL • Data regarding repeat dosing lacking
PCC (Profilnine or Kcentra)	50 U/kg
FEIBA	50–100 U/kg
Cryoprecipitate	• 2 pools • Administer for patients with fibrinogen

(FEIBA: factor VIII inhibitor-bypassing activity; PCC: prothrombin complex concentrate)

TABLE 4: Reversal agents for factor Xa inhibitors.

Reversal agents	*Doses*
Four-factor PCC (Kcentra)	• 25–50 U/kg repeat doses beyond 50 U/kg not advised • Maximum dose to be administered: 5,000 U
Factor VIII inhibitor-bypassing activity (FEIBA)	50–100 U/kg repeat dosing may be considered after 6 h if significant bleeding persists

TABLE 5: Antifibrinolytic agents.

Reversal agents	*Doses*
Tranexamic acid	1 g IV (requires dosing adjustment for renal impairment)
Aminocaproic acid	4–5 g IV infusion during the first hour of treatment followed by 1 g/h for 8 h or until control of bleeding (rapid IV administration should be avoided: It may induce hypotension, bradycardia, or arrhythmia)

REVERSAL OF HEPARIN AND LOW-MOLECULAR-WEIGHT HEPARINS

Heparin and the LMWHs (enoxaparin), dalteparin (Fragmin), and fondaparinux (Arixtra) are approved for the prophylaxis and treatment of DVT and PE. Another indication of enoxaparin is for the treatment of acute ST-segment elevation MI (STEMI), while enoxaparin and dalteparin may be used in non-STEMI (NSTEMI). Heparin and the LMWHs bind to antithrombin III, activating the antithrombin III complex, which inhibits factor Xa, and exhibits a variable inhibitory effect on factor IIa (thrombin). The aPTT is used to measure the anticoagulation effects of heparin, with a range of 1.5–2.5 times the control considered therapeutic. LMWH therapy is best monitored by the chromogenic antifactor Xa assay (gold standard). Discontinuation of heparin and protamine sulfate initiation is needed in case where urgent or emergent heparin reversal is required.

Protamine sulfate is a positively charged polypeptide, capable of reversing antithrombin III inhibition. Protamine dosing should be calculated based on time elapsed since heparin administration, and the dose of heparin delivered. If immediately after heparin administration, 1.0–1.5 mg of protamine sulfate should be given for every 100 U of heparin delivered. If 30–60 minutes have elapsed since the most recent dose of heparin, 0.50–0.75 mg/100 U of heparin are advised, and if >2 hours since the previous dose of heparin, 0.250–0.375 mg/100 U of heparin should be given.

Protamine sulfate may be used to reverse the anticoagulation effects of the LMWHs, enoxaparin, and dalteparin. It is important to note, however, that protamine is only 60% effective in reversing these anticoagulants owing to its limited ability to address factor Xa inhibition. Fondaparinux is not neutralized by protamine sulfate. If using protamine to reverse enoxaparin or dalteparin, it is recommended that 1 mg of protamine be administered for every milligram of these LMWHs previously administered (1:1 ratio). If bleeding continues, an additional 0.5 mg per 1 mg of enoxaparin or dalteparin is advised. Total protamine dosing should not exceed 50 mg because, at this concentration, paradoxical anticoagulation may occur secondary to factor V inhibition. Protamine is associated with the risk of anaphylaxis, hypotension, and bradycardia, so infusions should not exceed 20 mg/min. Andexanet alfa (Annexa) was designed in 2008 as a reversal agent for all factor Xa inhibitors. Additional data are required before making recommendations regarding the use of andexanet alfa in the reversal of heparin and LMWHs. Further studies are currently underway, **Table 6** contains a summary of the reversal agents for heparin and the LMWHs.

REVERSAL OF ANTIPLATELET THERAPY

Antiplatelet agents include aspirin, an irreversible inhibitor of cyclooxygenase-1, and cyclooxygenase-2; the thienopyridines, clopidogrel (Plavix), prasugrel (Effient), and ticlopidine, which irreversibly inhibit the P2Y12 receptor for adenosine diphosphate on platelets; ticagrelor (Brilinta) and cangrelor (Kengreal), adenosine diphosphate receptor inhibitors; and dipyridamole, a reversible inhibitor of adenosine diphosphate uptake by platelets.

Antiplatelet therapy is used in acute MI, NSTEMI, and unstable angina to prevent platelet aggregation and thrombosis. Antiplatelet agents are also indicated for the prevention of ischemic cerebrovascular accidents, MIs, and death in patients who have experienced acute coronary syndrome, and for the prevention of stent thrombosis after percutaneous coronary intervention. Currently, there are no clinical practice guidelines that direct the treatment of life-threatening bleeding in the setting of antiplatelet therapy (discontinuation of all antiplatelets and anticoagulants agents). Although in the PATCH trial platelet transfusion for spontaneous intracranial hemorrhage is ineffective in the reduction of bleeding.

At this point in time, further research is required before making recommendations regarding platelet transfusion for the reversal of antiplatelet therapy. Desmopressin (Stimate), or DDAVP, is a synthetic analog of antidiuretic hormone,

TABLE 6: Reversal agents for heparin and low-molecular-weight heparins.

Reversal agents	*Dose*	*Comments*
Protamine for heparin	Time elapsed since heparin dose: • *Immediate*: Administer 1–1.5 mg/100 U heparin • *30–60 min*: Administer 0.5–0.75 mg/100 U heparin • *>2 h*: 0.25–0.375 mg/100 U heparin	Doses should not exceed 50 mg at one time given the inhibition of factor V and potential for further anticoagulation
Protamine for low-molecular weight heparins	Dalteparin: • 1 mg of protamine neutralizes 100 U of dalteparin • If bleeding persists or aPTT remains prolonged 2–4 h after protamine: Consider administration of an additional protamine dose: 0.5 mg/100 U dalteparin Enoxaparin: • If <8 h since previous dose give 1 mg protamine per 1 mg of enoxaparin • If 8–12 h after the previous dose of enoxaparin, 0.5 mg protamine per 1 mg enoxaparin • If 12 h after previous dose of enoxaparin, protamine not required • If bleeding persists or aPTT remains prolonged, consider administration of a second dose of protamine: 0.5 mg per 1 mg enoxaparin	Protamine is only partially effective for the reversal of low-molecular-weight heparins. Fondaparinux is not neutralized by protamine sulfate

indicated for the treatment of bleeding episodes in persons with type I von Willebrand disease, or hemophilia. Current guidelines from the Neurocritical Care Society and Society of Critical Care Medicine support the use of a one-time 0.3 mg/kg intravenous dose of desmopressin in patients receiving antiplatelet therapy who experience intracranial hemorrhage (**Table 7**).

TABLE 7: Reversal agents for platelet inhibitors.

Reversal agents	*Dose*
Platelets	2–3 apheresis units or 2–3 units of pooled platelets (human studies have failed to demonstrate morbidity and mortality reduction following administration)
Desmopressin (DDAVP)	0.4 mg/kg IV (consider in addition to platelet transfusion)

SUMMARY

Rapid evaluation and treatment are required in actively bleeding anticoagulated patient presenting to emergency department. Evaluation and managing such patient are complicated by the ever-evolving antithrombotic treatment options used in medicine and the timeliness with which reversal decisions need to be made. Thus, emergency physician should be aware of the properties and general characteristics of a variety of antithrombotic agents. The available antithrombotic reversal agents include vitamin K, FFP, PCC, rFVIIa, platelets, and desmopressin. The novel anticoagulant medications, such as dabigatran and rivaroxaban, present particular challenges because there are no uniformly effective reversal options. Furthermore, the ability to measure anticoagulant effect of these medications is limited in the emergency setting. The approach to reversal is often guided by institutional protocol, with close attention to potential benefits of reversal carefully balanced against potential harm.

Peripheral Arteriovascular Disease

80
CHAPTER

Prasad Rajhans, Ujwal Prakash Dhundi

INTRODUCTION

Acute limb ischemia is the major complication of peripheral vascular disease with the potential of loss of limb or life. Emergency physician should be able to diagnose and manage the acute limb ischemia promptly as this is the one of the common presentation to emergency room.

ETIOLOGY/CAUSES

- Atherosclerosis
- Embolism—atrial fibrillation, valvular vegetation, aneurysm, atheroemboli, etc.
- In situ thrombosis
- Inflammation—drugs, radiation, mechanical trauma, and bacterial invasion
- Trauma—vascular surgeries
- Vasospasm—Raynaud's disease, Raynaud's phenomenon, livedo reticularis, acrocyanosis erythromelalgia, etc.

PATHOPHYSIOLOGY

Lack of blood supply to meet the tissue oxygenation and nutrient leads to acute limb ischemia. As time progresses, lack of nutrient and oxygen leads to cell death and irreversible tissue damage. Peripheral nerves and skeletal muscles are more sensitive to ischemia and irreversible changes occur in these tissues with 6 hours of anoxia. After the restoration of perfusion in complete or partial occlusion, reperfusion injury can occur due to the formation of oxygen free radicals. Reperfusion injury is characterized by the presence of myoglobinuria, renal failure, and peripheral muscle infarction. Laboratory features of reperfusion injury include hyperkalemia, myoglobinuria, metabolic acidosis, and an elevation in creatinine kinase level. The severity of the injury depends on the extent, location, and duration of blockage, collateral flow, and previous health of the limb involved. One-third of the deaths due to occlusive arterial disease occur due to metabolic complication on revascularization. *Atherosclerosis is the major cause of nonembolic limb ischemia in the vast majority of the patients.* Formation of atheromatous plaque within the artery intima results from lipid accumulation, the proliferation of smooth muscle cells, and fibrogenesis with the ultimate narrowing of the vessel lumen. Plaque rupture or endothelial erosion followed by thrombus formation can lead to complete or high-grade obstruction. Ischemic injury can then propagate through several *mechanisms*: (1) extension of the clot to occlude collateral vessels, (2) compartment syndrome due to ischemia-related distal edema, (3) fragmentation of clot into the microcirculation, and (4) edema of the microvasculature cells. Seldom, arterial thrombosis can occur in apparently normal vessels without atherosclerotic plaque, this should prompt evaluation for hypercoagulability.

CLINICAL PRESENTATION

Patient with peripheral arterial disease presents with change in appearance such as discoloration, swelling, or temperature change, or change in sensation. *Risk factors* such as cardiac disease, myocardial infarction, stroke, arrhythmias, transient ischemic attacks, renal disease, prior injuries, surgeries, history of pulmonary embolism, phlebitis, coagulation abnormality, or autoimmune diseases may be present at the presentation. Embolic or thrombotic peripheral arteriovascular disese can be differentiated by their distinct clinical feature as given in **Table 1**.

Acute Arterial Occlusion

It manifests as sudden limb-threatening ischemia. A typical patient description is of sudden struck to the leg by severe shocking pain. The patient often has to sit or fall to the floor during such sudden episodes. The patient often has some of the components of famous *five 'P's, i.e., (1) pain, (2) pallor, (3) pulselessness, (4) paresthesia, and (5) paralysis*. Paralysis and paresthesia warn about limb-threatening ischemia that will need surgical intervention regardless of the cause. In the patient with nonlimb-threatening ischemia, the pathophysiological distinction between the causes of ischemia whether embolic or in situ thrombosis in the vessel determines the line of management. Nonlimb threatening ischemia from arterial embolism can be managed by Fogarty catheter embolectomy. In situ thrombosis is managed nonoperatively as surgical interventions tend to aggravate the thrombosis. Patients with in situ thrombosis usually have long-standing peripheral arterial atherosclerosis with well-developed collateral circulation. History of claudication can be obtained from these patients while it is not available with the patient with acute embolism.

TABLE 1: Difference between arterial embolism versus thrombosis.

Clinical findings	*Embolus*	*Thrombosis*
Identifiable source of embolus	Usual, particularly atrial fibrillation	Less common
History of claudication	Rare	Common
Physical findings of occlusive disease	Few, proximal and contralateral limb pulses normal	Often present, proximal or contralateral limb pulses diminished or absent
Demarcation of ischemia	Sharp	Diffuse
Arteriography	Minimal atherosclerosis, sharp cutoff, few collateral	Diffuse atherosclerosis, tapered, irregular cutoff, well-developed collateral

Source: Brewster DC, Chin AK, Fogarty TJ. Vascular Surgery. Philadelphia: WB Saunders;1990.

Chronic Arterial Insufficiency

Chronic arterial insufficiency usually presents with two types of pain:

1. Intermittent claudication
2. Ischemic rest pain

Location of pain in claudication depends upon the location of arterial occlusion. In femoropopliteal disease, claudication present as cramping calf pain and complete relief with rest. In aortoiliac occlusive disease, claudication occurs in buttocks, hips, and calves. Calf pain in aortoiliac disease is more severe than that of hips and buttocks and is described as aching, weakness, or discomfort. Aortocclusive disease resulting in bilateral claudication usually presents with impotence in men. Progression of chronic arterial insufficiency leads to ischemic pain at rest. Rest pain usually occurs in feet distal to metatarsals and often awakens the patient from sleep. This type of pain is severe and nonresolving with limb elevation or analgesic but has a prompt relief by the activity involving standing position. Patients are often observed to sleep with feet dangling over the side of the bed or sleep in a chair to increase perfusion pressure to distal tissues. In the case of suspected arterial insufficiency, palpation of all peripheral pulses should be documented on a scale of 0 to +4. It is important to note that dorsalis pedis artery pulsations are absent in a 10% population.

Chronic and advanced ischemia is suggested by signs such as muscular atrophy, loss of hairs, delayed growth of fingernails, and their thickening. With advanced ischemia, skin becomes shiny and skeletonized from the atrophy of skin subcutaneous tissue and muscle. Delayed return of normal color as compared to the contralateral side on blanching of skin suggests reduced perfusion. Another clinical bedside test is Buerger's sign to detect severe advanced ischemia. In absent or questionable pulses, Doppler ultrasonography and measurement of ankle-brachial reflexes serve the purpose. Similarly, Allen's test will be helpful to assess the patency of radial and ulnar arteries in the upper limb.

DIAGNOSTIC STRATEGIES

Ankle Brachial Index (ABI)

Systolic blood pressure is measured by Doppler ultrasound in each arm, in dorsalis pedis and in posterior tibial arteries in each ankle. The higher or 2 arm pressure is selected. ABI of both limbs are estimated by formula given below:

$$\text{Right ABI} = \frac{\text{Increase right ankle pressure}}{\text{Increase right arm pressure}}$$

$$\text{Left ABI} = \frac{\text{Increase left ankle pressure}}{\text{Increase left arm pressure}}$$

Interpretation of Ankle Brachial Index (ABI) (**Flowchart 1**):

- *ABI*: >1.3 noncompressible
- *ABI*: 0.91–1.3 normal
- *ABI*: 0.41–0.90 mild-to-moderate peripheral arteriovascular disease
- *ABI*: 0.00–0.40 severe peripheral arteriovascular disease (critical leg ischemia).

Doppler Ultrasonography

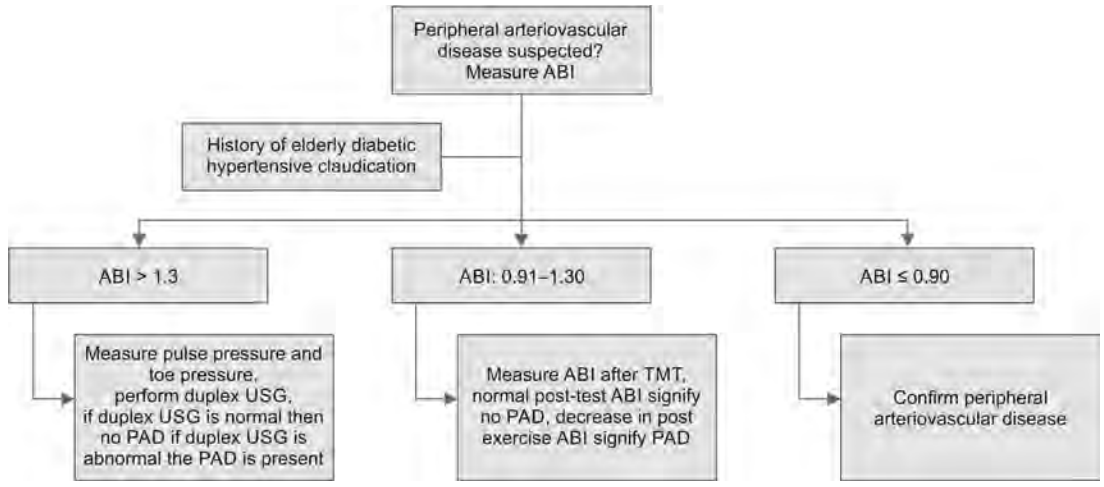
It measures the blood flow velocity using the frequency shift of sound reflected from RBCs as they move toward or away from the ultrasound probe.

A normal signal creates a triphasic velocity waveform. The arterial narrowing causes to change the waveform to biphasic or monophasic depending on severity. This examination detects significant arterial occlusive disease but can not identify the exact location of the occlusion. B-mode duplex ultrasonography is cheap, bedside noninvasive accurate diagnostic test for peripheral vascular disease. Colored imaging of blood flow with duplex scanning is also available and provides accurate detection of atherosclerotic plaque and stenosis and their effect on intraluminal blood flow. It is a procedure of choice for most conditions.

Contrast Arteriography

It is the definitive diagnostic test of abnormal arterial anatomy. It is more invasive and is associated with catheter and contrast-related complications. The indications of emergency angiography are:

- Acute arterial embolism or thrombosis where clinical diagnosis is uncertain.
- Conditions where emergency vascular bypass grafting is being considered.
- Characterization of vascular abnormality before emergency surgery.



Peripheral arteriovascular disease suspected? Measure ABI
History of elderly diabetic hypertensive claudication
ABI > 1.3
ABI: 0.91–1.30
ABI ≤ 0.90
Measure pulse pressure and toe pressure, perform duplex USG, if duplex USG is normal then no PAD if duplex USG is abnormal the PAD is present
Measure ABI after TMT, normal post-test ABI signify no PAD, decrease in post exercise ABI signify PAD
Confirm peripheral arteriovascular disease

FLOWCHART 1: Evaluation of patient in whom peripheral arteriovascular disease suspected.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) angiography is useful for the evaluation of abdominal aorta. In the peripheral arterial-vascular system, CT angiography is useful for atherosclerotic infected and false aneurysm and cerebral circulation. MR angiography can make an axial coronal sagittal section to provide accurate visualization of the anatomy. MRI also can differentiate between blood, thrombus, fat, and fibrosis.

MANAGEMENT

The objective of the treatment of acute arterial obstruction is to restore the blood flow, preservation of limb and life, prevention of thrombosis, and embolism. The definitive treatment of an obstructing clot should be done in conjunction with a vascular surgeon. Major treatment options available are catheter-directed thrombolysis and percutaneous mechanical thrombectomy revascularization procedures such as percutaneous transluminal angioplasty or direct surgical revascularization. Aspirin should be administered to all the patients if not contraindicated. Administration of aspirin reduced vascular mortality by 25%. Management of acute arterial occlusion is based on degree and cause of ischemia.

- *Patients with limb-threatening acute ischemia* from embolism should undergo emergency Fogarty catheter-directed embolectomy. While those with due to thrombosis should undergo direct or catheter-directed thrombectomy with vascular bypass grafting as thrombectomy alone often fails due to recurrence of thrombosis. Primary amputation is required in patients in whom the lesions cannot be bypassed, who have evidence of irreversible ischemia or who are too ill to tolerated revascularization.
- *Patients with nonlimb-threatening limb ischemia* due to embolism are treated with embolectomy while those with thrombosis are managed medically with immediate systemic heparinization with APTT monitoring and with intra-arterial fibrinolytic therapy. The intent of early heparinization is to prevent clot propagation, embolization, venous thrombosis, and occlusion after perfusion.
- *Systemic heparinization* is relatively contraindicated in patient with recent neurosurgery within 2 weeks, major surgery within 48 hours, labor within 24 hours, bleeding diathesis thrombocytopenia, and potentially hemorrhagic lesion and active bleeding
- *Fibrinolytic therapy* is reserved for the patient with nonlimb-threatening ischemia as clot take 6–72 hours to lyse and patient with limb-threatening ischemia cannot tolerate this period without limb loss or tissue loss. Intra-arterial fibrinolysis may uncover critical stenosis which may lead to another even of thrombosis. Hence, patient with successful fibrinolysis needs secondary bypass grafting or percutaneous angioplasty. Agents used for fibrinolysis are streptokinase urokinase and tissue plasminogen activator. Intravenous fibrinolysis is less effective than direct administration into the clot. Clots older than 30 days are less likely to achieve lysis.
- *Fogarty catheter thrombectomy*: It is more frequently used for iliac femoral and popliteal vessels and performed under local anesthesia. Newer thrombi are more likely to be removed than older one as older one are more firmly adhered to the vessel wall and will need direct surgical thrombectomy.
- *Supportive therapy*: Supportive therapy includes the administration of an analgesic, dependent positioning of the affected limb fluid administration and management of associated cardiac failure or arrhythmias, if present to improve the perfusion pressure to the affected limb.
- *Nonsurgical management of chronic obstructive arterial disease*: Nonsurgical management should focus on the combination of smoking cessation exercise and pharmacotherapy. Medical treatment of hypercholesteremia high blood pressure and good glycemic control and drugs to help in the cession of smoking help to modify risk factors associated with the progression of the disease. Cilostazol and pentoxifylline are also considered therapies for the treatment of claudication, however, pentoxifylline is no more recommended.

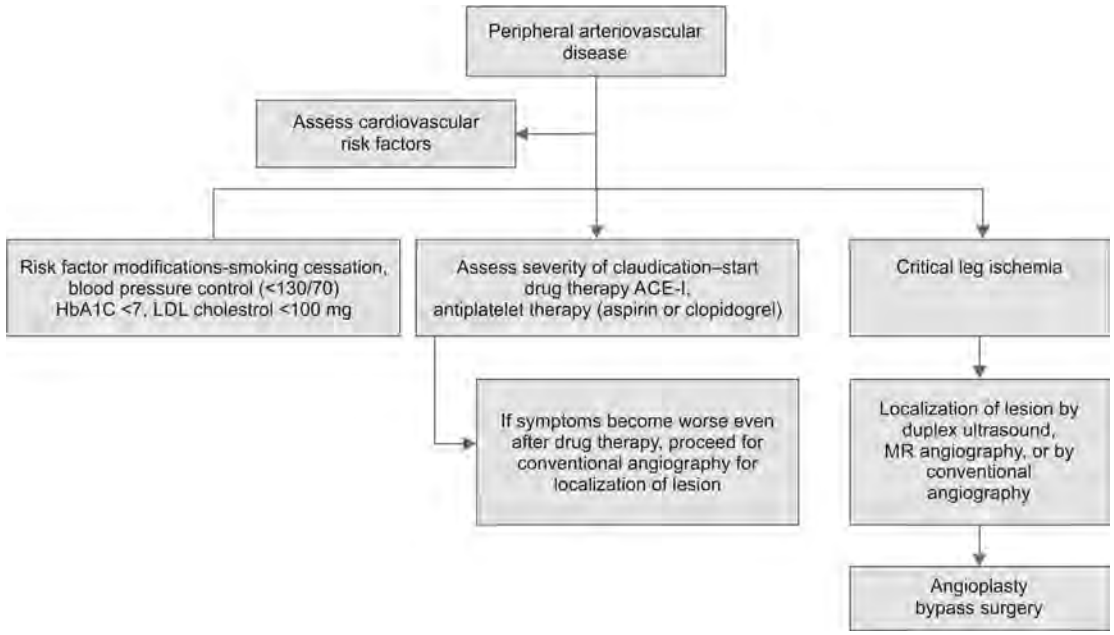
DISPOSITION

All patients requiring surgical intervention should be admitted to the hospital. Patients with the chronic peripheral arterial disease without an immediate threat to limb and lacking comorbidities needing immediate attention can be discharged and asked to follow-up with a primary care physician or a vascular surgeon. The patient should be informed to return to

the hospital in case of a worsening of symptoms. Aspirin 75–100 mg daily can be prescribed if there are no contraindications.

SUMMARY

Peripheral arteriovascular disease is a serious medical problem and an indicator of systemic atherosclerosis. Atherosclerosis is principally a systemic disease not limited to an isolated vessel segment and manifest as atherothrombosis in other vessel areas. In patients with primary diagnosis of the peripheral arteriovascular disease atherosclerotic manifestations in other vessel areas is higher than in coronary or cerebrovascular vessels. The diagnosis of peripheral arteriovascular disease is, therefore, a marker for more generalized and severe atherosclerosis. Patients with intermittent claudication have a relatively good prognosis, while otherwise the prognosis concerning overall survival is poor, with coronary artery disease being by far the most common cause of death. Patients with chronic critical limb ischemia have an even worse prognosis with a 20% mortality in the first year after presentation. A careful history taking and clinical examination remain the gold standard in diagnosis of peripheral arteriovascular disease. Calculation of the ankle–brachial index is established worldwide as the initial screening test. Duplex sonography as the primary diagnostic step for evaluation of morphology and for planning the kind of revascularization—endovascular or surgical technique—enables visualization and quantification of severity of lesions. This can be done by duplex ultrasound, computed tomographic angiography or magnetic resonance angiography (**Flowchart 2**). Technology and techniques of endovascular revascularization as a minimally invasive therapy for treatment of patients with peripheral arteriovascular disease have evolved rapidly during the last decade in the treatment of even complex cases.



Peripheral arteriovascular disease
Assess cardiovascular risk factors
Risk factor modifications-smoking cessation, blood pressure control (<130/70) HbA1C <7, LDL cholestrol <100 mg
Assess severity of claudication–start drug therapy ACE-I, antiplatelet therapy (aspirin or clopidogrel)
Critical leg ischemia
If symptoms become worse even after drug therapy, proceed for conventional angiography for localization of lesion
Localization of lesion by duplex ultrasound, MR angiography, or by conventional angiography
Angioplasty bypass surgery

FLOWCHART 2: Summary of evaluation and management of peripheral arteriovascular disease.

81
CHAPTER

Cough

Bhawana Sharma

INTRODUCTION

Cough is the most common symptom observed in pulmonary disease patients and most frequent cause of visit to clinics. The patient's anxiety associated with the serious underlying cause is significant. Troublesome-associated symptoms such as chest pain from intercostal muscle strain or even a fractured rib and cough-induced urinary or fecal incontinence may lead to fear of social isolation, besides considering cough as communicable disease symptom by peer group. *What is cough*—a forceful expiration expels mucus and foreign material from the airways protecting lung against aspiration. Effectiveness of cough, i.e., ability to take deep breath and exhale forcefully—it depends on ability of an individual to take a deep breath, lung elastic recoil, expiratory muscle strength, and level of airway resistance.

- *Cough is usually ineffective in patients with*:
  - Cardiopulmonary diseases
  - Neurologic diseases, especially involving respiratory muscles and gag reflex
  - Systemic neuromuscular diseases
  - Early postoperative period due to painful respiratory movements, especially after pulmonary or upper abdominal surgeries and trauma
- *Often expiratory flow is limited by factors such as*:
  - Bronchospasm (e.g., asthma)
  - Reduced lung elastic recoil (as in emphysema)
  - Muscle weakness
- *Consequences of ineffective cough*:
  - Atelectasis
  - Retained secretions
  - More prone to develop pneumonia and/or hypoxemia

ACUTE, SUBACUTE, AND CHRONIC COUGH

Broadly acute cough is defined as which last for a maximum of 3 weeks, upper respiratory tract infections (URTIs), acute bronchitis, or tracheobronchitis due to bacterial or more frequently viral infections are the common causes. Acute cough of viral etiology are self-limiting and subsides within 1–2 weeks along with the clearing of the infection and very few need medical attention. But there is no parameters to predict which cough will persist into the subacute (pneumonia) or chronic cough (tuberculosis). Further situation may be complicated by the ineffective therapy which leads to persistent cough and later progress to subacute (3–8-week duration) or chronic cough (>8 weeks duration). Emergency physician should be aware that recurrent acute episodes of cough can be a manifestation of an undiagnosed chronic disease (e.g., asthma). Nevertheless, keeping these pitfalls in mind, a relatively "standard" diagnostic and therapeutic approach based on the duration of the cough should be used.

MECHANISM OF COUGH

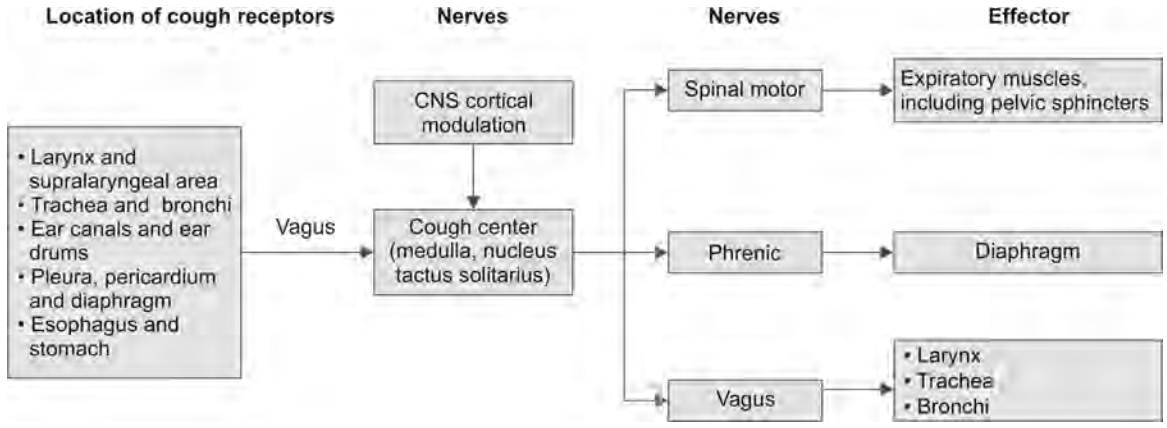
When cough receptors are stimulated by inflammation, mucus, foreign materials, or noxious gases. Receptors are located primarily in larynx, trachea, and large bronchi. Mechanism of cough explained in the **Flowchart 1**.

ETIOLOGY OF COUGH

Most common cause of acute and self-limiting cough is a viral infection of upper airway. Chronic cough is one lasting 8 weeks or longer. Chronic cough carries with it considerable frustration and anxiety for patients with decreased quality of life and depression. When a detail history and thorough examination fail to find evidence of disease [e.g., cancer and human immunodeficiency virus (HIV) disease] and the chest radiograph is normal, >90% of chronic cough cases are accounted for by upper airway cough syndrome (formerly called postnasal drip), asthma, and gastrointestinal reflux. Chronic cough has numerous common and uncommon causes that sometimes may have multiple sources (**Box 1**).

CHARACTERISTICS OF COUGH

Characteristics of cough are described (**Table 1**) in terms of productive or nonproductive cough, acute or chronic cough, nocturnal or day time cough. Dry or nonproductive cough



(CNS: central nervous system)

FLOWCHART 1: Mechanism of cough signaling pathway in development of cough.

BOX 1: Etiology of chronic cough in adults (>8 weeks duration).

Common causes:
- Upper airway cough syndrome (formerly known as "postnasal drip")
- Pulmonary tuberculosis
- Asthma
- Gastroesophageal reflux
- Chronic bronchitis associated with cigarette smoking
- Environmental exposure
- Angiotensin-converting enzyme-1 (ACE-1) cough (caused by antihypertensive drug ACE inhibitors)
- Nonasthmatic eosinophilic bronchitis

Less common causes:
- Postinfection (e.g., pertussis and mycoplasma)
- Interstitial lung disease
- Bronchiectasis
- Obstructive sleep apnea
- Primary lung cancer
- Heart failure

Uncommon causes:
- Sarcoidosis
- Recurrent aspiration
- Chronic tonsillar enlargement
- Chronic auditory canal irritation
- Foreign body aspiration
- Endemic fungi
- Peritoneal dialysis
- Cystic fibrosis
- Tracheomalacia
- Habit or "tic cough"

typical of restrictive lung disease. *Loose or productive cough*—more often associated with inflammatory obstructive disease such as bronchitis or asthma.

ASSOCIATED FEATURES OF CONCERN (RED FLAGS)

- Fever
- Rashes
- Chest pain
- Palpitations
- Hemoptysis
- Breathlessness
- Dizziness or vomiting with cough
- Loss of consciousness while coughing
- Hypotension

COMPLICATIONS OF COUGH

- *Circulatory*: Decrease in cardiac output due to raised intrathoracic pressure, especially in patients with cor pulmonale or right heart failure
- *Syncope*: Post-tussive—nearly always occur in man
- *Raised intra-abdominal pressure*: Hernia, collapse of rectum, or vagina
- Intraocular hemorrhage

INVESTIGATIONS

Depending on history, clinical examination investigation may be decided as:
- Throat swab for Gram stain and culture
- Ear, nose, and throat (ENT) evaluation
- Sputum examination—Gram stain, culture for bacterial, fungal or protozoal causes
- Complete blood count (CBC), erythrocyte sedimentation rate (ESR), serologic markers for various bacterial, fungal, protozoal, or viral infections
- Chest X-ray
- High-resolution computed tomography (HRCT) or contrast-enhanced computed tomography (CECT) chest
- Blood culture
- Bronchoscopy
- Mediastinoscopy
- Video-assisted thoracoscopic surgery (VATS)
- Open lung biopsy

TABLE 1: Characteristics of cough in specific etiologies.	
Causes	***Characteristics of cough***
Sinusitis or nasopharyngitis	Cough following an upper respiratory syndrome or sinus symptoms; sensation of a need to clear the throat; postnasal drip
Acute infections of lung	
Tracheobronchitis	Cough associated with sore throat, running nose and eyes
Lobar pneumonia	Cough often preceded by symptoms of upper respiratory infection; dry cough—initially painful later become productive
Bronchopneumonia	Cough dry/productive, usually begins as acute bronchitis
Mycoplasma and viral pneumonia	Paroxysmal cough, productive—mucoid/blood-stained sputum associated with flu-like syndrome
Exacerbation of chronic bronchitis	Productive cough—mucoid then purulent
Chronic infections of lung	
Bronchitis	• Productive cough on most days for > 3 consecutive months and for > 2 years • Mucoid sputum until acute exacerbation, when it becomes mucopurulent
Bronchiectasis	Copious, foul smelling, purulent sputum often since childhood; forms layers on standing
Tuberculosis or fungal infection	Persistent cough for weeks to months, often with blood-tinged sputum
Parenchymal inflammatory disease	
Interstitial fibrosis and infiltrations	Persistent, nonproductive cough—depends on origin
Smoking and inhalation of irritants	Persistent slightly productive cough, mostly in mornings, usually associated with infected pharynx, if succeeded by chronic bronchitis copious purulent sputum may be present
Tumors	
Bronchogenic carcinoma	Nonproductive cough→productive in weeks to months, may be associated with recurrent mild hemoptysis
Adenocarcinoma in situ or minimally invasive adenocarcinoma	Same as above, some cases may present with copious, watery to mucoid sputum
Benign tumors in airways	Nonproductive cough, occasional hemoptysis
Mediastinal tumors	Cough with dyspnea—caused by compression of trachea and bronchi
Aortic aneurysm	Brassy cough
Gastrointestinal	
Gastroesophageal reflux disease (GERD)	Nonproductive cough—often followed by meals or with recumbency, may or may not be associated with other symptoms of GERD (e.g., heart burn, bitter oral taste, and belching)
Foreign body	
Immediate while still in upper airway	Cough associated with progressive evidence of asphyxiation
Later, when lodged in lower airway	Persistent, nonproductive cough associated with localized wheeze
Cardiovascular	
Left ventricular failure	Cough and dyspnea worsens when supine
Pulmonary infarction	Cough with hemoptysis, usually with pleural effusion
Drug induced	
Angiotensin-converting enzyme (ACE) inhibitors	More common in females, dry cough, may occur at any time (soon after starting drug or many years later)

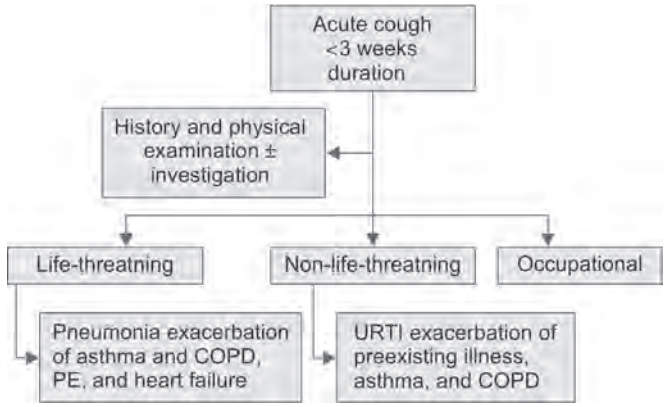
TREATMENT

Acute and subacute cough is need to be treated effectively as soon as possible to maintain adequate quality of life and productivity of the patient. Many patients resulting in substantial morbidity, if cough is not controlled adequately. First symptom-related approaches are adopted in the treatment of the cough. Then various interventions are required (history, physical examination, and investigations) to identify the causes of cough and aim at removing the underlying cause of cough (**Table 2**). Ideally, treatment of the underlying cause(s) of cough with specific treatments of underlying cause is the only strategy which eliminate cough. Sometime no cause could be found to establish the diagnosis and treatment of underlying cause could not be initiated, so in view of deterioration in the quality of life of the patient empiric treatment with antitussive agents is often needed. Another concept of treating the cough earlier is to prevent it becoming

TABLE 2: Specific treatment approaches to cough.

Etiology of cough	*Treatment approach*
Upper/lower respiratory infection	Appropriate antibiotics
Smoking/chronic bronchitis	Cessation of smoking/avoidance of pollutants
Pulmonary tuberculosis	Antitubercular drugs
Asthmatic cough	Inhaled beta-2 agonists/ipratropium/corticosteroids
Postnasal drip due to allergic/perennial rhinitis	Avoidance of precipitating factors, corticosteroid nasal spray, and H1 antihistaminic
Gastroesophageal reflux disease	Bed head elevation, light dinner, diet modification, H2 blocker, proton pump inhibitors, and cisapride
ACE inhibitor-associated cough	Substitute ACE inhibitor by losartan, calcium channel blocker, and NSAIDs

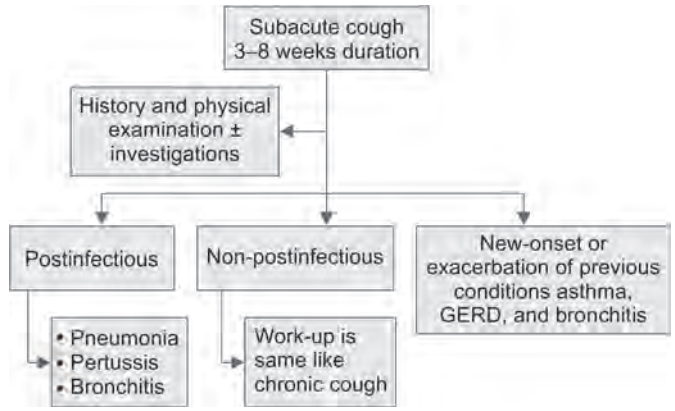
(ACE: angiotensin-converting enzyme; NSAIDs: nonsteroidal anti-inflammatory drugs)



(COPD: chronic obstructive pulmonary disease; PE: pulmonary embolism; URTI: upper respiratory tract infection)

FLOWCHART 2: Evaluation of management of acute onset cough <3-week duration.

the persistent cough and decreasing the spread of infectious virus and bacteria. Cough-related complications are also can be prevented, such as fatigue, sleep deprivation, hoarseness, musculoskeletal pain, sweating, and urinary incontinence. Two mechanisms can be involved for the development of acute phase of the cough; a respiratory virus or by gastroesophageal reflux disease (GERD) through direct stimulation of cough receptors. Sometime this could be a possibility that a cough that does not respond to specific therapies "idiopathic"



(GERD: gastroesophageal reflux disease)

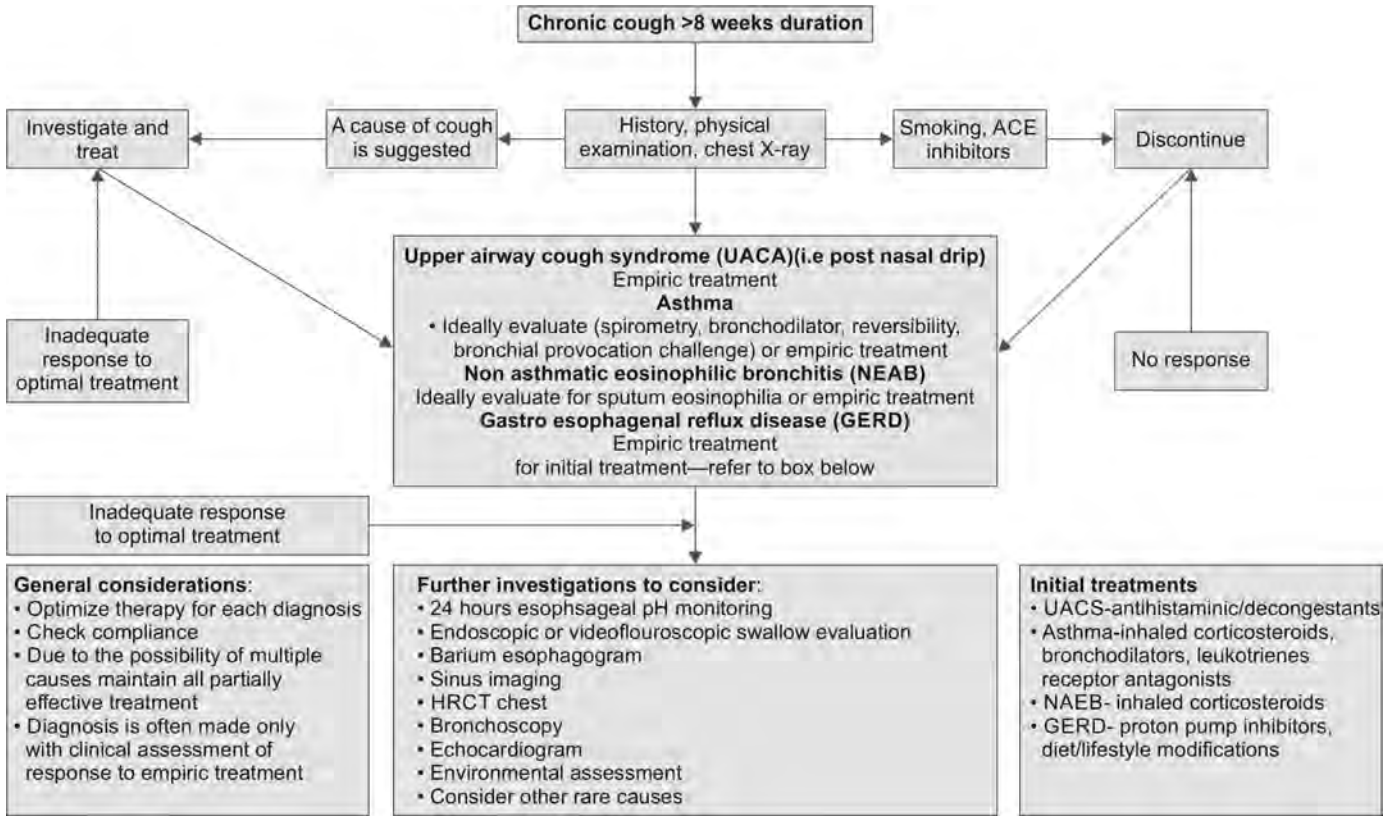
FLOWCHART 3: Evaluation and management of subacute onset cough 3–8 weeks duration.

cough which need a nonspecific approach to evaluation of cough. Evaluation and management of acute, subacute, and chronic onset of cough are summarized in **Flowcharts 2** to **4**.

SUMMARY

Cough is one of the most common symptoms that results in medical consultations and is the most frequent complaint of patients seeking advice from practicing pulmonary physicians, accounting for up to 40% of the practice outpatient care activity. Coughing is considered as defensive reflex that helpful in clearance of secretions and particulate matter from the airways and protects from aspiration of foreign materials occurring as a consequence of aspiration or inhalation of particulate matter, pathogens, accumulated secretions, postnasal drip, inflammation, and associated inflammatory mediators. Under normal conditions, cough plays an important protective role in the airways and lung parenchyma, but in some conditions, coughing may become excessive and nonproductive, and is troublesome and potentially harmful to the airway mucosa. Treating of cough should be started early, helps in preventing the vicious cycle of cough perpetuating cough. Symptom-related approaches are beneficial in treatment of cough. Antitussive agents are usually helpful as empiric treatment particularly needed when associated with deterioration in the quality of life. Drugs available for symptomatic treatment of cough include both peripheral and central products. Recommendation is against the use of over the counter products for coughs and colds, including central antitussives, in infants, and young children. Various academies and society have advised not to use dextromethorphan as well as codeine for treating any type of cough in the pediatric as well as adult population. Treatment of cause should be the priorities.

"Do not suppress the cough—Treat the Cause"!



Chronic cough >8 weeks duration
Investigate and treat
A cause of cough is suggested
History, physical examination, chest X-ray
Smoking, ACE inhibitors
Discontinue
Upper airway cough syndrome (UACA)(i.e post nasal drip)
Empiric treatment
Asthma
• Ideally evaluate (spirometry, bronchodilator, reversibility, bronchial provocation challenge) or empiric treatment
Non asthmatic eosinophilic bronchitis (NEAB)
Ideally evaluate for sputum eosinophilia or empiric treatment
Gastro esophagenal reflux disease (GERD)
Empiric treatment
for initial treatment—refer to box below
Inadequate response to optimal treatment
No response
Inadequate response to optimal treatment
General considerations:
• Optimize therapy for each diagnosis
• Check compliance
• Due to the possibility of multiple causes maintain all partially effective treatment
• Diagnosis is often made only with clinical assessment of response to empiric treatment
Further investigations to consider:
• 24 hours esophsageal pH monitoring
• Endoscopic or videoflouroscopic swallow evaluation
• Barium esophagogram
• Sinus imaging
• HRCT chest
• Bronchoscopy
• Echocardiogram
• Environmental assessment
• Consider other rare causes
Initial treatments
• UACS-antihistaminic/decongestants
• Asthma-inhaled corticosteroids, bronchodilators, leukotrienes receptor antagonists
• NAEB- inhaled corticosteroids
• GERD- proton pump inhibitors, diet/lifestyle modifications

(ACE: angiotensin-converting enzyme; HRCT: high-resolution computed tomography)

FLOWCHART 4: Evaluation and management of chronic cough 3–8-week duration.

CHAPTER

Hemoptysis

Veerottam Tomer

INTRODUCTION

Hemoptysis is the expectoration of blood from the airways; it can originate from the alveoli to glottis. Hemoptysis is derived from Latin "hemo-" "of blood" + Greek *ptusis* "spitting". It can range from blood-tinged to severe life-threatening. For most patients, any degree of hemoptysis can be frightening and needs earliest medical evaluation. The location may be upper respiratory tract, vocal cords, tracheobronchial tree, or lung parenchyma. Identification of location is important for proper management of the symptom. It is very scary to see patients dying from asphyxiation even in spite of intubation. It is the most challenging emergency faced by emergency physician and intensivist because course of bleeding is unpredictable and varies from trivial to large amount.

Hemoptysis is a manifestation of underlying disease process. Till now there is no consensus regarding the optimal management of these patients. A quick history, examination, investigations, and timely intervention play a very crucial role in the management of hemoptysis. At the same time, it is very important to differentiate hemoptysis from pseudohemoptysis, hematemesis, and epistaxis (**Table 1**).

The most common causes of mild hemoptysis are bronchitis, bronchiectasis, bronchogenic carcinoma, and tuberculosis. 20–40% of cases of minor hemoptysis are due to bronchitis and bronchiectasis; while bronchogenic and metastatic carcinomas account for 20% of the cases. However, in India, tuberculosis is the most common cause of mild-to-massive hemoptysis, where it can be seen in active disease or as its sequelae. In Western part of the world, malignancies are the main cause of massive hemoptysis.

It is important to keep in mind that the cause of death in hemoptysis is asphyxiation and not blood loss. It is also dependent on rate of blood loss and underlying lung condition. There is no clear definition for the degree of hemoptysis, however according to the general consensus we can grade hemoptysis into the following grades. *Minor hemoptysis* usually is <15–20 mL/day and is commonly seen to resolve spontaneously. *Massive hemoptysis* ranges from ≥100 mL in 24 hours to >1 L in 24 hours. It can also be judged by its clinical consequences such as requiring hospitalization, the risk of airway occlusion, laboratory evidence of blood loss, or even risk of death. *Bad prognostic factors* if bleeding rate: ~1,000 mL/24 h, aspiration into contralateral lung, massive bleeding requiring single lung ventilation, and bronchogenic carcinoma as an underlying etiology.

PULMONARY CIRCULATION

Lungs have dual blood supply:

- *Pulmonary artery*: Primarily involved in gas exchange process, arises from right ventricle. It is a low resistance system and a high-volume system. It accounts for >99% of blood supply and <10% of causes of hemoptysis. Beyond terminal bronchioles it anastomoses with bronchial circulation for gas exchange.
- *Bronchial artery*: Serves as a nutritional source of circulation. It arises from the systemic vascular bed. There are one or two arteries per lung commonly arising from aorta and at times from intercostal arteries. It is a high pressure (systemic pressure) system. In diseased lungs it often

TABLE 1: Differentiating points: Hemoptysis, hematemesis epistaxis.

Symptoms	*Hemoptysis*	*Hematemesis*	*Epistaxis*
Cough	Common	Uncommon	Uncommon
Dyspnea	Common	Uncommon	Uncommon
Abdominal symptoms	Uncommon	Common	Absent
Frothy secretions	May be present	Absent	Absent
Mixed with food	Absent	May be present	Absent
Mixed with sputum	Common	Uncommon	Uncommon
Color	Bright red	Coffee	Bright red
pH	Alkaline	Acidic	Alkaline
Chest symptoms	May be present	Absent	Absent
Nasal bleed	Absent	Absent	Present

becomes tortuous and anastomosis with the pulmonary veins also get exaggerated (e.g., Rasmussen's aneurysm). Thus bleeding from bronchial artery rupture is more profuse than pulmonary artery rupture.

ETIOLOGY OF HEMOPTYSIS

When considering the etiology of hemoptysis, it is important to be familiar with the pulmonary circulation. Lung has dual blood supply from pulmonary and bronchial circulations. Pulmonary circulation is mainly for gas exchange and accounts for 99% of total blood supply to the lungs. It is a low-pressure (25 mm Hg systolic, 8 mm Hg diastolic, and 15 mm Hg mean) high-flow system that receives the entire cardiac output and causes bleeding in <10% of cases. The bronchial circulation is high-pressure (systemic), low-flow system, which tends to be the major source of hemoptysis because it is more likely to be the source of the collaterals and neovascularization that characteristically occurs in the setting of chronic infection or malignancy. It supplies bronchial mucosa by formation of anastomosis in the peribronchial space and gives rise to small penetrating arteries in mucosa. It causes bleeding in 90% cases. Nonbronchial circulation can also contribute to hemoptysis, especially in lung parenchymal diseases where pleural involvement is present. The neovascularization arises from internal mammary, thyrocervical, coronary, and carotid arteries. Etiology of hemoptysis is summarized in **Table 2**.

EVALUATION OF PATIENT WITH HEMOPTYSIS

History and physical examination are useful in localization of lesion in around 50% of cases (**Table 3**).

As the patient presents to the emergency, one should try to answer the following questions:

1. Rate of bleed and amount of bleeding
2. Underlying pulmonary reserve
3. Etiologic diagnosis
4. Site of bleed

The following questions can be asked regarding present episode:

1. Amount of blood coughed out
2. Nature of expectoration—purulent or mucoid
3. Is the episode recurrent?
4. Any other site of bleed—nose, rectum, and gums
5. Is it associated with breathlessness, rash or loss of weight, and fever?

Determine any risk factors:

1. Is the patient smoker? If yes then pack years, whether current or past
2. Is there a known bleeding disorder?
3. Is the patient taking any medication—antiplatelet, anticoagulant, and aspirin?
4. History of tuberculosis or exposure to the same?
5. Was there history of thoracic stenting, recent hospitalization, deep vein thrombosis or any other suspected pulmonary, and renal or cardiac disease?

TABLE 2: Etiology of hemoptysis.

Airway disease	*Infection*	*Pulmonary vascular disease*	*Others*
• Airway trauma • Bronchitis • Bronchiectasis • Bullous emphysema • Bronchovascular fistula • Bronchial adenoma • Bronchogenic carcinoma • Metastatic cancer (bronchus, trachea) • Foreign body in airway	• Tuberculosis (active or cavitary) • Invasive mycetoma • Bronchiectasis • Cystic fibrosis • Pneumonia (*Staphylococcus*, *Klebsiella*, and *Legionella*) • Lung abscess • Hydatid cyst	• Congenital heart defects • Congestive heart failure • Mitral stenosis • Tricuspid endocarditis • Pulmonary arteriovenous malformation • Pulmonary artery *pseudoaneurysm* • Pulmonary embolism • Pulmonary veno-occlusive disease • Pulmonary hypertension	• *Drugs and toxins* (*Argemone* alkaloid and cocaine use) • *Pulmonary renal syndrome* (Wegener's granulomatosis and Goodpasture syndrome) • Immunologic lung disease and SLE • *Genetic defects of collagens* (Ehlers–Danlos syndrome) • Bone marrow transplantation • *Disorders of coagulation:* ○ Anticoagulant and antiplatelet medications ○ DIC ○ Thrombocytopenia ○ Liver disease ○ Von Willebrand disease • *Iatrogenic*: ○ Bronchoscopy with endobronchial biopsy or TBLB or TBNA ○ Transthoracic needle aspiration ○ Pulmonary artery catheterization ○ Airway stent ○ *Idiopathic*: Idiopathic pulmonary hemosiderosis • *Trauma*: ○ Blunt trauma chest ○ Penetrating lung injury • *Catamenial hemoptysis*

(DIC: disseminated intravascular coagulation; SLE: systemic lupus erythematosus; TBLB: transbronchial lung biopsy; TBNA: transbronchial needle aspiration)

TABLE 3: Evaluation (history and physical examination) of patient with hemoptysis.	
History	
Smoking and asbestos exposure	Bronchogenic carcinoma
Risk factors for aspiration (alcohol, swallowing disorder, altered sensorium, or diminished conscious)	Lung abscess, pneumonia, and FB aspiration
Recent chest trauma or procedure	Traumatic or iatrogenic lung injury
Previously diagnosed pulmonary cardiac or systemic disease	Important clue
Symptoms	
Hoarseness of voice	Bronchogenic carcinoma
Purulent sputum	Pneumonia, lung abscess, bronchiectasis, and bronchitis
PND/orthopnea	MS/LVF
Dyspnea and pleuritic chest pain	• Pneumonia • Pulmonary embolism
Weight loss, night sweats, cough, and fever	• Tuberculosis • Bronchogenic carcinoma
Signs	
• Localized decreased breath sounds • Localized wheeze • Stridor	• Bronchogenic carcinoma • FB aspiration • Tracheal tumor
Bronchial breath sounds	Pneumonia
Pleural rub	Pneumonia and pulmonary embolism
Diastolic murmur	Mitral stenosis
Clubbing	Suppurative lung disease, bronchiectasis, and bronchogenic carcinoma
S3 gallop	LVF
• Oral aphthous ulcers, genital ulcers, and uveitis • Saddle nose, rhinitis, and septal perforation	• Behçet's disease in which AVMs are present • Wegener's granulomatosis

(AVM: arteriovenous malformations; FB: foreign body; LVF: left ventricular failure; MS: mitral stenosis; PND: paroxysmal nocturnal dyspnea)

Ask few questions related to family history:

1. Similar episode in family—in addition history of gastrointestinal bleed and epistaxis
2. History of pulmonary embolism in family

Note down finding on physical examination:

1. Is the patient dyspneic (using accessory muscles of respiration, tachypneic, or cyanotic)?
2. Is the patient clubbed (suggestive of bronchiectasis and lung cancer)?
3. Is there blood in the nose?
4. Are there telangiectasias in the lips, tongue, or oral cavity?
5. Are there skin rashes suggestive of vasculitis, systemic lupus erythematosus (SLE), infective endocarditis, or fat embolism?
6. Are there any adventitious sounds on auscultation (crepitations and bronchial breath sounds)?
7. Is there a P2 component or murmur of tricuspid component (TR) suggestive of pulmonary hypertension?
8. Is there a bruit suggestive of pulmonary arteriovenous malformation (AVM)?
9. Is there a heart murmur suggestive of mitral stenosis, mitral regurgitation, or septic emboli?
10. Is there calf muscle tenderness suggestive of deep vein thrombosis?
11. Saddle nose deformity with septal perforation and rhinitis suggestive of Wegener's granulomatosis.

MANAGEMENT OF PATIENT WITH HEMOPTYSIS

Initial Immediate Management

The initial approach to managing life-threatening hemoptysis involves resuscitation and protection of airway [airway, breathing, and circulation (ABC) approach]. The second step is directed at localizing the site and cause of bleeding and final step is the application of definitive and specific treatments to prevent recurrent bleeding. Hemoptysis can be mild or severe requiring intensive care unit (ICU) admission, so thorough history and complete physical examination to confirm that the patient truly has hemoptysis and not hematemesis or epistaxis. Massive hemoptysis remains a challenge for critical care expert. After a quick physical examination of the patient, resuscitation should be started without delay followed by laboratory investigations chest radiograph.

Airway Protection

Patency of the airway should be the first priority to prevent exsanguination. To achieve immediate control of the airway, patient should be intubated with large single-lumen endotracheal tube (ETT) for proper suctioning; it will also help in initial diagnostic and therapeutic bronchoscopy. Double-lumen ETT can be placed to isolate and ventilate the lung if bleeding from one side. If the bleeding can be localized from one side then with the help of bronchoscope, ETT can be placed in normal lung side to protect it from aspiration. Double-lumen ETT should be placed by experienced person with the help of pediatric bronchoscope to confirm the tube position (**Fig. 1**).

Breathing

The patient must lie in lateral decubitus position towards the bleeding side to prevent the normal lung from exsanguination, and supplement the oxygen to maintain oxygen saturation (SpO_2) > 95%.

Circulation

A large bore intravenous (IV) cannula or central venous line should be inserted and IV fluid started. Intra-arterial catheter is necessary for more accurate monitoring of blood pressure. If the general condition of the patient is rapidly deteriorating

FIG. 1: Double-lumen endobronchial tube—blue colored part is the bronchial tube and transparent one is the tracheal tube. ***(For color version, see plate 10)***

FIG. 2: Chest X-ray posteroanterior (PA) view suggestive of bilateral lower and middle zones, cystic shadows suggestive of bronchiectasis.

O-positive (in childbearing women O-negative) should be transfused while waiting for blood grouping—crossmatching. Arterial blood gas (ABG) should be sent immediately.

Specific Medical Therapy

On the basis of history and physical and laboratory examination, specific therapy should be started to correct the cause because invasive therapeutic interventions do not help to control bleeding secondary to coagulopathies, immunologically-mediated disorder like Goodpasture syndrome. Specific therapies such as antibiotics, correction of coagulopathies with platelet, fresh frozen plasma (FFP), cryoprecipitates, blood transfusion, steroids, immunosuppressive therapies, or plasmapheresis are mandatory to control the precipitating factor. Vitamin K supplements and tranexamic acid are also used to control bleeding. IV vasopressin has also been used but caution is advised in patients with coexistent coronary artery disease or hypertension. Vasoconstriction of the bronchial artery may also hamper effective bronchial artery embolization (BAE) by obscuring the site of bleeding, leading to difficulties in cannulation of the artery. Recombinant activate factor VIIa (rFVIIa) has been used in hemoptysis with community-acquired pneumonia. Danazol or gonadotropin-releasing hormone (GRH) has been used in catamenial hemoptysis. Systemic antifungal agents have been tried in the management of hemoptysis related to mycetoma, but results are not satisfactory. However, percutaneous or bronchoscopic direct instillation of these drugs in cavity is having promising results. This technique is useful in cases bleeding after failed BAE and in those who are not fit for surgery. Radiation therapy has been used in vascular tumor or mycetoma-related massive hemoptysis by necrosis of feeding vessel and vascular thrombosis due to perivascular edema.

Laboratory Investigations

The following investigations are essential in all patients: Complete hemogram, coagulation profile, renal function test, liver function test, ABG, D-dimer, urine analysis, and any other specialized tests needed according to the suspected underlying disease. Sputum and bronchoalveolar lavage should be sent for examination of Gram stain, aerobic culture, acid-fast bacilli (AFB), fungus culture, and cytological.

Chest X-ray

It helps in localizing the bleeding in 33–82% of cases and underlying cause in 35% like tuberculosis or tumors; however, found inconclusive in about 20–60% cases but rarely normal in massive hemoptysis. Chest X-ray is useful in identifying lung mass, cavitary lesion, or vasculitis lesion (**Fig. 2**).

Multidetector Computed Tomography

Multidetector computed tomography (MDCT) angiography is more useful in localizing the site, source of bleeding, and underlying lung pathology. With the help of MDCT, mapping of thoracic vasculature can be done and a detailed study of bronchial and nonbronchial circulation can be seen. Contrast computed tomography (CT) was found accurate in 84% of patients to find feeding vessels in massive hemoptysis. However, it is not wise to shift an unstable patient from ICU to CT unit, unless some therapeutic intervention is planned. In such patients, bed side bronchoscopy should be performed initially. Computed tomography is useful in determination of site of bleed and parenchymal lesions such as pulmonary tuberculosis, bronchogenic carcinoma, aspergilloma, and airway lesions like bronchiectasis (**Figs. 3** and **4**). Contrast-enhanced films are preferred as these would show structures such as AVMs and aneurysms.

Bronchoscopy

Localization of Site

Bronchoscopy is the first investigation of choice. Bronchoscopy done early during massive hemoptysis increases the likelihood of localization. However, during bouts of massive hemoptysis, fiberoptic bronchoscope usage becomes difficult given its narrow working channel.

FIG. 3: Bilateral upper lobar cavities with aspergilloma with bronchiectasis changes.

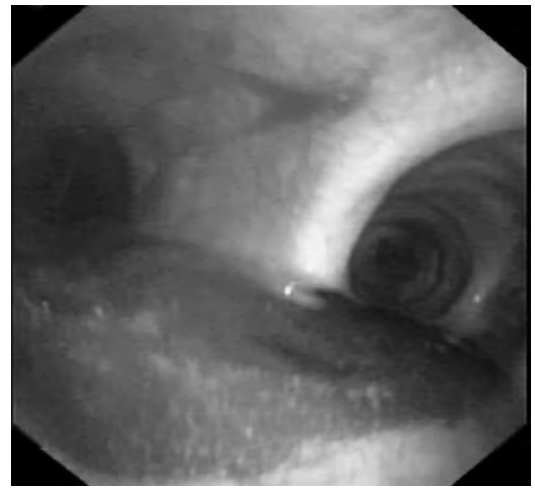

FIG. 5: Bronchoscopy showing bleeding from left main bronchus and spilling into right main bronchus. ***(For color version, see plate 10)***

FIG. 4: Bilateral consolidation—patient presented with moderate hemoptysis.

Spiral contrast-enhanced computed tomography (CECT) chest can be ordered before bronchoscopy. It gives clue for type and site of lesion and can also detect bronchial and nonbronchial arterial vascular lesions like AVMs. The ideal time for bronchoscopy is controversial, however general consensus is to perform it early in rapidly deteriorating patients, delayed bronchoscopy, that is within 24–48 hours of admission can be done in stable patients. Rigid bronchoscopy is ideally recommended in massive hemoptysis for better suctioning and maintenance of airway. Flexible fiberoptic bronchoscopy (FOB) is a very friendly tool for pulmonologist that can be done bedside without the use of general anesthesia. Overall accuracy in localizing the site of bleeding is 10–50%. FOB can reach up to the upper lobe and lesions located distal up to the sixth bronchial generation. The disadvantage of FOB is nonvisualization and clogging of channel by blood clots. Due to limitations with both flexible and rigid bronchoscopy, they can be combined to achieve maximum bleeding control and evaluation (**Fig. 5**). In case of blood clot seen in a segment, it is advisable not to remove it as it may restart massive hemoptysis.

Topical bronchoscopic therapy: Various therapeutic measures can be done with FOB to control bleeding—lavage with 4°C cold saline in the involved lung. Lavage with cold saline up to 1,000 mL in 50 mL aliquots at the bleeding site. Administration of topical hemostatic agents like diluted epinephrine (1:20,000) or thrombin fibrinogen. *Topical epinephrine* should be used with caution as it can precipitate tachyarrhythmias and accelerate hypertension. Newer agents like alcohol dehydrogenase (ADH) derivatives like ornipressin have been successfully used.

Bronchoscopy-guided Topical Hemostatic Tamponade

Oxidized regenerated cellulose (ORC) mesh, a sterile kitted fabric is use. It saturates in contact with blood and swells up to form a brownish gelatinous mass clot and can immediately stop bleeding with success rate of up to 98%. In life-threatening hemoptysis, endobronchial tamponade using balloon catheter (**Fig. 6**) (4 Fr 100 cm Fogarty balloon catheter) has a good success rate to prevent aspiration to the contralateral normal lung and preserve gas exchange; they can be inserted through working channel of FOB. A double-lumen balloon catheter with detachable valve at proximal end can be passed through working channel of bronchoscope and can leave the catheter in bronchus by removing detachable valve. They can be used as bridge therapy before embolization and surgery. Disadvantages are that they can cause ischemic mucosal injury and postobstructive pneumonia.

Endobronchial airway blockade (silicone spigot) can be placed with the help of flexible bronchoscope to control bleeding and stabilize the patient before embolization or surgery. Endobronchial biocompatible glue n-butyl cyanoacrylate which has prothrombin activity is commonly used in mild hemoptysis. It is injected into the bleeding airway through a catheter via flexible bronchoscope. It solidifies on contact with humidity.

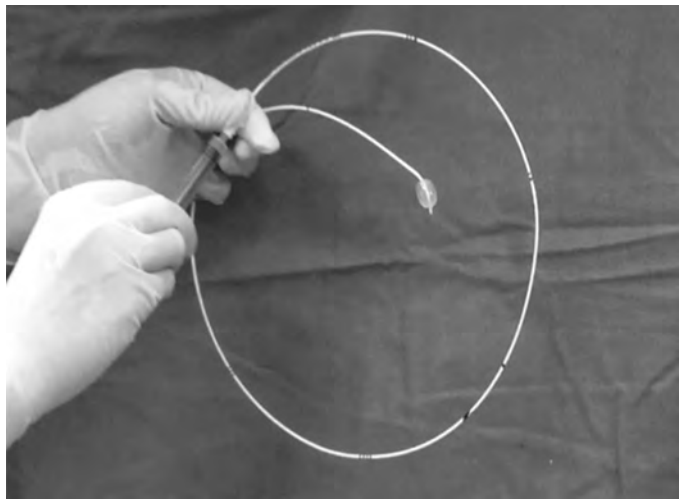

FIG. 6: Fogarty catheter with inflated balloon before insertion.

Bronchial Artery Embolization

This procedure was first reported by Remy and colleagues in 1973 and has been found very useful in massive hemoptysis. Once the bleeding bronchial artery is identified and cannulated, particles of polyvinyl alcohol foam, isobutyl-2-cyanoacrylate, Gianturco steel coils, or absorbable gelatin pledgets are infused into the artery. The immediate success rate is 64–100%, although the recurrent nonmassive bleeding has been reported in 16–46% of patients. 13% technical failure are reported and caused by nonbronchial artery collaterals from systemic arteries such as internal mammary, subclavian, intercostal, and phrenic arteries. Complications of BAE include vessel perforation, intimal tears, chest pain, pyrexia, hemoptysis, systemic embolization, and neurological complication. When anterior spinal artery is identified as originating from bronchial artery, embolization should be avoided to prevent infarction and paraparesis. With newer coaxial microcatheter, selective catheterization and embolization of bronchial artery can be achieved and occlusion of anterior spinal artery can be avoided. BAE is time-buying procedure so definitive diagnosis and definitive treatment should be given. In AVM, BAE is the definitive treatment. In case of normal bronchial artery angiography, pulmonary angiogram should be obtained to investigate pulmonary circulation.

Surgical Management

With the development of different endobronchial tamponade and BAE techniques and higher success rates, practice of thoracic surgery has decreased. Recently, however, surgical resection is indicated when BAE is unavailable or the bleeding is unlikely to be controlled by embolization. It remains the treatment of choice for the management of life-threatening hemoptysis due to a leaking aortic aneurysm, hydatid cyst, iatrogenic pulmonary rupture, chest injuries, bronchial adenoma, selected case of AVMs, or hemoptysis related to mycetoma resistant to other treatments. Surgery is considered the treatment of choice for the localized lesions. Surgical mortality ranges from 1 to 50% in different series depending upon surgical criteria. Surgery is contraindicated in patients with inadequate respiratory reserve or those with inoperable lung cancer due to direct thoracic spread, inability to lateralize the bleeding site, diffuse disease like vasculitis, multiple AVMs, and cystic fibrosis. In patients with poor respiratory reserve or extensive pleural adhesions, physiological lung exclusion strategy has been used. Here the bronchus and pulmonary artery to the involved lobe or segment are surgically ligated and the pulmonary veins left intact and without lung resection.

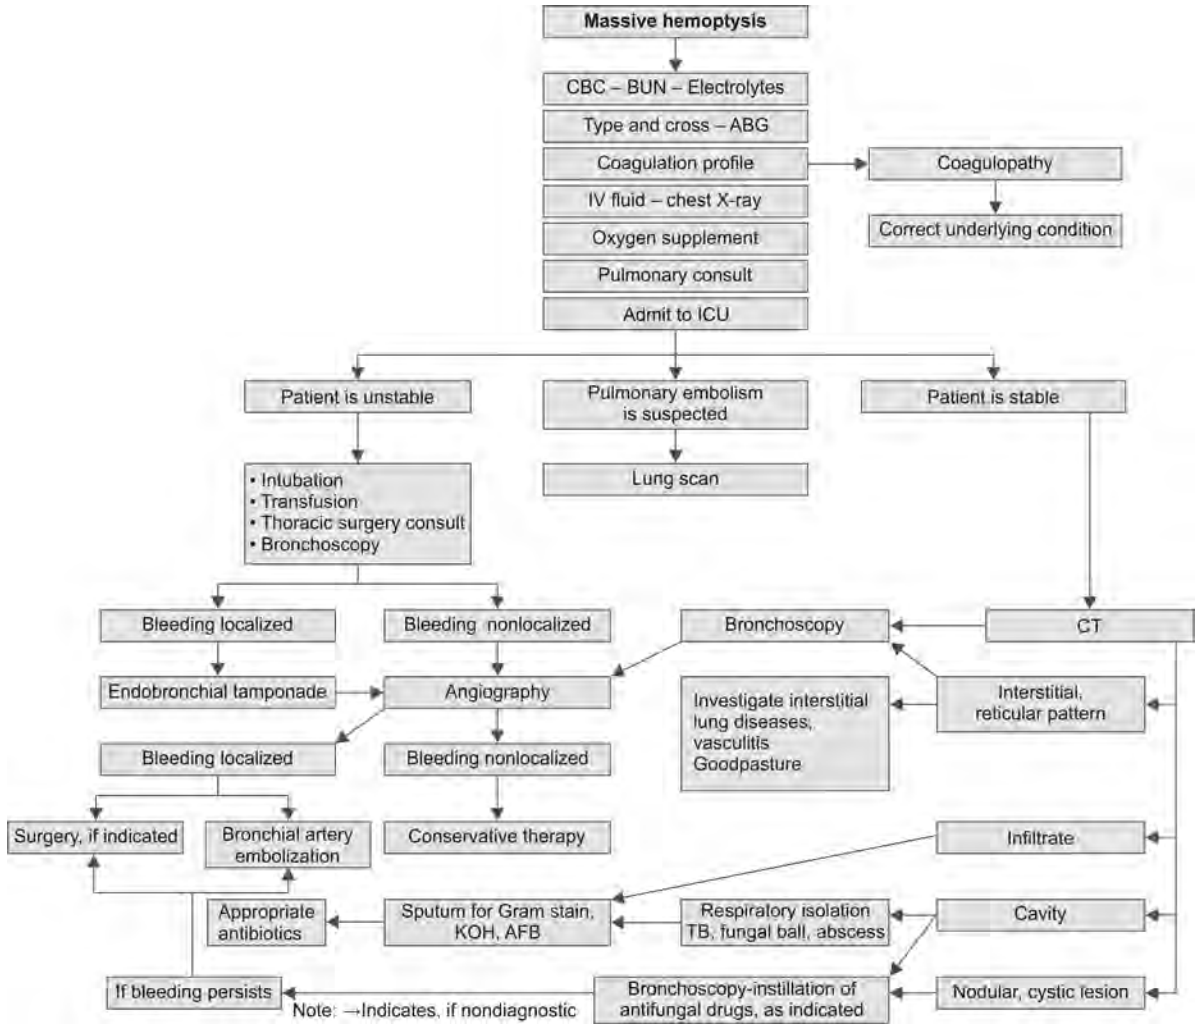
Radiation Therapy

It has been used in hemoptysis due to vascular tumor or mycetoma. It acts by inducing vascular necrosis of feeding vessel or vascular thrombosis due to perivascular edema.

Neodymium-doped yttrium aluminum garnet (Nd:YAG) or argon plasma coagulation (APC) are also used in tumors in which chemotherapy and radiotherapy have been exhausted with success rate up to 60%. APC is a noncontact electrocoagulation tool.

SUMMARY

Hemoptysis is a condition that warrants evaluation. Due to unpredictable course of massive hemoptysis, quick resuscitation, airway protection, and correction of coagulopathy is required. Massive hemoptysis is potentially life-threatening condition and patients should be admitted in ICU. History and clinical evaluation is helpful in assessing site of bleed. Laboratory investigations such as coagulation profile and hemoglobin should be sent on an urgent basis. Radiological investigations such as chest X-ray and MDCT thorax are indicated. Bronchoscopy, especially flexible one is the first-line investigation, tamponade measures may be unsuccessful in massive cases; however, it is useful in localizing site. BAE is successful in stopping bleeding in about 74–90% of cases. Surgery is the definitive management in some cases. Massive hemoptysis has a worser outcome when underlying lung is diseased, rate of bleed is high, and bleeding volume is massive. However, timely interventions, especially choosing proper candidates for interventions have significantly improved outcomes. An algorithm approach to hemoptysis is shown in **Flowchart 1**.



(ABG: arterial blood gas; AFB: acid-fast bacilli; BUN: blood urea nitrogen; CBC: complete blood count; ICU: intensive care unit; IV: intravenous; KOH: potassium hydroxide; TB: tuberculosis)

FLOWCHART 1: Algorithm approach to patient with massive hemoptysis.

CHAPTER

Clubbing and Cyanosis

Vivek Chauhan, Suman Thakur

CLUBBING

Examination of nails is an integral part of physical examination. While examining nails we specifically look for presence or absence of clubbing. Diagnosis is easy when the grade of clubbing is high, but clinical value lies in picking up earlier grades of clubbing. The diagnosis of digital clubbing should always be taken seriously and needs further workup. The diseases of lung, heart, gastrointestinal, and hepatobiliary system predominate the causes of clubbing. Rare presentations of clubbing include congenital clubbing and unilateral clubbing. In this chapter we will know more about the pathophysiology and approach towards a case of clubbing.

Causes

Causes of clubbing have been classified into various systems such as cardiac, pulmonary, gastrointestinal, and endocrinal. We have classified them into common and uncommon causes for the ease of understanding (**Table 1**).With a careful history taking, examination, and focused investigation most of the common causes can be ruled out.

TABLE 1: Common and uncommon causes of clubbing.

Clubbing	*Etiology*
Common causes	• Lung cancer • Cyanotic congenital heart diseases • Infective endocarditis • Pulmonary tuberculosis • Interstitial lung diseases • Lung abscess, empyema, and bronchiectasis • Metastatic cancers and lymphomas • Inflammatory bowel disease • Biliary cirrhosis
Uncommon causes	• Uncommon malignancies and metastatic cancers • Asbestosis • Pulmonary AV malformations • Celiac disease • Chronic active hepatitis • Thyroid acropachy • Cystic fibrosis • Atrial myxoma

(AV: arteriovenous)

Pathophysiology of Clubbing

- Historic attempts were directed at the growth hormone as the cause of clubbing, but it was not found elevated in patients of lung cancer having clubbing.
- In 1987, megakaryocytes and platelet clumps were reported to be associated with clubbing. In normal patients, megakaryocytes from bone marrow get trapped in the pulmonary capillaries and are later fragmented into platelets to be released into the circulation. However, in those patients with a right-to-left blood shunt or platelet excess such as cyanotic congenital heart diseases, lung cancers, subacute bacterial endocarditis, and inflammatory bowel disease, the megakaryocytes and platelet clumps get impacted in the nail capillaries.
- *Platelet-derived growth factor (PDGF)* released by the impacted platelets and megakaryocytes is shown to be responsible for the excessive growth of the tissue in the nail bed resulting in clubbing.
- *Vascular endothelial growth factor (VEGF)* is another factor released by the clumped platelets which along with the PDGF was found to be significantly elevated in the patients with clubbing.
- *Additional factors* that were studied but not found elevated in clubbing include basic fibroblast growth factor, transforming growth factor-beta 1 and carbonic anhydrase IX.
- *Hypoxia* is an important inducer of VEGF and PDGF from platelets and therefore many conditions that cause clubbing are also having hypoxemia. Octreotide is a powerful inhibitor of VEGF and hypertrophic osteoarthropathy (HOA), a form of clubbing, was shown to be responsive to treatment with octreotide. This provided strong indirect evidence of pathogenic role of VEGF in clubbing.
- *Prostaglandin E2 (PGE2)* was demonstrated to be elevated in lung cancer patients with debilitating symptoms of HOA

that reduced on taking cyclooxygenase-2 (COX-2) inhibitors and recurred on stopping them. PGE2 can upregulate VEGF messenger ribonucleic acid (mRNA) expression that is inhibited by dexamethasone. In addition, PGE2 stimulates osteoblasts and osteoclasts and is, therefore, capable of inducing periostosis and acro-osteolysis, in addition to local vasodilatation, all features of HOA.

- *PDGF, VEGF, and PGE2* are the three factors currently most strongly associated with the development of clubbing and are helped by the conditions favoring malignancy, hypoxia, or right-to-left shunting of blood.

Clinical Presentation

- Patients are mostly asymptomatic for clubbing unless it is associated with a syndrome (HOA) that involves periostosis of long bones and occasionally painful joint enlargement. Most cases of HOA are associated with lung malignancies which gave it the name of hypertrophic pulmonary osteoarthropathy (HPOA), but later it was found to be associated with nonpulmonary causes and the word "pulmonary" was thus dropped. Nonpulmonary HOA is also called pachydermoperiostosis.
- Thus, patients with clubbing can present with asymptomatic enlargement of nail folds or can be associated with painful debilitating periostosis of long bones and joints (HOA).

Various Signs in Clubbing

- *Schamroth's sign*: This sign is present in normal persons without clubbing. When the dorsal surfaces of terminal phalanges of corresponding right and left fingers are placed together, a diamond-shaped window is formed between the two fingers. This window gets obliterated in clubbing.
- *Fluctuation test*: Increased fluctuation and softening of the nail bed is the earliest sign of clubbing that can be elicited.
- *Profile sign or Lovibond's angle*: In normal people, the angle made by nail as it exists from the proximal nail fold is usually <180° and is called profile sign or Lovibond's angle.
- *Phalangeal depth ratio*: It is the ratio of digit's depth measured at the junction between skin and nail and at the distal interphalangeal joint. Normally, the depth at distal interphalangeal joint is more than the depth at nail bed. In clubbing fingers, connective tissue deposition expands the pulp in the terminal phalanx and the ratio becomes reversed. This ratio is also independent of age, sex, and ethnicity of population. A phalangeal depth ratio of over 1 measured by calipers or a photograph is indicative of clubbing.
- *Digital index*: It is the sum of phalangeal depth ratio of all 10 fingers. Digital index is more specific for clubbing and an index of 10.2 or higher is suggestive of clubbing.

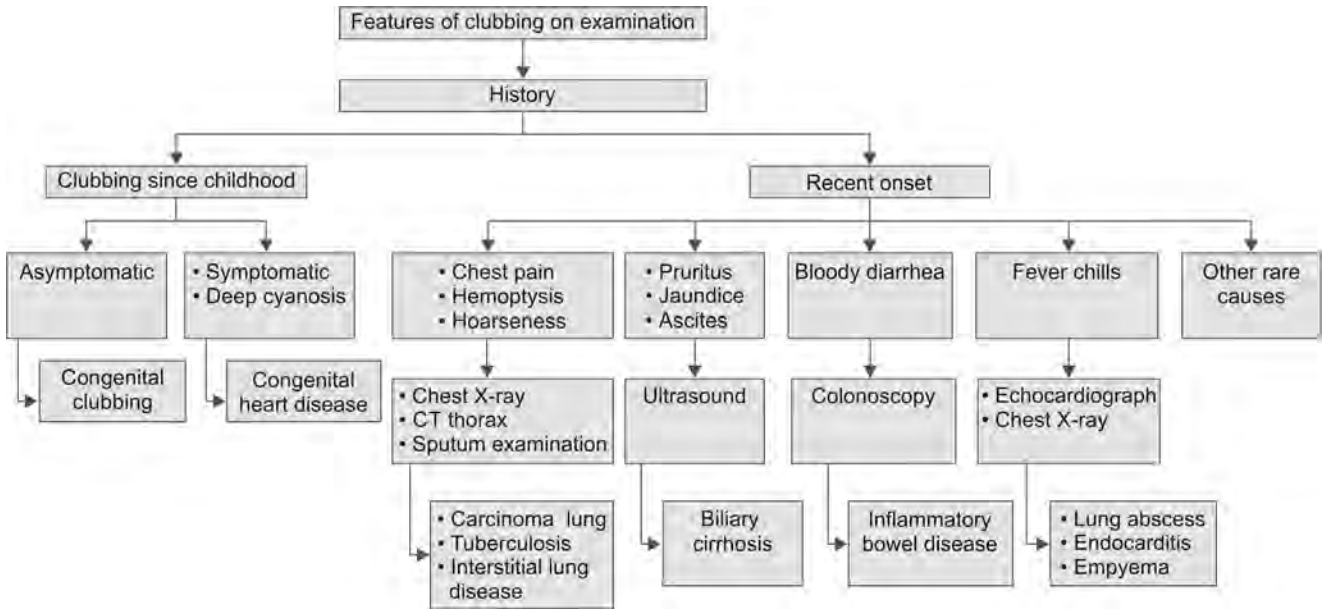
Features of Concern (Red Flags)

- *HOA* is a red flag sign in a patient with clubbing as it is more often than not associated with an underlying serious disorder like malignancy. So in patients with clubbing, we must always palpate the wrists and ends of long bones for tenderness arising from periostosis.
- Presence of hoarseness, hemoptysis, engorged neck veins, generalized lymphadenopathy, and pleural effusion are also red flag signs pointing towards possibility of an advanced malignancy in a patient of clubbing.
- Similarly, presence of diffuse cyanosis in a previously acyanotic congenital heart disease patient points towards Eisenmenger's syndrome that has poor prognosis for the patient.

Evaluation (History and Physical Examination)

Evaluation (**Flowchart 1**) starts with careful history taking can lead us to the etiology for clubbing.

- *Congenital clubbing*: Long-standing history since childhood points towards this etiology. Patients are



FLOWCHART 1: Approach towards a patient of clubbing.

mostly asymptomatic and this condition may be familial and present in other members of the family too. Further investigation may not be needed for congenital clubbing.

- *Congenital cyanotic heart diseases*: History of cyanotic spells, differential cyanosis, repeated childhood pneumonias, palpitations, and dyspnea points toward a possibility of congenital heart diseases with right-to-left shunts. These patients will need cardiology consultation for definitive diagnosis.
- *Lung carcinoma*: Chest pain, sputum production, hemoptysis, dyspnea, hoarseness, dysphagia, swollen, and engorged neck and chest veins in a chronic smoker point towards a lung carcinoma. These patients will need a pulmonary workup to rule out lung carcinoma.
- *Biliary cirrhosis*: Prolonged icterus, pruritus, and abdominal distention in a middle-aged female with clubbing points towards biliary cirrhosis.
- *Inflammatory bowel disease*: Chronic diarrhea with clubbing and blood in stools points towards inflammatory bowel disease.
- *Tuberculosis*: History of past or recent tuberculosis may be present in many patients with cough, dyspnea, and clubbing.
- *Pulmonary infections*: Production of excess sputum and localized chest pain point towards bronchiectasis or lung abscess and empyema, respectively.

Physical examination and signs pointing towards various etiologies of clubbing:

- Engorged neck and chest veins are seen in lung cancer with mediastinal syndrome due to secondaries in lymph nodes or local spread.
- Jaundice, itch marks, and ascites are seen in biliary cirrhosis.
- In a dyspneic patient, bilateral end inspiratory fine crepts, more so in the basal regions, are found in interstitial fibrosis of lungs.
- Unilateral loss of lung volume with crowding of ribs in previously treated tuberculosis is suggestive of post-tubercular lung fibrosis.
- Differential cyanosis, diffuse cyanosis, heart murmurs, parasternal heave, and precordial thrill are found in various congenital heart diseases.
- Fever with chills and rigors, heart murmurs, splenomegaly, Roth spots, Janeway lesions, etc., lead towards infective endocarditis.
- Unilateral absence of breath sounds and local tenderness over the region, mostly in the basal portion of the lungs points towards empyema.
- Various authors and books have divided clubbing into grades. The earliest is increased fluctuation *(Grade 1)* followed by increase in the Lovibond's angle > 180° *(Grade 2)* and later increased phalangeal depth ratio *(Grade 3)*. Finally, the clubbing becomes obvious due to its clubbed appearance *(Grade 4)* (**Fig. 1**).
- The clinical importance of various grades of clubbing in clinical setting is uncertain. Clubbing should be picked up early when the associated diseases are still treatable. To be confident of early clubbing, fluctuation sign should be practiced in all patients routinely.
- Imaging of individual fingers from a side angle using digital cameras is helpful in measurement of phalangeal depth ratio, digital index, and Lovibond's angle.

FIG. 1: Grade 4 clubbing of all nails of the hands. ***(For color version, see plate 10)***

- Painful HOA must be looked for in all patients of clubbing. Its presence requires further investigation to rule out lung cancers and other malignancies.

Investigation

- Investigations should be directed towards the probable etiology of the clubbing based upon history and physical examination. A chest X-ray must be done in all patients of clubbing to rule out pulmonary etiologies. Specific tests are directed towards specific etiologies, e.g., CT chest is done for diagnosing lung cancer, idiopathic pulmonary fibrosis, lung abscess, empyema, post-tubercular fibrosis, bronchiectasis, lymphoma, etc.
- Colonoscopy gives diagnosis of inflammatory bowel disease.
- Ultrasound, ascitic fluid examination, and serology are needed to diagnose biliary cirrhosis.
- Electrocardiography, echocardiography, and cardiac catheterization studies for congenital heart disease, pulmonary arteriovenous (AV) malformations, and atrial myxoma.
- Echocardiography and paired blood cultures are done for subacute infective endocarditis.
- Thyroid functions must be done to rule out thyroid acropachy. It may also be associated with thyroid dermopathy and ophthalmopathy.
- Bone scan may be needed to confirm the presence and extent of HOA.

Treatment

- In cases of clubbing, the treatment is directed towards specific etiologies. Cancers may be treatable or untreatable depending upon their stage and grade. Clubbing regresses with treatment over months.
- Many conditions associated with clubbing are treatable, e.g., lung abscess, empyema, deep abscesses, some congenital heart diseases, inflammatory bowel diseases, infective endocarditis, and atrial myxoma.
- The painful debilitating HOA responds to COX-2 inhibitors and corticosteroids.
- Congenital clubbing does not require any treatment and is mostly asymptomatic.

CYANOSIS

Cyanosis word has been derived from *cyan,* a blue green color. Cyanosis of the skin or mucus membranes is an important finding on examination needing careful workup to find its genesis in each patient. The etiology behind cyanosis may be anything from innocuous (polycythemia of high altitude) to grave (severe interstitial lung disease). Physicians have started relying more on pulse oximeter values and oxygen saturation (SpO_2), forgetting that there are many cases where oximeters are unreliable, e.g., methemoglobinemia, sulfhemoglobinemia, and carboxyhemoglobin. Knowledge of cyanosis, its origin, testing, and clinical implications are thus essential for better patient care.

Causes

Skin and mucosae become cyanotic when concentration of any the following pigments is increased in the blood. Various causes of cyanosis in different type of pigments are given in **Table 2**.

- Deoxyhemoglobin
- Methemoglobin (MetHb)
- Sulfhemoglobin (SulfHb)
- Methemalbumin
- Metals (silver, gold, and hemosiderin)
- Miscellaneous causes (chlorpromazine and amiodarone)

TABLE 2: Various causes of cyanosis in different types of pigments.

Type of pigment	*Causes*
Deoxyhemoglobinemia	
Decreased arterial oxygenation	Cardiopulmonary diseases, high altitude, hypoventilation syndromes, neuromuscular and skeletal defects, vascular shunts, etc.
Increased tissue extraction	Sluggish blood flow, heart failure, local ischemia, exercise, shock, atherosclerosis, deep venous thrombosis, Raynaud's phenomenon, hypothermia, etc.
Abnormal hemoglobin	Hemoglobin M (HbM)
Methemoglobinemia	
Genetic	Autosomal recessive
Dietary	Fava beans, nitrate-containing foods, and *Ginkgo biloba*
Toxic/drug induced	Dapsone, benzocaine, nitroglycerine, nitroprusside, and mothballs
Idiopathic	
Sulfhemoglobinemia	
Drugs	Sulfonamides, sulfasalazine, sumatriptan overdose, and metoclopramide
Industrial exposures	Hydrogen sulfide (H_2S) gas, phenazopyridine, and volatile sulfur-containing compounds
Methemoglobin	Massive hemolysis
Metals	Silver, gold, and hemosiderin
Miscellaneous causes	Chlorpromazine and amiodarone

Pathophysiology of Cyanosis

The normal skin color results from a combination of oxyhemoglobin, deoxyhemoglobin, melanin, carotene, and from the optical effect of scattering (Tyndall effect that gives blue color to the sky). White light that falls upon our skin has a spectrum ranging from blue at one end and red at the other. Blue skin coloration would result if the quantity of blue wavelengths reflected is disproportionately increased or if the quantity of red wavelengths reflected is disproportionately decreased. The same venous blood that gives blue color to our skin does not appear blue when taken out in a test tube. Deoxyhemoglobin is less red than oxyhemoglobin and absorbs more red spectrum therefore appearing bluish. By subtraction of red wavelengths, the blue spectrum is allowed to predominate in the reflected light (i.e., something that is less red is more blue).

Deoxygenated hemoglobin (Hb) is apparent as cyanosis on clinical examination of skin and mucosa when its amount is >4–6 g/dL in the capillaries. In presence of a normal cardiac output, Hb, and tissue extraction of oxygen, an arterial SpO_2 of <80% would be required to cause cyanosis. Cyanosis cannot be produced in severe anemia if Hb concentration is below the threshold of cyanosis, i.e., 4–6 g/dL. Also anemic individuals need more profound oxygen desaturation to produce cyanosis.

Methemoglobin is normally formed in body around 3% per day when ferrous form of iron is converted to ferric form in the Hb. MetHb is not capable of binding to oxygen and thus leads to hypoxia when in excess. Cytochrome b5 reductase reduces MetHb to Hb using nicotinamide adenine dinucleotide as a cofactor and keeps its levels below 1%.

Sulfhemoglobin excess is relatively rare in the blood and the pigment is a greenish derivative of Hb, with an absorption peak at 620 nm, but cannot be converted back to normal, functional Hb unlike deoxyhemoglobin and MetHb. In vitro, SulfHb forms when hydrogen sulfide (H_2S) is added to Hb, hence the name; in vivo, naturally occurring SulfHb is postulated to be derived from H_2S produced by intestinal bacteria, but the mode of formation has not yet clear. Cyanosis is reported to be detectable at SulfHb levels as low as 0.5 g/dL.

Gold- or *silver*-containing substances when ingested can produce bluish skin coloration. It is most prominent in sun-exposed portions of the body. The bluish skin color associated with *hemosiderin* deposition is more apparent in parts of the body with less melanotic pigment and a more bronze color is seen in the presence of melanin.

The oxidation products of *chlorpromazine*, when deposited in the skin and other organs, can result in a blue to purple color. A new antiarrhythmic agent, *amiodarone*, can cause lipofuscin deposition in the skin. In sun-exposed areas, a blue skin color is seen in a small percentage of patients on long-term therapy.

Clinical Presentation

Many authors divide cyanosis into central and peripheral cyanosis.

Central cyanosis: It is mostly seen with systemic disorders. Some common diseases presenting with central cyanosis include chronic obstructive lung disease, pneumonia, interstitial lung disease, embolism and ventilation perfusion mismatch, acute respiratory distress syndromes, high altitude, congestive heart failure, anatomic shunts, right-to-left shunt in congenital heart disease, AV malformation, and intrapulmonary shunts.

Peripheral cyanosis: All causes of central cyanosis have peripheral cyanosis too. Isolated peripheral cyanosis however, is seen in conditions with sluggish blood flow with increased oxygen extraction, e.g., Raynaud's phenomenon, congestive heart failure, hypovolemic shock, and hypothermia.

Clinical signs of deoxygenation vary depending upon the etiology. A resident of high altitude can have deep cyanosis, polycythemia, and still be asymptomatic. A patient of anemia on the other hand may be markedly desaturated with only mild or no cyanosis. Thus, knowledge of Hb levels of the patient helps us understand the correlation with the severity of cyanosis and oxygen desaturation.

Cyanotic individuals are expected to have SpO_2 levels of <80% and thus have worse outcomes if associated with some underlying pathological condition. Prolonged desaturation can lead to hypoxic encephalopathy, which may become irreversible.

Cyanosis occurs at MetHb levels of level of 1.5 g/dL, 15% of total Hb. Anxiety, headache, and dizziness can occur at MetHb levels >20%. Levels between 30% and 50% can produce fatigue, confusion, and tachypnea. At levels >50%, arrhythmias, acidosis, seizures, and coma can occur.

Sulfhemoglobin produces cyanosis at 0.5 g/dL levels, but the patient may have normal SpO_2 and be asymptomatic.

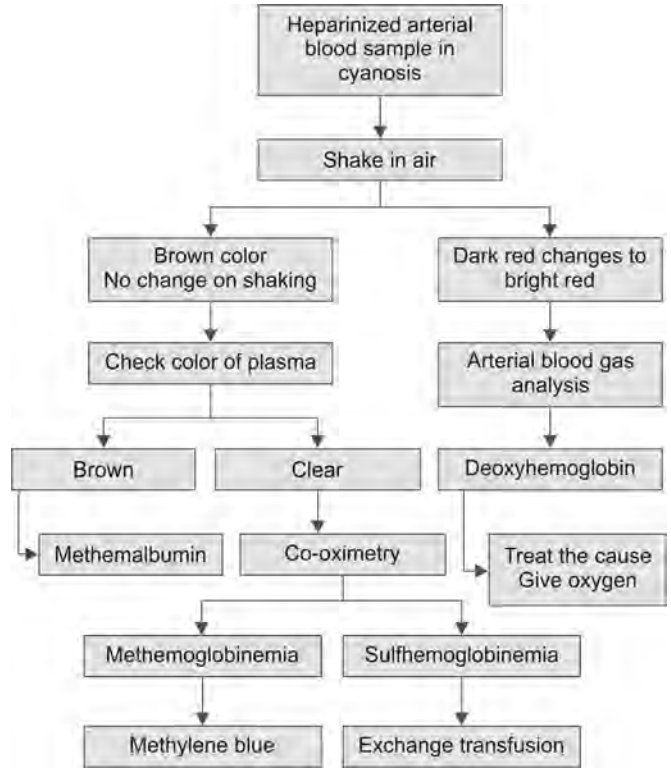
Features of Concern (Red Flags)

In the presence of cyanosis, the following additional findings may be the red flags:

- Low blood pressure
- Altered sensorium
- Tachypnea and dyspnea

Evaluation (History and Physical Examination)

- Approach to patient with cyanosis starts with history and physical examination (**Flowchart 2**).
- History should be focused towards the presenting complaint and contributing past history of illness.
- A high proportion of cases with cyanosis have a long-standing cardiopulmonary illness. The acute events such as viral or bacterial infection, arrhythmia, pneumothorax, pleural effusion, myocardial infarction, pulmonary embolism, congestive heart failure, and myocarditis can worsen a stable long-standing cardiopulmonary illness and produce cyanosis.
- In absence of a long-standing illness and obvious cardiopulmonary involvement, we must take history of recent drug intake or toxin exposure (both intentional and accidental) and rule out cyanosis due to rare pigments such as MetHb, SulfHb, and nonheme pigments.
- Since the sensitivity to detect cyanosis at the threshold levels of deoxyhemoglobin is not very high, it becomes important to know the technique and practice it routinely. Lighting is important as cyanosis is best appreciated when lighting matches the spectral composition of that of the sunlight. So, the artificial sources of light should be similar to sunlight. Tungsten filament bulbs and certain fluorescent bulbs are satisfactory for detecting cyanosis. Too intense light is also inappropriate to detect cyanosis. Some people recommend <20 footcandles of illumination for this purpose.
- *Sites to look for cyanosis:* Parts of skin and mucosa that lack melanin pigment are appropriate to look for cyanosis. Lips, tongue, hands, and ears are the most commonly observed sites (**Fig. 2**). Trunk, nail bed, conjunctiva, and circumoral areas also have been described to look for cyanosis. The tongue is the most sensitive, but lips are more specific sites for cyanosis.



FLOWCHART 2: Approach towards a patient of cyanosis.

FIG. 2: Peripheral cyanosis in one of the hands. ***(For color version, see plate 10)***

- Many cases of cyanosis also have associated clubbing. These conditions mostly have some form of right-to-left shunt either within the heart, lungs, or in the periphery.

Cyanosis as a tool for detecting arterial hypoxemia is neither sensitive nor specific. Definite cyanosis was not apparent to 25% of observers even at arterial SpO_2 of 71–75% [partial pressure of oxygen (PaO_2) 35–40 mm Hg]. In contrast, 6% and 17% of the observers believed definite cyanosis to be present when arterial SpO_2 were 96–100% and 91–95%, respectively. The sensitivity of this sign is decreased when examining deeply pigmented individuals. In blacks, 3–6% more arterial oxygen desaturation may be required for detection of cyanosis. Still, early detection of cyanosis may point toward an underlying serious disorders such as congenital heart disease like tetralogy of Fallot in children, methemoglobinemia, and sulfhemoglobinemia in absence of profound symptoms of any disease.

Investigations

Whenever we detect cyanosis, we must confirm the arterial saturation by pulse oximetry followed by arterial blood gas (ABG) analysis. Nail polish can decrease the oximetry values by 6% therefore the pulse oximeter should be applied sideways to the fingers.

In cases where there is a mismatch between the oximetry values and ABG, we go for co-oximetry. Pulse oximeter measures light at two wavelengths, oxyhemoglobin and deoxyhemoglobin. Co-oximetry measures the absorption of light at four different wavelengths corresponding to oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and MetHb.

Once the diagnosis of the type of cyanotic agent is clear, we then focus our attention towards the etiological agent or disease. For deoxyhemoglobin based upon our probable diagnosis, we get further investigations done that may include chest X-ray, electrocardiogram, echocardiogram, computed tomography of chest, pulmonary and coronary angiogram, ventilation perfusion scan, sleep studies, etc. Diagnosis of the disease responsible for oxygen desaturation is often easily obtained with the above investigations. For rarer forms of heme and nonheme pigments responsible for cyanosis, we focus our attention towards the drug, toxin, or accidental exposures. Deficiency of nicotinamide adenine dinucleotide hydride (NADH) MetHb reductase system is inherited in autosomal recessive pattern.

Abnormal Hb like HbM that has decreased affinity for oxygen can be diagnosed with the help of electrophoresis.

A practical approach to the etiology of cyanosis has been described by snider et al.

- Obtain a heparinized arterial blood specimen.
- If the sample is dark red and becomes bright red on shaking in air, one should perform blood gas analysis on another specimen to confirm arterial hypoxemia.
- If the specimen obtained is brown and does not change color on shaking in air, the plasma should be allowed to separate.
    - If the plasma is brown, methemalbumin is likely to be present.
    - If the plasma is clear, one should suspect the presence of MetHb or SulfHb.
- A bright red arterial specimen obtained in a patient with generalized blue skin color should lead one to suspect deposition of nonheme pigment in the skin.

Treatment

Deoxyhemoglobin

Treat the underlying cause and give supplemental oxygen to improve the Hb oxygenation.

Methemoglobin

First step in treatment of MetHb is to remove the culprit medication. This often is sufficient in mild cases. Methylene blue is the treatment of choice in severe cases of methemoglobinemia. It accelerates the reduction of MetHb via the nicotinamide adenine dinucleotide phosphate (NADPH) MetHb reductase pathway and it should be given intravenous (IV) at a dose of 1–2 mg/kg for 5 minutes. The maximum effect of methylene blue occurs quickly, at 30 minutes. Additional doses of methylene blue may be given after 1 hour if response is inadequate. Co-oximetry is not helpful in monitoring these patients because it does not have the ability to distinguish between MetHb and methylene blue. High doses (7 mg/kg) can lead to hemolysis and a paradoxical rise in MetHb levels of up to 10%. Less responsive forms of include aniline and dapsone induced MetHb. MetHb can cause hemolysis in glucose-6-phosphate dehydrogenase (G6PD) deficiency too.

Sulfhemoglobin

These patients can show cyanosis at 0.5 g/dL levels of SulfHb. Cyanosis is not responsive to oxygen administration. Patients may be asymptomatic at much higher levels of SulfHb and PaO_2 is usually normal. SulfHb is irreversible and stays till the life span of affected red blood cells, i.e., 120 days. Oxygen should be given to all patients and exchange transfusion has been suggested and tried as a treatment modality in cases that are symptomatic.

SUMMARY

To summarize, testing for presence of clubbing is an integral part of routine examination of all patients. To pick up subtle clubbing early in the disease process may be of huge clinical value as it may lead to curative treatment of cancers. Patients are usually unaware of the presence of changes in their nails and the clinical utility of various grades of clubbing beyond presence or absence of clubbing is uncertain. However, association of clubbing with HOA portends ominous value to clubbing diagnosis as it is mostly associated with malignancies. VEGF, PDGF, and PGE2 in the setting of hypoxemia and malignancies are responsible for most proliferative changes in the clubbed nails. Careful history taking, directed physical examination, and focused investigations often lead the clinicians to the etiological diagnosis of clubbing. Changes of clubbing reverse upon successful treatment of the underlying etiology, but in case of malignancies and progressive disorders, it persists. Knowledge of various tests to pick up early clubbing is important for every clinician and use of digital photographs of fingers is a handy tool to diagnose and measure clubbing in fingers.

Cyanosis is visible on specific body parts when various types of heme and nonheme pigments accumulate in our body beyond normal limits. Some of these pigments such as deoxyhemoglobin and MetHb are normally produced in our body, but they are regularly replaced by oxygenated Hb. Many physiological and pathological states are associated with cyanosis. The clinical examination is now aided by oximetry, ABG analysis, and co-oximetry in finding the cause of cyanosis. Careful history and focused examination gives us the diagnosis in most cases. Treatment of cyanosis revolves around the inciting agent or disease. Oxygen administration helps in most cases, but IV methylene blue injection in MetHb and exchange transfusion in SulfHb may be needed to remove the abnormal pigments.

CHAPTER

Acute Respiratory Failure

Chitra Mehta

INTRODUCTION

Acute respiratory failure (ARF) is a commonly encountered condition in intensive care unit (ICU) and emergency department (ED). It may be the primary disease, or may be a complication of other conditions like cardiac failure or acute renal insufficiency.

DEFINITION

Acute respiratory failure occurs when the respiratory system fails to meet the oxidative, ventilatory and metabolic demands of the body. There is a failure of gas exchange mechanisms in maintaining adequate oxygen delivery to the tissues, and/or adequate removal of carbon dioxide (CO_2) from the body. Acure respiratory failure is one of the common presentation in emergency department and major cause of morbidity and mortality in ICU setting, its incidence increases with the presence of comorbidities and in the geriatric age group. Hospital mortality has been found to be 30–40% in patients requiring ventilatory support. Mortality also varies according to the etiology. For acute respiratory distress syndrome (ARDS) it is about 40–45%, and for acute exacerbation of chronic obstructive pulmonary disease (COPD) it is around 30%.

CLASSIFICATION

Acute respiratory failure has been divided into four types primarily:

1. *Type I (hypoxemic) respiratory failure*: It is characterized by the arterial oxygen tension [partial pressure of oxygen (PaO_2)] below 60 mm Hg (8.00 kPa) with normal or low arterial CO_2 tension [partial pressure of carbon dioxide ($PaCO_2$)]. This is the most common form of respiratory failure.
2. *Type II (hypercapnic) respiratory failure*: It is characterized by $PaCO_2$ of >45 mm Hg, often accompanied by hypoxemia that gets easily corrected with supplemental oxygen.
3. *Type III (perioperative) respiratory failure*: It specifically occurs in postoperative patients, most commonly secondary to atelectasis, related to low functional residual capacity in the setting of altered chest wall and/or abdominal wall compliance. Both type I and II respiratory failures can occur during this period.
4. *Type IV (shock related) respiratory failure*: This refers to hypoperfusion-induced respiratory failure. It commonly occurs in a hemodynamically unstable patient during the process of resuscitation.

Acute versus Chronic Respiratory Failure

It is also important to differentiate between acute, chronic, and acute on chronic respiratory failures. This is particularly important in type II respiratory failure. Acute hypercapnic respiratory failure develops rapidly over minutes to days with inadequate compensation. This results in pH less than 7.3. On the other hand, chronic hypercapnic respiratory failure develops gradually over days to months, allowing adequate time for renal compensation to take place. So there is a near-normal pH with raised serum bicarbonate levels. Elevated $PaCO_2$ with partial compensation, resulting in pH less than 7.35, characterizes acute-on-chronic ventilatory failure. Other signs such as polycythemia and cor pulmonale may also help in identifying them. Acute and chronic differentiation may be relevant to type I respiratory failure as well. This is important in patients with interstitial lung diseases, and in patients residing at high altitude areas.

Some people consider definition of hypoxemic respiratory failure too simplistic, as it gives no idea about the tissue oxygenation, and overlooks the major determinants of oxygen delivery—cardiac output and hemoglobin level.

PATHOPHYSIOLOGY

Efficacy of the lung is evaluated by its oxygenation and ventilation capacity. PaO_2 reflects oxygenation and $PaCO_2$ reflects ventilation. Alveolar-arterial oxygen gradient ($AaDO_2$)

aids in evaluating oxygenation. It also helps in understanding the pathophysiological mechanisms. $AaDO_2$ can be determined with the help of alveolar gas equation:

$$PaO_2 = FiO_2 \times (P_{atm} - pH_2O) - PaCO_2/R$$

Where, PaO_2 = Alveolar PO_2
FiO_2 = Fraction of inspired oxygen
P_{atm} = Barometric pressure, 760 mm Hg at sea level
pH_2O = Pressure of water vapor at standard temperature, normally 23 mm Hg
$PaCO_2$ = Arterial PCO_2
R = Respiratory quotient (R = 0.8)

The normal value of $AaDO_2$ increases with age and FiO_2. $PaCO_2$ is a function of CO_2 production and alveolar ventilation, as can be seen in following relationship:

$$PaCO_2 = VCO_2 \times k/V_A$$

Where, $PaCO_2$ = partial pressure of CO_2 in arterial blood
VCO_2 = CO_2 production
V_A = Alveolar ventilation
K = constant (0.863)

And

$$V_A = V_T - V_D$$

Where, V_T = Tidal volume and V_D = Dead space volume

So $PaCO_2$ will rise if there is an increased CO_2 production, fall in tidal volume, or an increase in dead space volume.

Respiratory failure may occur as a result of malfunction of any of respiratory components such as airways, parenchyma, chest wall, respiratory muscles (intercostal + diaphragm), and central and peripheral nervous systems.

Hypoxemic Respiratory Failure Type 1

Pathophysiological mechanisms responsible for type I failure are:

- Low FiO_2
- Ventilation/perfusion mismatch (V/Q)
- Shunt
- Diffusion abnormalities
- Hypoventilation
- Venous admixture (low mixed venous oxygen)

Low FiO_2 as a cause of hypoxemia is of importance at high altitude where barometric pressure is low. In clinical practice, one can suspect this, if there is sudden desaturation of a patient receiving supplemental oxygen. Interruption or disconnection of oxygen supply should be ruled out in this condition. Diffusion abnormalities become clinically relevant only if there is a significant decrease in blood transit time in the pulmonary capillary bed, and if there is coexistent V/Q abnormalities.

For all practical purposes, V/Q mismatch and shunt mechanisms are the dominant causes of hypoxemia. Both result in an elevated $AaDO_2$.

Ventilation/Perfusion Mismatch

It is the most common mechanism resulting in hypoxemia. Ideal gas exchange can only exist if V/Q ratio is 1. Normal V/Q ratio is 0.8. A relative decrease in ventilation reduces the ratio, which impairs oxygenation and ventilation. If this ratio becomes near zero, it represents a shunt mechanism. A relative decrease in perfusion results in ratio more than 1, representing increased dead space. Clinically, this becomes important only if the abnormality is quite severe. Response to supplemental oxygen can help in differentiating between V/Q mismatch and shunt.

Shunt

It is the right-to-left shunting of deoxygenated blood, which is responsible for causing hypoxemia. The deoxygenated blood bypasses the gas exchange area and mixes with the oxygenated blood coming from other ventilated alveoli resulting in fall in oxygen content. This may occur in presence of anatomical right-to-left shunts (like atrial septal defect) or may occur in presence of physiological shunting when the V/Q ratio approaches (like collapse, and ARDS). Under normal circumstances also the anatomical shunts are present. This is secondary to admixture of blood from pulmonary circulation with bronchial circulation. It amounts to about 2–3% of shunt. Both anatomical and physiological shunts show poor response to supplemental oxygen.

In addition to above mechanisms, it has been observed that tissue hypoperfusion exacerbates the degree of hypoxia caused by other diseases. This is due to excess oxygen extraction at tissue level, resulting in low mixed venous oxygen saturation. Hypoxia can also occur if there is an increase in abnormal hemoglobin like carboxyhemoglobin or methemoglobin. In this situation, PaO_2 may remain normal but oxygen saturation falls resulting in low arterial oxygen content. Various causes of type I respiratory failure are elicited in **Box 1**.

Hypercapnic Respiratory Failure Type II

This type results when there is an imbalance between ventilatory demand and ventilatory capacity. Excessive increase in load or a drastic fall in capacity may precipitate it. It may also occur when there is coexistent increased load and reduced capacity, though each may be of moderate severity. Pure hypoventilation as a sole cause can be identified by presence of normal $AaDO_2$. Hypercapnia can also occur as a part of hypoxic failure if the gas exchange derangements are quite severe. Causes of hypercapnic respiratory failure are shown in **Box 2**.

BOX 1: Causes of type I respiratory failure.

- *Low FiO_2*: High altitude
- *Airways*: COPD, asthma, postintubation laryngeal edema, mucus plug, bronchiectasis, and vocal cord paralysis
- *Lung parenchyma*: Pulmonary edema, ARDS, pulmonary hemorrhage, lung contusion, pneumonia, alveolar proteinosis, hypersensitivity pneumonitis, transfusion-related lung injury, lung resection, aspiration, and radiation injury
- *Interstitial*: Pulmonary fibrosis and viral or atypical pneumonia
- *Pulmonary vasculature*: Pulmonary veno-occlusive disease, pulmonary embolism, and intracardiac or intrapulmonary shunt
- *Pleural*: Pneumothorax and pleural effusion
- *Chest wall*: Kyphoscoliosis, thoracoplasty, massive obesity, chest wall trauma—flail chest, burns

(ARDS: acute respiratory distress syndrome; COPD: chronic obstructive pulmonary disease; FiO_2: fraction of inspired oxygen)

BOX 2: Causes of type II respiratory failure.

- *Respiratory drive* (reduced): Ondine's curse, drug overdose, obesity hypoventilation syndrome, traumatic brain injuries, carotid body resection, and metabolic alkalosis
- *Neural transmission* (reduced)
- *Spinal cord*: Cervical spine injury and tumor
- *Anterior horn cells*: Poliomyelitis and amyotrophic lateral sclerosis
- *Peripheral nerves*: Phrenic nerve injury, Guillain–Barré syndrome, critical illness polyneuropathy, Lyme disease, beriberi, and diphtheria
- *Neuromuscular junction*: Neuromuscular blocking agents, tick paralysis, organophosphorus poisoning, botulism, tetanus, myasthenia gravis, and Lambert–Eaton syndrome
- *Respiratory muscles*: Muscular dystrophy, polymyositis, malnutrition, dyselectrolytemia, and hypothyroidism
- *Chest wall*: Kyphoscoliosis, thoracoplasty, fibrothorax, flail chest, ankylosing spondylitis, and asphyxiating thoracic dystrophy

TABLE 1: Clinical manifestations.

Hypoxic respiratory failure	*Hypercapnic respiratory failure*
Central or peripheral cyanosis	Coma
Tachycardia or bradycardia	Asterixis
Hypertension or hypotension	Headache
Tachypnea accessory muscle use	Somnolence
Diaphoresis	Abdominal paradox (diaphragmatic fatigue)
Altered mentation	Warm extremities with bounding pulses
Anxiety	Myoclonic jerks
Confusion	Papilledema
Lactic acidosis	Slurred speech
Seizures	Signs of airway obstruction

TABLE 2: Berlin definition 2012 of acute respiratory distress syndrome (ARDS).

Timing	Within 1 week of known clinical insult or new or worsening respiratory symptoms
Chest imaging	Bilateral opacities on chest radiograph or chest computed tomographic scan
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload
Oxygenation	
Mild	PaO_2/FiO_2 ratio 200–300 mm Hg with PEEP or CPAP ≥ 5 cmH_2O
Moderate	PaO_2/FiO_2 ratio 101–200 mm Hg with PEEP ≥ 5 cmH_2O
Severe	PaO_2/FiO_2 ratio ≤ 100 mm Hg with PEEP ≥ 5 cmH_2O

(CPAP: continuous positive airway pressure; FiO_2: fraction of inspired oxygen; PaO_2: partial pressure of oxygen; PEEP: positive end-expiratory pressure)

CLINICAL PRESENTATION

Patients with respiratory failure have a varying clinical presentations. Dyspnea is the hallmark of respiratory failure. Neurological symptoms may also be present. Various clinical presentations are shown in **Table 1**.

DIAGNOSTIC APPROACH

Given the vast differential diagnosis of ARF, it is imperative to obtain an extensive history from the patient. History of fever with chills indicates underlying infection. Sudden onset shortness of breath or chest pain may point toward pulmonary embolism, pneumothorax, or myocardial infarction (if left-sided chest pain). Increased cough and sputum in a smoker suggests acute exacerbation of COPD. Cardiogenic pulmonary edema is associated with chest pain, paroxysmal nocturnal dyspnea, or orthopnea. Presence of sensorimotor abnormalities may suggest neuromuscular respiratory failure. Additional exposure history may help in diagnosing inhalational injury, aspiration, transfusion-related lung injury, hypersensitivity pneumonitis, pneumoconiosis, etc. A focused physical examination of cardiopulmonary system is also necessary.

All patients must have basic investigations including arterial blood gas analysis, chest radiography, electrocardiogram, and routine blood chemistry. A normal $AaDO_2$ gradient indicates hypoventilation as the only cause for respiratory failure. Abnormal hemoglobins can also be picked up in arterial blood gas analyzer with co-oximetry facility. Oxygen requirement gives an idea about the severity of the disease. A chest X-ray may help in making the correct diagnosis. A clear chest X-ray in presence of hypoxia and hypo- or normocapnia points towards pulmonary embolism, shock, or anatomical shunts. A clear chest X-ray in presence of hypercapnia would indicate COPD, asthma, drug overdose, or neuromuscular pathology. Localized shadow may indicate pneumonia or an infarct. Diffuse infiltrates suggest pulmonary edema, atypical pneumonia, pulmonary hemorrhage, or pulmonary fibrosis. ARDS, which is a common cause of type I respiratory failure, has been redefined (**Table 2**).

Some special investigations may be required to substantiate the diagnosis such as computed tomography of chest, echocardiography, serum chemistry such as thyroid profile, calcium, magnesium, phosphorus levels, sputum, and blood cultures, urinalysis, and cardiac biomarkers like troponins. Diagnostic pleural tap should be done if pleural effusion is present. In presence of severe hypoxemia, therapeutic decisions may have to be taken even if the data is incomplete. Decisions can later be revised when additional information is available. In recent times, bedside cardiothoracic ultrasound has been found to be a useful complementary diagnostic tool.

MANAGEMENT

The management of respiratory failure is directed towards its cause, its clinical impact, and patient's underlying status. *Primary aims of treatment are: (1) to ensure adequate oxygenation, (2) to improve respiratory acidosis, (3) to improve*

cardiac output if reduced, (4) to treat the primary condition, and (5) to avoid predictable complications. It is essential to do the airway-breathing-circulation assessment right at the time of presentation.

When encountered in the ED, timely decision for hospitalization should be taken. Clinical features indicating the need for ICU admission are as follows:

- Severe breathlessness
- Poor/deteriorating general condition
- Altered mentation
- Significant comorbidities
- Cyanosis
- Acute onset
- Not able to speak full sentences
- Severe acidosis
- High oxygen requirement
- Hypotension

Supplemental Oxygen

A reasonable goal is to achieve PaO_2 of 65–70 mm Hg with oxygen saturation of >90%. Various devices are used to deliver oxygen. They are divided into low- or high-flow systems, or open or closed systems. This depends upon their capacity to deliver oxygen at sufficient flow rates so as to meet the patient's flow demands. In a low-flow system, lower the oxygen flow, and higher the patients flow requirements, higher the probability of entraining room air leading to lower FiO_2. Examples of low-flow systems are nasal cannula or face mask. Examples of high-flow devices are Venturi masks, face masks with reservoir bag, and resuscitation bag-valve-mask unit. Venturi mask is a fixed performance device ensuring delivery of precise oxygen concentrations from 24% to 60%. These are extremely useful in COPD patients where oxygen saturation has to be carefully titrated so as not to blunt the hypoxic drive of the patients.

Initial choice of the device is dependent on the severity of hypoxemia. A higher FiO_2 of 0.5–1.0 can be achieved with a non-rebreathing face mask with reservoir bag. For FiO_2 requirement of more than 0.7, early institution of mechanical ventilation (MV) should be considered, especially in the presence of hemodynamic instability.

The level of acidosis, which needs to be treated, remains debatable. Recently it has been advocated that pH of more than 7.15 does not require bicarbonate therapy. However, in presence of coexistent cardiac arrhythmias, shock or decreased level of consciousness, secondary to no other obvious cause, pH may need to be increased to around.

In addition to above, optimization of cardiac output and adequate hemoglobin concentration are essential in managing compromised oxygenation state. Intravenous fluids should be infused in a targeted and controlled manner. This is to prevent positive fluid balance, which is a predictor of poor outcome in ICU.

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) therapy maintains a continuous positive airway pressure throughout the respiratory cycle, and is similar to positive end-expiratory pressure (PEEP) of MV. It has been found useful in alleviating hypoxemia by recruiting collapsed alveoli. It has been found beneficial in acute cardiogenic pulmonary edema, postsurgical respiratory failure, and in chest trauma patients. It can be provided either by a face mask or nasal mask or helmet as an interface.

Noninvasive Ventilation

It is defined as a process of delivering positive-pressure ventilation through a noninvasive interface (nasal mask and face mask). It can be delivered through either the modern ventilators or portable noninvasive ventilation (NIV) devices. It has been found to be useful in acute exacerbation of COPD, immunocompromised patient with respiratory failure, acute cardiogenic pulmonary edema, postextubation support, and postoperative respiratory failure. Both NIV and CPAP have proven clinical benefit in above situations. They, however, have been found to have no impact on outcome in patients with ARDS or pneumonia. In fact, therapeutic trial with either of them in these two conditions may actually cause unnecessary delay in intubation. NIV has been found to obviate the need for intubation in >50% of properly selected patients. *Contraindications to NIV* use are:

- Inability to protect airway or clear secretions
- Cardiac or respiratory arrest
- Facial surgery or trauma
- Recent upper airway or esophageal surgery
- High risk of aspiration
- Anticipation of prolonged ventilatory support
- Obtundation except hypercapnic encephalopathy
- Acute Physiologic Assessment and Chronic Health Evaluation II (APACHE II) score > 34
- Initial pH < 7.1
- Excessive secretions
- Upper airway obstruction
- Nonrespiratory organ failure—upper gastrointestinal bleeding and hemodynamic instability
- Facial burns
- Nonacceptance of NIV
- Excessive air leak around the interface

Mechanical Ventilation

Initiation of MV is a clinically based bedside decision. Broad indications for mechanical ventilation are:

- Inadequate oxygenation by noninvasive means
- Increased $PaCO_2$ resulting in obtundation and respiratory muscle fatigue
- Increased work of breathing
- Inability to clear secretions
- High risk of aspiration
- Decreased level of consciousness [Glasgow Coma Scale (GCS) < 8]
- Bulbar dysfunction
- Severe respiratory acidosis

Current initial recommendations for ventilator strategies are:

- FiO_2 = 1.0
- Tidal volume = 8–10 mL/kg
- PEEP = 5
- Mode = volume control

This can be later be modified to following settings:

- Low tidal volume strategy (<6 mL/kg)
- Peak airway pressure < 35 cmH_2O
- Permissive hypercapnia
- Higher levels of PEEP (5–15 cmH_2O)
- Early use of ventilator modes allowing spontaneous respiratory efforts

Additional approaches for improving pulmonary gas exchange are recruitment maneuvers, prone positioning, high frequency ventilation, inverse ratio ventilation, inhaled nitric oxide and extracorporeal membrane oxygenation (ECMO), or extracorporeal CO_2 removal ($ECCO_2R$). None of the above approaches except prone positioning and extracorporeal gas exchange therapy have been found to have unequivocal benefit.

High-flow Oxygen Therapy

It is a technique where heated and humidified oxygen is delivered at high-flow rates (up to 50 L/m) through an especially designed nasal cannula. It can provide FiO_2 of 30–100%. This modality has been found to be associated with an enhanced patient comfort and decreased work of breathing. It acts primarily by generating a low level of PEEP and by reducing the physiological dead space. Its use is now being advocated prior to use of NIV in patients with ARF. It can also be safely used if NIV is contraindicated. All the above-mentioned therapies provide only temporary benefit if the underlying disease is not treated simultaneously.

Definitive Therapy

Appropriate empirical antimicrobial agents should be initiated at first suspicion of underlying pneumonia. Bronchodilators and steroids should be prescribed in presence of asthma or COPD. Adequate humidification and mucolytics should be used for avoiding secretions from becoming tenacious. Diuretics should be started when pulmonary edema or fluid overload are suspected. Intercostal drains should be inserted for pneumothoraces or pleural effusions. Chest physiotherapy should be started timely and early mobilization of the patients should be done.

Type III or postoperative respiratory failure presents usually to the ICU. It has to be managed on similar lines. Various strategies have been suggested to prevent its development such as preoperative optimization of chronic lung diseases, early initiation of lung expansion maneuvers (incentive spirometry and deep breathing exercises), adequate analgesia, and use of CPAP where appropriate.

SUMMARY

Acute respiratory failure is one of the most common conditions encountered in general emergency practice. Timely decision of admission to ICU is a prerequisite to successful treatment. ARF can have wide clinical manifestations ranging from sympathetic overactivity to encephalopathy with somnolence. All patients must have arterial blood gas analysis and chest radiography at the earliest. Supplemental oxygen and assisted ventilation should be initiated while waiting for the ICU shift.

85
CHAPTER

Acute Severe Asthma

Bhawana Sharma, Devendra Richhariya

INTRODUCTION

Bronchial asthma (BA) is a chronic respiratory illness which is because of hyper-responsive airways and is mainly characterized by symptoms of wheezing, dyspnea, chest tightness cough, and by variable expiratory airflow limitation. The most important aspect of asthma is that it is very much reversible and variable. Though various phenotypes of asthma such as allergic, nonallergic, late onset, with fixed airflow, and obesity have been identified, but genetic influence and family history still remains very important. Asthma predominantly involves the larger airways. It affects 1–18% of populations in different countries. In India, the estimated prevalence of asthma is 2.05% among those aged >15 years, and a total burden of 18 million asthmatics. The global initiative for asthma has defined asthma as *"Asthma is a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath (SOB), chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation"*.

ACUTE ASTHMA

Exacerbations of asthma are episodes characterized by a progressive increase in symptoms of SOB, cough, wheezing or chest tightness, and progressive decrease in lung function, i.e., they represent a change from the patient's usual status that is sufficient to require a change in treatment.

PATHOPHYSIOLOGY

Pathophysiologic hallmarks of asthma are airways are abnormally filled with eosinophil, lymphocytes, mast cells macrophages, and myofibroblast. Further diameter of airways is reduced due to contraction of smooth muscles, vascular congestions, bronchial wall edema, and thick secretions. *Pathophysiologic changes lead to airflow obstruction and give rise to various clinical manifestations, i.e.,* increased work of breathing, increased airway pressure, decreased in expiratory flow rates, hemodynamic instability, ventilation perfusion mismatch, hypoxemia, hypercarbia, and ventilatory failure due to respiratory muscle fatigue. Continuous airway inflammation and prolonged bronchospasm leads to permanent airway remodeling, fibrosis hyperplasia, hypertrophy of smooth muscle cells, mucous gland hyperplasia and hypersecretion, and angiogenesis. All these changes leads to irreversible loss of lung functions. Stimulus or triggers for acute asthma are acute respiratory viral infections (most common 40–80%) pollution, indoor agents like dust, occupational exposures, vapors, gases, aspirin, β blockers, and nonsteroidal anti-inflammatory drugs (NSAIDs). Cold air exposure, hormonal changes during menstruation, and pregnancy emotional stress also can give rise to acute asthma.

Though the clinical presentation of both the diseases asthma and chronic obstructive pulmonary disease (COPD) is very similar, both present as acute onset dyspnea but there is no histopathological correlation. They have got different involvement at cellular level as cited in the **Table 1**, which is very important for management point of view. Chronic asthma sometimes behaves like COPD and there is now a clinical entity called *asthma–COPD overlap syndrome (ACOS)*. The pathogenesis may be similar to some extent and the Dutch hypothesis though disproved.

TABLE 1: Histopathological changes in asthma and COPD.

Inflammation	*Asthma*	*COPD*
Cells	Mast cells, eosinophil, CD4+ T cells, and macrophages +	Neutrophils, CD8+, T cells, and macrophages+++
Mediators	LTD4, histamine, IL-4, IL-5, and ROS+	LTB4, IL-8, TNF-α, and ROS+++
Effects	All airways, little fibrosis, epithelial shedding	Peripheral airway, lung destruction, fibrosis, and squamous metaplasia
Response to steroids	+++	–

(COPD: chronic obstructive pulmonary disease; IL: interleukin; LTB4: leukotriene B4; LTD4: leukotriene D4; TNF-α: tumor necrosis factor-α)

CLINICAL EVALUATION

History Taking

Breathing difficulty (acute dyspnea) is the most common manifestation with which the patients come to emergency department (ED). It requires several steps for differentiation and the risk stratification of patients presenting with SOB (**Table 2**). There should be methodological approach by the doctors present in ED. A proper history as well as a quick determination of the best management is mandatory. History taking should include:

- Family history of asthma
- Cough—perennial or seasonal/wheezing/smoking history
- Any cardiac disease
- Fever/sputum/hemoptysis/chest pain
- Previous intubation and intensive care unit (ICU) admission
- Chronic use of oral corticosteroid and medication compliance
- Use of short-acting beta2-agonists (SABA), nocturnal awakening, and night symptoms

Clinical Examination

After taking brief history patient needs to be evaluated for severity of symptoms and clinical examination done. Typically, asthma present with dyspnea wheezing and cough. Physical examination includes vital signs (tachycardia and tachypnea) and chest findings (wheezing). Clinical finding must be correlated with possible associated clinical conations (**Table 3**). Clinical examination findings help us to identify the associated comorbid illness like pneumonia pneumothorax, upper airway obstruction due to foreign bodies generally mimic the acute severe asthma and fail to respond to therapy and revisit ED and labeled as "refractory asthma".

Severity of Asthma

The *assessment of severity can be done based on Global Initiative for Asthma (GINA) guidelines*. On physical examination, cyanosis, nasal flaring, use of accessory muscles of respiration leading to intercostal or supraclavicular indrawing, tachycardia, tachypnoea, hypotension, and altered level of consciousness are at higher risk of fatal asthma and need special attention. On auscultation bilateral ronchi can be present. Silent chest without wheezing indicated severe airflow obstruction. Symptoms and finding do not correlate well with severity of symptoms so forced expiratory volume in 1 second (FEV_1) and peak expiratory flow rate (PEFR) are important parameters in categorizing the severity of acute asthma. *The other parameters to classify severity of asthma are summarized in **Flowchart 1***.

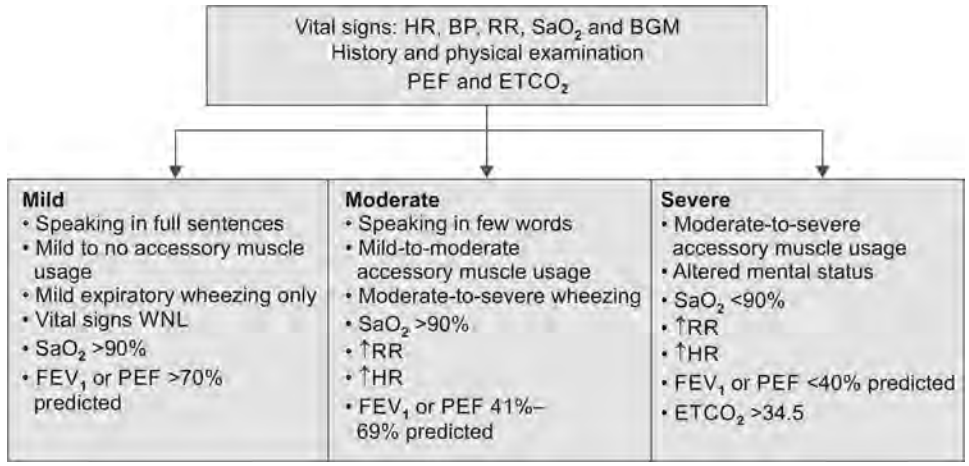
TABLE 2: The differential diagnosis for acute dyspnea.

Head and neck	***Cardiac***	***Miscellaneous***
Angioedema	ACS	Hyperventilation
Anaphylaxis	Decompensated heart failure	Anxiety
Pharyngeal infection	Pulmonary edema (flash)	Pneumomediastinum
Deep neck infection	High output failure	Lung tumor
Foreign body	Cardiomyopathy	Massive pleural effusion
Neck trauma	Arrhythmia	Intra-abdominal process
Pulmonary	Valvular dysfunction	Ascites
COPD exacerbation	Cardiac tamponade	Pregnancy
BA exacerbation	***Toxic/metabolic***	Massive obesity
Pulmonary embolism	Organophosphate	***Neurological***
Pneumothorax	Salicylate	Stroke
Pneumonia	CO poisoning	Neuromuscular disease
ARDS	Toxic ingestion	***Chest wall***
Lung contusion or injury	DKA	Rib fracture
Hemorrhage	Sepsis	Flail chest
	Anemia	

(ACS: acute coronary syndrome; ARDS: acute respiratory distress syndrome; CO: carbon monoxide; DKA: diabetic ketoacidosis)

TABLE 3: Correlating finding with associated condition in acute dyspnea patient.

Breath sound (BS)	***Quality***	***Associated conditions***
Wheeze or rhonchi	Whistling/sibilant and musical	Caused by narrowing of airways, such as in asthma, chronic obstructive pulmonary disease, and foreign body
Stridor	Whistling/sibilant and musical	Epiglottitis, foreign body, laryngeal edema, and croup
Crackles	Cracking/clicking/rattling	Pneumonia, pulmonary edema, interstitial lung disease, and heart failure
Hamman's sign (or mediastinal crunch)	Crunching and rasping	Pneumomediastinum and pneumopericardium
Silent chest	Decreased or no breath sound	Acute severe asthma, bilateral emphysema, or bullous lung
Unilateral decreased BS	Breath sound decreased or absent on one side	• Pleural effusion (dull percussion note) • Pneumothorax (hyper-resonant percussion note)



(BGM: blood glucose monitoring; BP: blood pressure; $ETCO_2$: end-tidal CO_2; FEV_1: forced expiratory volume in 1 second; HR: heart rate; PEF: peak expiratory flow; RR: respiratory rate; SaO_2: arterial oxygen saturation; WNL: within normal limits)

FLOWCHART 1: Categories of severity of asthma.

INVESTIGATIONS

The base line (routine) investigations which needs to be done urgently are vital signs—heart rate (HR), blood pressure (BP), arterial oxygen saturation (SaO_2) and consciousness level [Glasgow Coma Scale (GCS) scoring], chest X-ray, electrocardiogram (ECG), blood glucose monitoring (BGM) [arterial blood gas (ABG)], peak expiratory flow (PEF) and end-tidal CO_2 ($ETCO_2$), total leukocytes count with differential, renal function test (RFT), liver function (LFT), C-reactive protein (CRP), and procalcitonin.

Laboratory Investigations

There is no specific laboratory test to clearly identify the as the etiology of dyspnea. The tests which are done to identify causes like infective exacerbations. The total leukocyte counts with differential count may show high neutrophil counts in bacterial infective exacerbations). RFT and LFT also should be done. Increased CRP and procalcitonin (procalcitonin) can be suggestive of infective exacerbations. Though these may be not accurate in settings of viral and fungal infections or may be falsely high in case of renal failure patients. N-terminal-pro-B-type natriuretic peptide (NT-proBNP) and cardiac enzymes [troponin I/T and creatine phosphokinase-myocardial band (CPK-MB)] may be raised indicating possible cardiac etiology. D-dimer although used for its negative predictive value, can be advised if pulmonary thromboembolism is suspected.

Microbiology

Sputum Gram stain and cultures are advice for all admitted patients. In emergency, first goal is to stabilize the patient then send samples. Sputum for acid-fast bacilli (AFB) should be obtained for nonresponders as per Revised National Tuberculosis Control Programme (RNTCP) guidelines. We can use sputum as well as other respiratory samples such as bronchial washings and endotracheal secretions for microbiological sampling.

Radiology

Chest X-ray is almost mandatory for patients with acute dyspnea. It is not very specific test but is very much sensitive in detecting lung/cardiac causes of dyspnea. Pneumothorax, pneumonia or patchy consolidation or interstitial pattern can be seen on chest X-ray. Signs of heart failure such as bat wing appearance, cardiomegaly, bilateral shadows, and Kerley B lines may be seen. If chest X-ray is not informative, then we may have to ask for chest CT or CT-pulmonary angiography. Two-dimensional (2D) echocardiography and venous Doppler are also advised based on chest X-ray findings. Ultrasound of chest is also useful for detection of pleural pathology.

Electrocardiogram

Electrocardiogram is an essential component in evaluating patients for acute dyspnea. Increased mortality has been linked to adverse cardiovascular events. ECG is very sensitive in detecting cardiac events such as acute coronary syndrome (ACS) and arrhythmias. We can also get ECG changes in pulmonary embolism (S1Q3T3). The ECG changes are COPD because of clockwise rotation of heart, right atrial and ventricular hypertrophy, and P-wave verticalization due to flattening of the diaphragm leading to downward displacement of heart. The ECG changes are:

- S waves in leads I, II, and III;
- R/S ratio less than 1 in leads V5 or V6; and
- The lead I sign—isoelectric P wave, QRS amplitude less than 1.5 mm, and T wave amplitude less than 0.5 mm in lead I.

Arterial Blood Gas Monitoring

Arterial blood gas is a routine practice in emergency for patients of asthma and COPD. Though oxygen saturation (SPO_2) is very sensitive and noninvasive, ABG is more accurate for hypercarbia and hypoxemia status. Sometimes the venous sample may also demonstrate about the CO_2 retention and can be used as surrogate to avoid the painful procedure of arterial puncture.

Ultrasonography

Ultrasonography (USG) is a very specific investigation and can be used if available in emergency to differentiate between cardiac or respiratory causes. It has been found to be very accurate in diagnosing COPD or asthma exacerbation. The protocols which have been used are *lung ultrasound in critically ill (LUCI), bedside lung sonography in emergency (BLUE), and fluid administration limited by sonography (FULL)*.

TREATMENT

Acute asthma is classified as mild, moderate, and severe and the management varies accordingly. Purpose of commonly used drugs such as oxygen therapy, β agonist, anticholinergics, inhaled/systemic intravenous (IV) corticosteroid is to reverse the airflow obstruction by repetitive and continuous administration (**Table 4**).

Oxygen Therapy

Severe repiratory distress, bronchospasm, and respiratory failure is more common with acute severe asthma. Hypoxia may be with hypercapnia (CO_2 narcosis) which is basically type 2 respiratory failure and is found commonly in advance stage COPD and is rare in acute asthma. In asthmatic attack, the patients are hyperventilating so hypocapnia or normocapnia are common. Oxygen therapy is recommended in both type 1 and 2 respiratory failure to relieve severe respiratory distress and prevent tissue hypoxia. Oxygen therapy in case of COPD should be judiciously used to prevent CO_2 retention and respiratory acidosis. SPO_2 to be maintained between 88 and 94%. Pulse oximetry must be used to continuously monitor SPO_2. Blood gas monitoring is very useful in guiding the oxygen therapy and gives information about CO_2 status. The various delivery devices for oxygen comprises of nasal cannula, venturi mask, non-rebreather mask, reservoir cannula, and transtracheal catheter.

TABLE 4: Drugs most commonly used for airway managements.

Beta2-agonists	
• *Short-acting beta2-agonists (SABA)*—salbutamol (albuterol), salmeterol, levosalbutamol, and terbutaline • *Long-acting beta2-agonists (LABA)*—formoterol, salmeterol, indacaterol, and arformoterol	• *Albuterol*—nebulizer 2.5–5 mg every 20 min total three doses then 2.5–10 mg every 1–4 hourly. MDI four to eight puffs every 20 min up to 4 h (90 µg/puffs) • *Injectable terbutaline*—2 *µg/kg over 5 min* then start infusion 5 µg/kg/h • *Epinephrine (α + β agonist)*—1:1,000 (1 mg/mL) 0.5 mg every 20 min by s/c or IM route
Anticholinergics	
• Short-acting anticholinergics (SAMA)—ipratropium and oxitropium • Long-acting anticholinergics (LAMA)—tiotropium, aclidinium, glycopyrronium, and umeclidinium	• *Ipratropium bromide*—nebulizer 0.5 mg every 20 min for three doses then as per requirement • *MDI*—eight puff every 20 min up to 3 h (18 *µg/puffs)*
Combinations (beta2-agonists + anticholinergics)	*Ipratropium + albuterol*
• Short-acting beta2-agonists + anticholinergic • Long-acting beta2-agonist + anticholinergic	• *Nebulizer* 3 mL every 20 min for three doses (nebulizer solution of 3 mL contains 0.5 mg of ipratropium and 2.5 mg of albuterol • *MDI*—eight puffs every 20 min (each puff contains 18 *µg/puffs ipratropium + 90 µg/puffs of albuterol)*
Inhaled corticosteroids (ICS)	
Beclomethasone, budesonide, fluticasone, and mometasone	
Systemic corticosteroids (IV)	
Hydrocortisone, methylprednisolone, and prednisolone	• *Prednisolone*—40–80 mg/day oral in two divided doses 5–10 doses till PEFR reaches 70% of predicted or 1–2 mg/kg/day IV for 5–10 days • *Methylprednisolone*—1 mg/kg IV every 4–6 h
Combination (beta2-agonists + corticosteroids)	
long-acting beta2-agonists + corticosteroids	
Others	
• Methylxanthines—aminophylline, theophylline • Phosphodiesterase-4 (PDE4) inhibitors—roflumilast • Leukotriene receptor antagonists—montelukast and zafirlukast	
• *Mild asthma*—short-acting bronchodilators (SABDs) • *Moderate asthma*—SABDs + oral corticosteroids ± antibiotics • *Severe asthma*—emergency visit and hospitalization, patients may be in respiratory failure	

Inhaled Bronchodilators

In emergency setup it is the most important aspect of therapy for acute bronchospasm. We have various modes of delivery for inhaled bronchodilators. Both nebulizers as well as handheld inhalers can be used in exacerbations. If patient is acidotic, nebulizers preferably should be given by compressed air rather than oxygen (to avoid CO_2 narcosis). In ED, nebulization with either single or dual bronchodilators like salbutamol with ipratropium bromide can be given. Nebulized salbutamol can be given back-to-back till resolution of bronchospasm.

Inhaled/Systemic Corticosteroids

Inhaled as well as systemic corticosteroids are regularly used for acute spasm. It is also considered first line in the emergency management of the acute asthma. *Inhaled corticosteroids like beclomethasone 50–400 μg; budesonide 100, 200, and 400 μg; fluticasone 50–500 μg through nebulization or handheld devices can be used.* Systemic corticosteroids are the main stay of therapy for acute severe spasm in asthma. Both the oral and the parenteral route have same bioavailability. If patient can take oral, parenteral treatment are reserved for patients who cannot take oral medication as there is no major difference between oral and IV with regards to relapse rate, treatment failure, or mortality. Patients during hospitalization can be given oral/IV steroids and once stable should be discharged on oral corticosteroids for 7–14 days. *The equivalent dose: ~20 mg hydrocortisone, ~5 mg prednisolone, ~4 mg methylprednisolone, and ~0.75 mg dexamethasone.* The mode of delivery is mostly in inhaled form, may be through metered dose inhalers, dry powder inhalers or nebulization which have their own pros and cons (**Table 5**).

Theophylline

If bronchospasm persists and the patient is still breathless in spite of adequate steroids and inhaled bronchodilators, we can add parenteral aminophylline after excluding cardiac cause. Because of its high toxicity and drug interaction (with commonly used drugs such as ciprofloxacin, clarithromycin, allopurinol, and phenytoin), it should be maintained within therapeutic range—10–20 μg/mL.

Other Drugs

Intravenous magnesium sulfate, though not supported by the Global Initiative for Obstructive Lung Disease (GOLD) or GINA guidelines, can be given as it has been found to reduce hospital admissions when other drugs had failed to reduce symptoms. It can be given slow IV over 20 minutes in normaly functioning kidneys. *Parenteral terbutaline and intramuscular epinephrine* can also be given in centers with experience of using the drugs. *Heliox (mixture of 80% helium and 20% oxygen)* can also be considered as an adjuvant in the management of severe asthma. For the penetration of drugs such as bronchodilator, anticholinergic, and anti-inflammatory agents, the lower density of helium serves as a better transport modality than room air or oxygen-driven nebulizers.

Antibiotics

Based on local bacterial resistance and stewardship guidelines, antibiotics can be started for patients with history of producing purulent sputum. Change in amount, color, and consistency of sputum leads towards infective exacerbations and antibiotics should be started. Initial empiric treatment should consist of an aminopenicillin, a macrolide, or a tetracycline. If *Pseudomonas* or Enterobacteriaceae is suspected, combination therapy with antipseudomonal antibiotics like piperacillin/tazobactam or imipenem or meropenem plus amikacin or levofloxacin can be given.

STATUS ASTHMATICUS

Status asthmaticus *or acute severe asthma (FEV_1 or PEFR <25% of predicted)* is clinically characterized by hypoxemia and tachypnea. Tachycardia accessory muscle use wheezing impending respiratory arrest and usual dose of bronchodilators and steroid does not improve the clinical conditions.

TABLE 5: Mode of delivery of corticosteroid.

	Advantages	***Disadvantages***
Pressurized metered-dose inhalers (pMDI)	• Compact and portable • Multidose • Quick treatment time • Drug in sealed canister • Inexpensive	• High oropharyngeal deposition • Difficulty in hand mouth coordination • Propellant may cause "cold Freon" effect and affect climate change
Dry powder inhaler (DPI)	• Compact and portable • Quick treatment time • Breath-actuated function removes need for coordination	• Need adequate inhalation flow to dispense • High oropharyngeal deposition • Humidity can cause drug degradation • Patients may be intolerant to additives, e.g., lactose
Nebulizers	• Large doses of drug can be given • Can be used with relaxed tidal breathing • Suitable for young, old, and acutely ill patients • Many drug solutions can be aerosolized	• Bulky cumbersome and expensive • Wasted drug in nebulizer reservoir • Variations in aerosol output performance between models • Time consuming • Need for power source • Regular cleaning and maintenance

Rapid and aggressive treatment is required to prevent the cardiopulmonary arrest. Adjuncts treatment is also required apart from the bronchodilators and early corticosteroid.

Magnesium

Up to 1–2 g IV over 30 minutes. Nebulized magnesium is also added along with aggressive bronchodilators and inhaled corticosteroid therapy and effective in improving the pulmonary functions. Doses for nebulization magnesium sulfate 95 mg in four divided doses, 20 minute apart. Monitor vitals and deep tendon reflexes while using magnesium in any form. Though hypotension and neuromuscular blockade are rare adverse effects.

Admission to Intensive Care Unit

If the patient's condition further deteriorates [persistent respiratory distress, inability to maintain oxygen level above 90%, persistent hypercapnia, abnormal ABG—partial pressure of oxygen (PaO_2) <60 mm Hg and/or partial pressure of carbon dioxide ($PaCO_2$) > 60 mm Hg, alteration of mental status, acute confusion, and drowsiness) even after above said measures then he can be shifted to ICU and noninvasive positive pressure [noninvasive ventilation (NIV)] should be tried.

Noninvasive Ventilation

For patients with respiratory failure, assisted mode of ventilation must be given first trial through noninvasive mode and if patients do not tolerate it or noncooperative then invasive mode of ventilation is applied after endotracheal intubation. NIV assists the patient in taking a breath and helps to maintain adequate oxygen. Noninvasive positive-pressure ventilation (NIPPV) is most popular mode of providing NIV, in combination with continuous positive airway pressure (CPAP) with pressure support ventilation (PSV). It is the treatment of choice for persistent hypercapnic ventilator failure. NIV has proven role in acute exacerbation of chronic obstructive pulmonary disease (AECOPD). However, use of NIV in acute severe asthma has no clear benefit for reduced intubation or mortality.

Mechanical Ventilation

Intubation can be considered in patients with the following:

- *NIV failure*: Worsening of ABG and/or pH in 1–2 hours; lack of improvement in ABG and/or pH after 4 hours
- *Severe acidosis* (pH <7.25) and hypercapnia ($PaCO_2$ > 60 mm Hg)
- *Tachypnea* >35 breaths/minute
- *Other complications*: Metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, and massive pleural effusion

PULMONARY FUNCTION TEST

Pulmonary function test (PFT) is helpful in quantifiable measurement of lung functions. PFT is useful in monitoring the course of the disease which affects either heart or the lung. PFT is also helpful in observing the environmental, occupation, and drug exposure on the lungs. PFT is also necessary as preoperative evaluation, preemployment, and insurance purposes.

SPIROMETRY

Spirometry is the most commonly used test to measure the volume and capacity of the lungs during various breathing manuvre. There are four lung volumes and four lung capacities are desribed. Lung volumes and lung capacities are mesured by spirogram (**Fig. 1**).

Lung Volumes

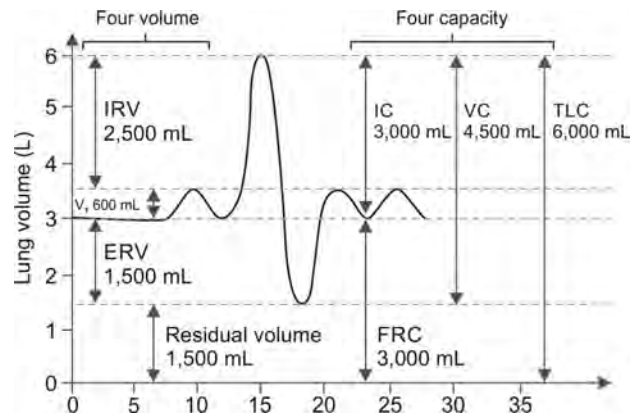
Lung volumes parameters are mesured directly by spirometer. There are four types of lung volumes, i.e., tidal volume (TV), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and residual volume (RV). Values are small.

Lung Capacities

Values are calculated by combining two or three volumes. There are four types of lung capacities, i.e., vital capacity (VC), inspiratory capacity (IC), total lung capacity (TLC), and functional residual capacity (FRC). Values are large. Spirometry is indicated in diagnostic and monitoring purposes (**Table 6**).

Method

Test is done with the help of spirometer, full inhalation is done by the patient before the exhalation. There shoud be no hesitation, coughing, and glottic closure during exhalation. There should be no evidence of leak and obstruction of the mouth piece. Satisfactory duration of the test is minimun of 6 seconds and up to 15 seconds in patient with airflow obstruction. Good initial effert of exhalation is indicatd by sharp increase in volume from zero in the volume-time curve and well-defined peak in expiratory flow in volume-flow curve (**Figs. 2A** and **B**).

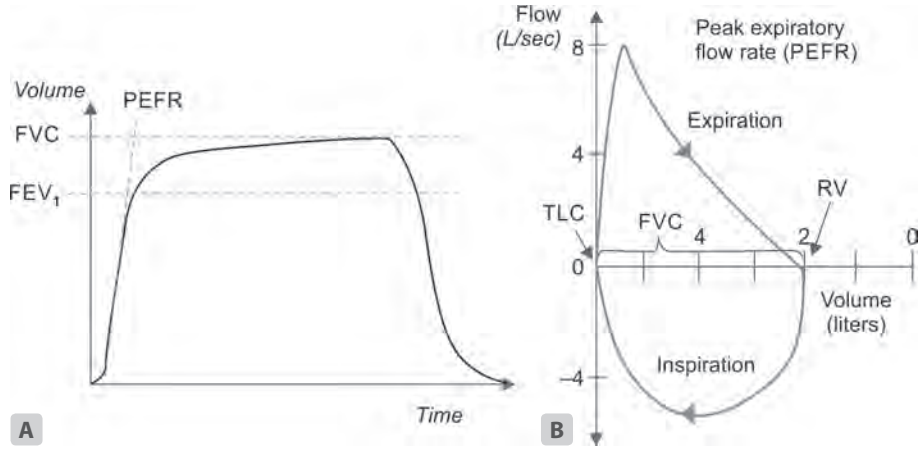


(ERV: expiratory reserve volume; FRC: functional residual capacity; IC: inspiratory capacity; IRV: inspiratory reserve volume; TLC: total lung capacity; VC: vital capacity)

FIG. 1: Spirogram showing volume and capacity of the lungs.

TABLE 6: Indications of spirometry.		
Diagnostic	***Screening and monitoring***	***Others***
• Evaluation of clinical features and abnormal laboratory results • Assessment of effects of disease on the lungs • Spirometry is important in diagnosing and managing the asthma • Obstructive an restrictive pattern of the lung disease only be identified by the spirometry	• Spirometry is used to assess the efficacy of bronchodilators steroid treatment on asthma and heart failure patient • Assessment of course of disease (COPD, ILD, CHF, and neuromuscular disease) • Assessment of occupation exposure of asbestos, diisocyanates, and smoke	• Rehabilitation • Preemployment • As insurance evaluation • Preoperative evaluation

(CHF: congestive heart failure; COPD: chronic obstructive pulmonary disease; ILD: Interstitial lung disease)



(FEV_1: forced expiratory volume in 1 second; FVC: forced vital capacity; TLC: total lung capacity)

FIGS. 2A AND B: Normal spirogram. (A) Volume-time curve sharp incraese in volume from zero; (B) Volume-flow curve well-defined peak in expiratory flow.

INTERPRETATION OF THE PULMONARY FUNCTION TEST

Interpretation of PFT is done by comparing the measured value with the reference values (**Table 7**) of the normal healthy and nonsmoker person. Quality of the test is depending on the quality of equipment, good test performance, appropriate reference values, good algorithm for interpretation, and absence of artefact. There are two basic type of lung dysfunction; restrictive and obstructive lung diseases (**Table 8**). *Restrictive pattern* means that lung volume is reduced (reduction in TLC—volume of air in the lung at the end of maximum inhalation) and *airflow obstruction means—reduced FEV_1/VC. Response to bronchodilator therapy—15% change in forced vital capacity (FVC) or FEV_1 after bronchodilator is considered as substantial response.* Abnormal spirogram with obstructive and restrictive pattern is shown in **Figure 3**.

TABLE 7: Normal (reference) values of pulmonary function test.	
Pulmonary function test	***Normal values (95% confidence interval)***
FEV_1	80–120%
FVC	80–120%
Absolute FEV_1/FVC ratio	Within 5% of the predicted ratio
TLC	80–120%
FRC	75–120%
RV	75–120%
DLCO	>60 to <120%

(DLCO: diffusing capacity of carbon monoxide; FEV_1: forced expiratory volume in 1 second; FRC: functional residual capacity; FVC: forced vital capacity; RV: residual volume; TLC: total lung capacity)

SUMMARY

Asthma is a common and potentially serious chronic inflammatory disorder of the airways, characterized by variable expiratory flow, airway wall thickening, respiratory symptoms, and exacerbations (flare-ups), which sometimes require hospitalization and may be fatal. Exposure to external agents, such as indoor and outdoor allergens, air pollutants, and respiratory tract infections are the most common causes of the exacerbations of asthma. Severe asthma exacerbations are a major cause of functional impairment and increased risk of

TABLE 8: Types of lung dysfunction.

Obstructive lung diseases	*Restrictive lung disease (parenchymal)*	*Restrictive (extraparenchymal)*
• Asthma • COPD • Bronchiectasis • Cystic fibrosis • Bronchiolitis	• Sarcoidosis • IPF • Pneumoconiosis • Drugs or radiation-induced lung disease	• Neuromuscular (diaphragmatic paralysis, myasthenia gravis, muscular dystrophies, and cervical spine injuries) • Chest wall related-kyphoscoliosis obesity, and ankylosing spondylitis)

(COPD: chronic obstructive pulmonary disease; IPF: idiopathic pulmonary fibrosis)

morbidity and mortality. Despite optimal guideline-directed treatment and irrespective of underlying disease severity, asthma patients experience exacerbations. Risk for future severe exacerbations in any asthma patients can be estimated by frequent emergency department visits and frequent hospitalization in intensive care unit. It is important to note that prevention of exacerbations of asthma remains a major need in asthma management. Thus, it is important to identify high-risk patients who can progress to severe exacerbations. To prevent and/or decrease exacerbations patient education, written plans of management, control of triggering/risk factors and comorbid conditions, monitoring of asthma control and pulmonary function and optimal pharmacotherapy are important aspects. A better understanding of the pathogenesis of asthma exacerbations is helpful in development of better strategies and novel treatments in view of preventing and treating severe asthma exacerbations.

Chronic Obstructive Pulmonary Disease

86 CHAPTER

Sudha Kansal

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is currently the fourth leading cause of death in the world, but is projected to be the third leading cause of death by 2020. COPD is a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases and influenced by host factors including abnormal lung development. Significant comorbidities may have an impact on morbidity and mortality.

RISK FACTORS

Cigarette smoking is the most common cause of COPD. However, airflow limitation is seen in nonsmokers as well though the severity of illness is less in nonsmokers. There is a complex relationship between COPD, smoking, sex, environmental exposure, and genetic predisposition. Poor socioeconomic status and longer life expectancy are also important factors.

Genetic Factors

Severe hereditary alpha 1 deficiency is an uncommon but well-known cause of emphysema, more if there is associated exposure to environmental pollutants. It should be considered in younger emphysema patients with genetic history. In the case of smokers, genetic predisposition increases the development of COPD.

Age and Gender

Age is considered as a risk factor, but it is not clear whether healthy aging leads to COPD or it is the cumulative exposure that leads to changes. Recent studies have shown that the prevalence of COPD is same in male and females, probably due to changing habits of smoking.

Lung Growth and Development

Lung growth during gestation and childhood infections are important factors in determining lung function in adulthood. This was shown in a large study and meta-analysis.

Smoke and Particles Exposure

Cigarette smoking is the most common cause for development of COPD. Passive smoking and smoking during pregnancy is also an important risk factor. Occupational exposure to organic and inorganic dust fumes are under recognized risk factors for COPD. This problem may be even higher in developing countries like India. A high level of air pollution is emerging as an important cause for COPD, especially in patients with preexisting lung and heart disease. This effect is especially important in causing impaired lung growth in children.

Preexisting Obstructive and Airway Disease

Preexisting asthma is an important risk factor for subsequent development of COPD as shown by multiple studies. Chronic bronchitis was associated with mucus hypersecretion and accelerated forced expiratory volume in one second (FEV_1) decline. Young smokers with chronic bronchitis have higher risk for developing COPD.

Infection

Recurrent childhood infections are associated with reduced lung function. Colonization with *Pseudomonas* increases the risk of exacerbation and all cause mortality. Tuberculosis is a risk factor and also an important comorbidity in COPD patients. Patients with human immunodeficiency virus (HIV) are at higher risk of COPD.

PATHOPHYSIOLOGY

It is now understood how the underlying disease process in COPD leads to characteristic symptoms and physiological abnormalities. Predominant changes include small airways, but there is involvement of lung parenchyma and pulmonary vasculature as well. The pathological changes include chronic inflammation, structural changes from repeated injury, repair, and fibrosis.

Airflow Obstruction and Gas Trapping

The reduction in the FEV_1, FEV_1/forced vital capacity (FVC) ratio, and the accelerated decline in FEV_1. Characteristic of

COPD is related to the extent of chronic inflammation, luminal exudates due to hyperplasia of mucus gland, increased number of goblet cells, and fibrosis in the small airways.

Mucus Hypersecretion

A chronic productive cough is due to an increased number of goblet cells and enlarged submucosal glands, both because of chronic airway irritation by cigarette smoke and other noxious agents.

Gas Exchange Abnormalities

Abnormalities in gas exchange result in hypoxemia and hypercapnia, and have several mechanisms in COPD.

Pulmonary Hypertension

Pulmonary hypertension may develop late in the course of COPD. It is mainly due to hypoxic vasoconstriction and chronic inflammatory changes in small pulmonary arteries which results in structural changes that include intimal hyperplasia and later smooth muscle hypertrophy/hyperplasia. Progressive pulmonary hypertension may lead to right ventricular hypertrophy and eventually to right-side cardiac failure. Pulmonary artery hypertension has shown to relate to the risk of exacerbation.

Systemic Features

Chronic obstructive pulmonary disease is now defined as a systemic disease. Most patients with COPD have concomitant chronic diseases linked to the same risk factors, i.e., smoking, aging, and inactivity, which may have a major impact on health status and survival. Airflow limitation and particularly hyperinflation affect cardiac function and gas exchange. In the circulation, these inflammatory mediators are present which may contribute to skeletal muscle wasting and cachexia, and may initiate or worsen comorbidities such as ischemic heart disease, heart failure, osteoporosis, normocytic anemia, diabetes, and metabolic syndrome.

INITIAL ASSESSMENT

Clinical Manifestations

The three cardinal symptoms of COPD are chronic cough, sputum production, and dyspnea. Symptoms which are less common include wheezing and chest tightness. History of decreasing level of activity or reduction in the speed of walking should be enquired. Other symptoms include weight loss or weight gain, anxiety, and depression.

History

The past history of exacerbations should be ascertained. A detailed history should include number of exacerbations in the previous year, need for emergency visits, hospitalization, intensive care admissions, need for ventilatory support, and need for glucocorticoids. History of cigarette smoking, exposure to biomass fuel, occupational exposure to organic or inorganic gases or metals should be elicited. The modified Medical Research Council (mMRC) dyspnea grading and COPD assessment test (CAT) scoring system can be used to assess the severity of symptoms. These scales should be used along with history of exacerbation and spirometry to plan management of the patients.

Physical Examination

On clinical examination findings can vary as per severity. Initial findings on chest examination may be normal, prolonged expiration, or wheezing on prolonged expiration. As the disease progresses the breath sounds are reduced, wheezing is heard, and increased anteroposterior (AP) diameter due to hyperinflation is seen. The percussion note will be hyperresonant. There may also be features of respiratory compromise such as difficulty in speaking due to respiratory effort, use of accessory respiratory muscles, and paradoxical chest wall/abdominal movements. There may be signs of right heart failure. It includes edema of the feet, ascites, and elevated jugular venous pressure (JVP). Clubbing is not seen in COPD and should search for other diseases such as lung cancer, bronchiectasis, or interstitial lung disease (ILD). If present, decreased mental status could reflect hypercapnia or hypoxemia and asterixis could indicate CO_2 narcosis.

DIAGNOSIS

Pulmonary function test, particularly spirometry, is the cornerstone for diagnosis of COPD. Besides for diagnosis, it also helps to assess the severity of airflow limitation, response to treatment, and progression of disease.

Spirometry

Chronic obstructive pulmonary disease is typically associated with $FEV_1/FVC < 0.7$ and no or partial post bronchodilator reversibility. FEV_6 obtained by stopping expiratory effort after 6 seconds rather than till complete cessation of airflow is an acceptable representative of FVC.

Lung Volume

In cases of obstructive airway disease including COPD, lung volume study is not routinely required. However, lung volumes help to differentiate the cause of FVC reduction. If reduction of FVC is due to hyperinflation, there is reduction of inspiratory capacity (IC) and vital capacity (VC) with increased total lung capacity (TLC), functional residual capacity (FRC) and residual volume (RV). If reduced FVC is due to air trapping without hyperinflation the TLC remains normal. Diffusing capacity of carbon monoxide (DLCO) is done if the symptoms are out of proportion to spirometry abnormality, hypoxemia [peripheral oxygen saturation (SpO_2) < 92%], and if there is a plan for lung reduction surgery. With increasing severity, the DLCO decreases. It is because of reduction in surface area for diffusion due to loss of alveoli in emphysema and loss of capillary bed. DLCO < 55% is an indication for assessment for home oxygen therapy.

*The Global Initiative for Chronic Obstructive Lung Disease (GOLD) has classified COPD based on severity of airflow limitation (**Box 1**).*

Imaging

Chest X-ray

Chest X-ray clues to COPD are hyperinflated lungs, flat diaphragm, dirty lung fields, bullae, increased translucency, and tubular heart. In case of pulmonary hypertension, there is prominence of hilum and relative cardiomegaly.

Computed Tomography Scan

High-resolution computed tomography (HRCT) chest is a very useful test to evaluate the type of emphysema, especially if lung reductive surgery or medical lung reductive surgery (endobronchial valve) is planned. Both inspiratory and expiratory scan should be done to assess for nonemphysematous air trapping.

Additional tests are obtained depending on the clinical evaluation of the patient.

- Cardiac evaluation
- *Alpha-1 antitrypsin levels*: Symptomatic patients with persistent airflow limitation, especially if nonsmoker or minimally smoker, emphysema in young patients (<45 years), predominantly basal involvement, or family history of emphysema. Genotyping can also be done.
- *6-minute walk test*: It is done to assess the functional status of the COPD patients.

BOX 1: GOLD classification of COPD.

In patients with $FEV_1/FVC < 0.70$:

GOLD 1: Mild: $FEV_1 > 80\%$ predicted

GOLD 2: Moderate: $50\% \leq FEV_1 < 80\%$ predicted

GOLD 3: Severe: $30\% \leq FEV_1 < 50\%$ predicted

GOLD 4: Very severe: $FEV_1 < 30\%$ predicted

(COPD: chronic obstructive pulmonary disease; FEV_1: forced expiratory volume in one second; FVC: forced vital capacity; GOLD: Global Initiative for Chronic Obstructive Lung Disease)

TREATMENT

General Measures

It is important to educate the patients about smoking cessation, avoidance of exposure to biomass and environmental pollutants, vaccination, inhaler technique, early signs of worsening status, and self-management of worsening. Regular physical therapy and pulmonary rehabilitation also play an important role in symptomatic improvement.

Pharmacologic Therapy

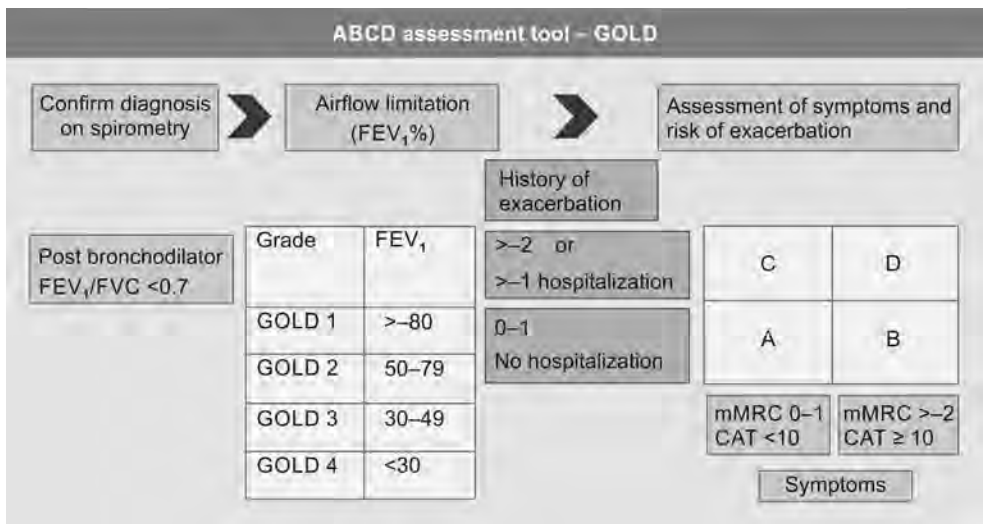
The therapy of COPD is based on risk assessment tool of GOLD guidelines (**Fig. 1**). It depends on severity of symptoms and history of exacerbation and hospitalization. Current recommendation for the management of COPD is described in **Table 1**.

Role of Bronchodilators

- Regular use of inhaled bronchodilators is required to reduce symptoms
- Long-acting beta-agonist—long-acting muscarinic antagonist (LABA-LAMA) combination improves symptoms, lung function, and reduce exacerbation rate.
- LAMA is more effective in reducing exacerbation and hospitalization than LABA
- Tiotropium improves exercise tolerance in pulmonary rehabilitation
- Theophylline has shown to improve symptoms modestly in stable COPD

Long-acting beta-agonists:

- *Salmeterol*: It is available as DPI.
- Dose is one puff (50 µg/inhalation) twice daily
- *Formoterol*: It is available as DPI
- Dose is one to two inhalations (12–24 µg total dose) twice daily
- *Indacaterol*: It is available as DPI (in capsule form)
- Dose is one to two capsule (75 µg/capsule) once daily



(COPD: chronic obstructive pulmonary disease; CAT: chronic assessment test; FEV_1: forced expiratory volume in one second; FVC: forced vital capacity; GOLD: Global Initiative for Chronic Obstructive Lung Disease; mMRC: modified Medical Research Council)

FIG. 1: Risk assessment tools for chronic obstructive lung disease.

TABLE 1: Recommendation of COPD treatment.

Group A	Group B	Group C	Group D
• SABA or SAMA • As per need only	• Preferred—LAMA • Alternative—LABA • As per need SABA/SAMA • Choice depends on patient's tolerance • Severe symptoms—LAMA • Can add theophylline	• LAMA • As per need SABA	• Preferred—LAMA • Severe symptoms—LAMA-LABA • LAMA-LABA-ICS • Eosinophil counts > 300/μL • LABA-ICS

(COPD: chronic obstructive pulmonary disease; ICS: inhaled corticosteroid; LABA: long-acting beta-agonist; LAMA: long-acting muscarinic antagonist; SABA: short-acting beta2 agonist; SAMA: short-acting muscarinic antagonist)

Long-acting antimuscarinic agents:

- *Tiotropium*: It is available as dry powder inhaler (DPI) and metered-dose inhaler (MDI). DPI is available as 18 μg and MDI as 9 μg. Dose is 18 μg/day.
- *Glycopyrronium*: It is available as DPI or respules for nebulization. Long-term use is found to be safe. DPI is available as 25 and 50 μg and 2 mL respules—25 μg/mL. Dose is twice a day.

Methylxanthines

There is evidence of a modest bronchodilator effect of theophylline compared to placebo in stable COPD. It has a small therapeutic ratio, so the window of safety is less. Higher doses can cause life-threatening atrial or ventricular arrhythmias, seizures irrespective of past history. In therapeutic doses also, it can cause nausea, vomiting, heartburn, headache, insomnia, etc. Being a nonselective phosphodiesterase inhibitor, it has several drug interactions, important being Digitalis and Coumadin.

Oral Glucocorticoids

Long-term steroids have no role in stable COPD. Moreover, it also has a significant side effect such as infection and myopathy.

Phosphodiesterase-4 Inhibitors

They have an anti-inflammatory effect by inhibiting breakdown of cyclic adenosine monophosphate (AMP). Roflumilast has been shown to reduce exacerbation in moderate and severe COPD treated with systemic steroids, severe to very severe COPD, and a history of exacerbation.

Antibiotics

Long-term use of azithromycin has shown to reduce exacerbation as per recent studies, but also increases risk of bacterial resistance, causes prolongation of QT interval.

Role of Mucolytics and Antioxidants (N-acetyl-L-cysteine)

In COPD, patients not receiving steroids regular treatment with mucolytic and N-acetyl-L-cysteine may reduce symptoms and reduce exacerbation. Though dose is not defined due to heterogeneity of studies.

Nonpharmacological Therapy

Other than smoking cessation nonpharmacological measures include vaccination, oxygen therapy, noninvasive ventilation, regular exercise, pulmonary rehabilitation and in severe cases supportive care and end of life hospital care.

Oxygen Therapy

In patients with arterial hypoxemia, partial pressure of arterial oxygen (PaO_2) < 55 mm Hg or SpO_2 < 88% with or without hypercapnia, confirmed twice over 3 weeks period, and long-term oxygen therapy (LTOT) have shown to improve survival and quality of life. Aim should be to keep arterial oxygen saturation (SaO_2) > 89%. If PaO_2 is between 55 and 60 mm Hg or SaO_2 of 88% and evidence of pulmonary arterial hypertension (PAH), LTOT is recommended. Patients should be evaluated after 60–90 days to determine long-term oxygen requirements.

Role of Noninvasive Ventilation at Home

Noninvasive ventilation has shown to have survival benefit and reduced need for hospitalization in patients with COPD and obstructive sleep apnea. A recent multicenter prospective randomized controlled trial (RCT) involving 13 centers included 116 patients with hypercarbia showed that using NIV with oxygen prolonged the time to readmission and death within 12 months significantly.

Pulmonary Rehabilitation

Respiratory therapist or physiotherapist plays a very important role in pulmonary rehabilitation. It involves exercise training, beginning at low level and slowly increasing the intensity to improve exercise capacity and reduce dyspnea. Pursed lip breathing, diaphragmatic breathing, and yogic exercises help to reduce air trapping and reduce work of breathing.

Palliative and End-of-life Issues

Palliative care refers to symptom control and reducing suffering of the patient with minimal invasive intervention. One of the most disabling symptoms in these patients is dyspnea. Opiates chest wall vibration and fan blowing over chest may help to offer relief. NIV may also help.

Bronchoscopy Intervention and Lung Transplant Surgery

Lung volume reduction either bronchoscopic (endobronchial one-way valve, coil, or thermal ablation) or surgical method may be considered in cases of heterogeneous or homogenous emphysema with significant hyperinflation which is refractory to optimum medical treatment. Lung transplant is also recommended for severe disease in specific indications.

ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The GOLD defines an exacerbation of COPD as "an acute worsening of the patient's respiratory symptoms that is beyond normal day-to-day variations and leads to a change in medication". This generally includes an acute change in one or more of the following cardinal symptoms:

- Cough increases in frequency and severity
- Sputum production increases in volume and/or changes character
- Dyspnea increases

Triggers

Respiratory infections are estimated to trigger approximately 70% of COPD exacerbations. Viral and bacterial infections cause most exacerbations, whereas atypical bacteria are a relatively uncommon cause. The remaining 30% are due to environmental pollution, pulmonary embolism, or have an unknown etiology. Some COPD exacerbations of unknown etiology may be related to other medical conditions, such as myocardial ischemia, heart failure, aspiration, or pulmonary embolism.

Risk Factors

According to observational studies, the risk of developing an exacerbation of COPD correlates with:

- Advanced age
- Productive cough
- Long-standing COPD
- Recent history of antibiotic therapy or oral steroids
- COPD-related hospitalization within the previous year
- Need for intensive care unit (ICU) admission in previous year
- Increase in pollution levels in air
- Chronic mucus hypersecretion
- Peripheral blood eosinophil count $>0.34 \times 10^9$ cells per liter
- Comorbidities (e.g., ischemic heart disease, chronic heart failure, or diabetes mellitus)

In general, worsening airflow limitation (FEV_1) is associated with an increasing risk of COPD exacerbation, although airflow limitation alone does not provide a good assessment of exacerbation risk.

Other potential contributors to an increased risk of exacerbations include the following:

- *Severity of COPD and history of prior exacerbations*:
  - *Low risk*: Typically, GOLD 1 or 2 (mild-to-moderate airflow limitation) and/or 0–1 exacerbation per year, no hospitalization due to an exacerbation.
  - *High risk*: Typically, GOLD 3 or 4 (severe or very severe airflow limitation) and/or ≥2 exacerbations per year or ≥1 hospitalization due to an exacerbation.
- *Gastroesophageal reflux disease* (GERD) may be an additional risk factor for COPD exacerbations.
- *Pulmonary hypertension*: Secondary pulmonary hypertension may be an additional risk factor for COPD exacerbations.

Clinical Features

By definition, patients present with the acute onset or worsening of respiratory symptoms, such as dyspnea, cough, and/or sputum production, over several hours to days. For patients with a mild exacerbation (absence of resting dyspnea or respiratory distress, preserved ability to perform activities of daily living), who do not require emergency department treatment, the evaluation may be limited to clinical assessment and possibly pulse oxygen saturation.

Patients who require emergency care, the evaluation should generally include the following:

- Assessment of pulse oxygen saturation
- A chest radiograph to look for pneumonia, pneumothorax, pulmonary edema, and pleural effusion
- Laboratory studies (e.g., complete and differential blood counts, serum electrolytes, and glucose).
- *Arterial blood gas (ABG) analysis*: Pulse oximetry is checked in routine follow-up of COPD patients. However, it does not give information on partial pressure of carbon dioxide (PCO_2). If the patient is stable and SpO_2 is >88%, ABG is not routinely required. However, if acute or chronic respiratory acidosis is suspected or if ventilatory support is anticipated, ABG should be checked.
- *Microbiology*: Sputum Gram stain and culture are often not useful for identifying bacterial infection in patients with COPD exacerbations and are not obtained for most exacerbations of COPD. Sputum culture may be helpful in patients who are strongly suspected of having a bacterial infection but fail to respond to initial antibiotic therapy.

While not necessary in most patients, evaluation for possible respiratory virus infection by polymerase chain reaction (PCR) diagnostic panels have been developed that can detect multiple respiratory viruses (e.g., influenza, adenovirus, parainfluenza virus, respiratory syncytial virus, human metapneumovirus, coronavirus, and rhinovirus) if clinically indicated. Although the exact indications for their use in COPD exacerbations are not clear.

Severity of Exacerbation

- *Mild*: Mild tachypnoea [respiratory rate (RR) 20–30 breaths/min], no accessory muscle of respiration, no altered sensorium, hypoxia easily correctable with low flow oxygen, and no hypercarbia.
- *Moderate*: Tachypnea (RR > 35 breaths/min), accessory muscle of respiration active, no altered sensorium, hypoxia easily correctable with low-flow oxygen (venturi 28–40%), and rise in PCO_2 above usual PCO_2 or between 50 and 60 mm Hg.
- *Severe*: Tachypnoea (RR > 35 breaths/min), accessory muscle of respiration active, altered sensorium present, hypoxia not easily correctable with low-flow oxygen (requiring >40% venturi), rise in PCO_2 above 60 mm Hg, or respiratory acidosis (pH < 7.25).

Patients with COPD who present to the hospital with acute worsening of dyspnea should also be evaluated for potential alternative diagnoses (**Table 2**). The importance of considering alternate diagnoses was illustrated in an autopsy

TABLE 2: Differential diagnosis of the chronic obstructive pulmonary disease (COPD).	
Pneumonia	Chest radiograph, C-reactive protein (CRP), and/or procalcitonin
Pneumothorax	Chest radiograph or ultrasound
Pleural effusion	Chest radiograph or ultrasound
Pulmonary embolism	• D-dimer and/or Doppler sonogram of lower extremities • Chest tomography—pulmonary embolism protocol
Pulmonary edema due to cardiac diseases	Electrocardiogram, cardiac ultrasound, and cardiac enzymes
Arrhythmias—atrial fibrillation/flutter	Electrocardiogram
Fluid overload	Chest X-ray and ultrasound chest to look for B lines

study of 43 patients with COPD who died within 24 hours of admission for a COPD exacerbation. The primary causes of death were heart failure, pneumonia, pulmonary thromboembolism, and COPD in 37, 28, 21, and 14%, respectively. A chest radiograph will differentiate among several of these possibilities. A clear chest radiograph may be a clue to pulmonary embolism, especially when dyspnea and hypoxemia are more prominent than cough or sputum production.

MANAGEMENT OF EXACERBATION

Goals

Goals are reversing airflow limitation with inhaled short-acting bronchodilators and systemic glucocorticoids, treating infection, ensuring adequate oxygenation, and averting intubation and mechanical ventilation. Other goals of care are to prevent complications of immobility, such as thromboembolic and deconditioning, improve nutritional status, and aid patients who smoke with smoking cessation.

Oxygen Therapy

Supplemental oxygen is a critical component of acute therapy. Because of the risk of worsening hypercapnia use controlled oxygen to maintain a pulse SpO_2 of 88–92% or an arterial oxygen tension (PaO_2) of approximately 60. In two small randomized trials, titrating supplemental oxygen to SpO_2 88–92% resulted in a lower mortality compared with high-flow (nontitrated) oxygen. Venturi masks are the preferred means of oxygen delivery because they permit a precise delivered fraction of inspired oxygen (FiO_2). Venturi masks can deliver a FiO_2 of 24, 28, 31, 35, 40, or 60%.

High-flow Nasal Cannula

Provides supplemental oxygen (adjustable FiO_2) at a high-flow rate (up to 60 L/min), resulting in a low level of continuous positive airway pressure. The specific indications for high-flow nasal cannula (HFNC) remain unclear, and robust comparisons of HFNC with NIV in patients with COPD exacerbations are lacking. Requirement for high FiO_2 to correct hypoxemia (> 4 L/min by nasal cannula or 35% by mask) should prompt consideration of pulmonary emboli, acute respiratory distress syndrome, pulmonary edema, or severe pneumonia as the cause of respiratory failure. Hypercapnia is generally well tolerated in patients with chronic hypercarbia. However, mechanical ventilation may be required if hypercapnia is associated with depressed mental status, profound acidemia, hemodynamic instability, or cardiac dysrhythmias.

β-adrenergic Agonist

These medications may be administered via a nebulizer or a MDI with a spacer device and may be combined with a short-acting antimuscarinic agent (e.g., albuterol and levalbuterol). Typical doses of albuterol for this indication are 2.5 mg (diluted to a total of 3 mL) by nebulizer every 1–4 hours as needed, or four to eight puffs (90 μg per puff) by MDI with a spacer every 1–4 hours as needed. Increasing the dose has not been shown to confer an advantage in COPD and can cause side effects. The British Thoracic Society guidelines suggest using air, rather than oxygen-driven bronchodilator nebulization, or limiting oxygen-driven treatments to 6 minutes to prevent risk of hypercarbia due to high-oxygen delivery. Subcutaneous injection of short-acting beta adrenergic agonists (e.g., terbutaline and epinephrine) carries a high risk for inotropic and chronotropic adverse effects, such as arrhythmias or myocardial ischemia, and is almost never used for COPD exacerbations.

Anticholinergic Agents

These agents are typically used with SABA for patients who require hospital-based treatment of a COPD exacerbation. Typical doses of ipratropium in this situation are 500 μg by nebulizer every 4 hours as needed. Alternatively, two to four puffs (18 μg per puff) can be administered by MDI with a spacer every 4 hours as needed.

Systemic Glucocorticoids

Addition of glucocorticoids to above therapies improve symptoms, lung function, and decrease the length of hospital stay. The optimal dose of systemic glucocorticoids for treating a COPD exacerbation is unknown. The GOLD guidelines advise using the equivalent of prednisone 40 mg once daily for the majority of COPD exacerbation. Frequently used regimens range from prednisone 30–60 mg, once daily, to methylprednisolone 60–125 mg, two to four times daily, depending on the severity of the exacerbation.

Antibiotics

Most clinical practice guidelines including the GOLD guidelines recommend antibiotics for patients having a moderate-to-severe COPD exacerbation that requires hospitalization. It has shown to shorten time to recover, reduce risk of early relapse, treatment failure, and hospitalization. The initial antibiotic regimen should target likely bacterial pathogens (*Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae* in most patients) and take into account local patterns of antibiotic resistance. The choice of

antibiotics is usually a beta lactam, macrolides, or tetracycline; however, in patients with frequent exacerbation anti-*Pseudomonas* or multidrug-resistant organisms cover should be given. Antiviral therapy is recommended for patients with clinical and laboratory evidence of influenza infection. Because of the risk of acute bronchoconstriction with inhalation of zanamivir, oseltamivir is preferred unless local resistance patterns suggest a likelihood of oseltamivir-resistant influenza.

Therapy without Documented Evidence

Mucoactive agents, methylxanthines, and mechanical techniques to augment sputum clearance have not been shown to confer benefit for patients with a COPD exacerbation.

Chest Physiotherapy

Mechanical techniques to augment sputum clearance, such as directed coughing, chest physiotherapy with percussion and vibration, intermittent positive pressure breathing, and postural drainage have not been shown to be beneficial in COPD and may provoke bronchoconstriction.

Supportive Care

Supportive care for patients hospitalized with an exacerbation of COPD may include one or more of the following therapies:

- *Cigarette smoking cessation*: Hospitalization may provide an opportunity for patients to move towards cigarette smoking cessation.
- *Thromboprophylaxis*: Hospitalization for exacerbations of COPD increases the risk for deep venous thrombosis and pulmonary embolism.
- *Nutritional support*: Electrolyte balance—keep a close watch on electrolytes, especially potassium levels.

TRIAGE TO HOME OR HOSPITAL

An important step in the initial evaluation is to determine whether the patient needs hospitalization or can be safely managed at home. More than 80% of exacerbations of COPD can be managed on an outpatient basis, sometimes after initial treatment in the outpatient department (OPD) or emergency department. *Criteria that might lead to a decision to hospitalize the patient have been proposed in the GOLD guidelines and include:*

- Inadequate response to outpatient or emergency department management
- Onset of new signs (e.g., cyanosis, altered mental status, and peripheral edema)
- Marked increase in intensity of symptoms over baseline increased oxygen
- Sever hemodynamic instability
- Altered or worsening of sensorium
- Worsening hypoxemia (PaO_2 < 40 mm Hg) or (pH < 7.25) despite NIV
- Need for invasive mechanical ventilation
- Underlying COPD (e.g., $FEV_1 \leq 50\%$ of predicted)
- History of frequent exacerbations or prior hospitalization for exacerbations
- Serious comorbidities including pneumonia, cardiac arrhythmia, heart failure, diabetes mellitus, renal failure, or liver failure
- Frailty
- Insufficient home support

If the exacerbation appears life-threatening or if there are indications for ventilatory support (e.g., hypoxemic or hypercapnic respiratory failure), the patient should be admitted to the ICU as quickly as possible.

NONINVASIVE VENTILATION

Noninvasive ventilation (also known as noninvasive positive pressure ventilation or NPPV) refers to mechanical ventilation delivered through a noninvasive interface, such as a face mask, nasal mask, or nasal prongs. NIV has shown a success rate of 80–85% in acute exacerbation of COPD. NIV has shown to improve hypercarbia, hypoxemia, reduce work of breathing, and dyspnea. It has shown to reduce mortality, intubation rate, length of hospital stay, and risk of ventilator-associated pneumonia (VAP).

Position statement of the Indian Society of Critical Care Medicine (ISCCM) also recommends use of NIV in COPD patients with acute on chronic respiratory acidosis (pH 7.25–7.35) and acute exacerbation of COPD (PCO_2 > 45 and pH < 7.25) unless immediate intubation is required.

Most commonly, NIV is initiated in the emergency department, ICU, or a specialized respiratory unit to enable close monitoring.

The optimal initial mode and settings for NIV have not been established. A reasonable approach is to initiate NIV in a spontaneously triggered mode with a backup RR, an inspiratory pressure of 8–12 cmH_2O, and an expiratory pressure of 3–5 cmH_2O. The inspiratory pressure is gradually increased as needed to achieve alleviation of dyspnea and good patient-ventilator synchrony. Expiratory positive airway pressure (EPAP) is slowly increased if there is ineffective triggering. It is very important that these patients are explained the procedure properly to improve compliance with the use and monitored closely for any deterioration. It is labor intensive. In case of failure, that is if the patient is not improving in 2–4 hours or any deterioration, you should immediately intubate these patients.

MECHANICAL VENTILATION

Indications of Mechanical Ventilation

The primary objectives include supporting oxygenation and ventilation, minimizing the work of breathing, reverting muscle fatigue, and avoiding dynamic hyperinflation (DHI).

- Cardiorespiratory arrest
- Failure of NIV or unable to tolerate NIV
- Severe dyspnea with clinical signs of respiratory muscle fatigue
- Increased work of breathing, not improving with NIV
- Respiratory acidosis [arterial pH ≤ 7.35 and arterial tension of carbon dioxide ($PaCO_2$) ≥ 45 mm Hg (≥6 kPa)]
- Life-threatening hypoxemia
- Worsening sensorium
- Hemodynamic instability and life-threatening asthma
- Unable to clear secretion and recurrent vomiting

For patients who require mechanical ventilation for acute respiratory failure complicating COPD, volume-targeted modes of ventilation should be preferred over pressure

support or pressure-limited modes of ventilation. Among the volume-targeted modes, choose assist control ventilation (ACV). Synchronized intermittent mandatory ventilation with pressure support ventilation (SIMV/PSV) may be used if ACV results in hyperventilation.

Endotracheal Intubation and Ventilation

Endotracheal intubation should be performed with utmost care to avoid DHI in these patients. It is important not to overventilate during bag-mask ventilation. The rate of bag-mask should be 10–12/min with adequate time for expiration. Sometimes patients develop hypotension or bradycardia during intubation. To prevent this it is advisable to give a fluid bolus before giving sedatives and reduce the rate of bagging further. If no contraindication, give ketamine and midazolam as inducing agents.

Initiate mechanical ventilation with the following initial settings for each mode:

- *Assist control mode:* For patients in whom ACV is chosen as the initial mode of ventilation, use the following settings:
  - FiO_2 to maintain the oxygen saturation of hemoglobin (SO_2) >92%
  - *Tidal volume*: 6–8 mL/kg
  - *Ventilator rate*: 10–16 breaths/min (target minute ventilation 115 mL/kg)
  - *Positive end-expiratory pressure (PEEP)*: 5–10 cmH_2O
  - *Inspiratory flow: 60 L/min. Aim inspiratory*: expiratory (I:E) 1:3 or more
  - *Trigger sensitivity*: –1 to –2 cmH_2O when pressure triggering is used or 2 L/min when flow triggering is used
- *Synchronized intermittent mandatory ventilation/ pressure support ventilation*: Usually less used for short-term ventilation. If chosen, use similar settings to ACV with the addition of pressure support (5–10 cmH_2O) for spontaneous breaths taken by the patient above the set rate. The pressure support can be subsequently increased as needed for patient comfort.
- *Pressure-limited ventilation*: Although rarely chosen as an initial mode of ventilation. Set the inspiratory pressure to target a tidal volume of 4–8 mL/kg and an I:E ratio of no less than 1:3. The FiO_2, ventilator rate, applied PEEP, flow settings, and trigger sensitivity are similar to those of ACV.
- *Pressure support volume*: Usually used as a weaning mode. Titrate pressure support to keep RR < 30 breaths/min.

Patients with COPD will often have higher than expected minute ventilation requirements and increased carbon dioxide retention, which typically improves over the patient's course.

Subsequent adjustments should be made based upon the patient's clinical status, comfort level, gas exchange, and propensity for developing *DHI. Intrinsic PEEP (also known as auto-PEEP)* is common in patients with COPD who are mechanically ventilated, due to a high prevalence of spontaneous or ventilator-induced DHI. Auto-PEEP can result in patient-ventilator dyssynchrony, increased work of breathing, barotrauma, cardiovascular collapse, and even death. The prevention and treatment of DHI is primarily achieved through a reduction in RR and/or or tidal volume, raising the inspiratory flow rate, the application of extrinsic PEEP, and treating underlying airflow obstruction (if present) with bronchodilators and glucocorticoids. Patients should receive adequate sedation and analgesia during ventilation. Narcotic (morphine or fentanyl) infusion plus midazolam infusion should be given. There is some data on use of midazolam causing delirium and some advice to use dexmedetomidine instead. Use of muscle relaxants should be minimized.

Patients should be aggressively treated with bronchodilators, glucocorticoids, and antibiotics. Major complications of mechanical ventilation include barotrauma, volutrauma, risk of VAP, and prolonged ventilation. It is recommended that the patient should be ventilated for 48 hours and if there is no major pneumonia and hemodynamic instability, the patient can be extubated to NIV. NIV has shown to improve the success of extubation and reduce the need for reintubation.

CRITERIA FOR DISCHARGE AND ADVICE

- Check all clinical and laboratory data
- Plan treatment advice and explain the plan
- Check inhaler technique. Assess need for oxygen and NIV
- Remember to give treatment for comorbid conditions
- Advice for early (4 weeks) and late (12 weeks) follow-up
- Reinforce smoking quitting

FOLLOW-UP ASSESSMENT

- Take detailed history including smoking history and examination
- On each follow-up check inhaler technique
- Perform spirometry with post bronchodilator study at least yearly
- Assess exercise tolerance. 6-minute walk test is useful to assess prognosis
- Assess health status
- Assessment of muscle strength and lower limb strength
- Check for vaccination
- Self-management plan for worsening symptoms and exacerbation should be given

PREVENTION

Smoking Cessation

Smoking cessation is the key to prevent progression of COPD. If effective resources and time is given, success rate is high approaching 25%. Use of nicotine replacement products such as nicotine gum, chewing gum, inhaler, transdermal patch, and pharmacotherapy may help to achieve long-term abstinence. However in case of recent myocardial infarction or stroke, nicotine replacement should only be started after 2 weeks. Use of E-cigarettes to aid cessation of smoking is controversial.

Vaccination

- *Influenza vaccine*: It is shown to reduce serious illness and death in COPD patients. Risk of reduced exacerbation

was seen by some studies. Either killed or live inactivated vaccines can be given.

- *Pneumococcal vaccine*: The 23-valent pneumococcal polysaccharide vaccine (PPSV23) and conjugate 13-valent pneumococcal conjugate vaccine (PCV13) has been recommended for all patients > 65 years of age. PPSV23 is also recommended for younger COPD with comorbidities like chronic heart or lung disease. PPSV23 has been shown to reduce the incidence of community-acquired pneumonia (CAP) in COPD patients < 65 years, FEV_1 < 40% predicted and associated comorbidities. PCV13 was shown to reduce vaccine-type CAP (45.6%) and vaccine-type pneumococcal disease by 75%.

PROGNOSIS

Exacerbations of COPD are associated with increased mortality. Even if the COPD exacerbation resolves, many patients never return to their baseline level of health.

Palliative Care

Given the high 1-year mortality rate after hospitalization for a COPD exacerbation, it may be appropriate to consider a palliative care referral during or shortly after a hospitalization for COPD. Palliative care assessment can help explore the patient's understanding of their illness and prognosis, assess and manage symptoms, discuss the patient's goals of care and advance care planning, and help plan end-of-life care.

SUMMARY

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease that makes it difficult to empty air out of the lungs. This difficulty in emptying air out of the lungs (airflow obstruction) can lead to shortness of breath or feeling tired because patient working harder to breathe. COPD is a term that is used to include chronic bronchitis, emphysema, or a combination of both conditions. Asthma is also a disease where it is difficult to empty the air out of the lungs, but asthma is not included in the definition of COPD. It is not uncommon, however, for a patient with COPD to also have some degree of asthma. The first and most important aspect of management in smokers is to stop smoking. Medications are usually prescribed to widen the airways (bronchodilators), reduce swelling in the airways (anti-inflammatory drugs, such as steroids), and/or treat infection (antibiotics). Surgical procedures such as lung volume reduction surgery or lung transplantation may be helpful for some cases of COPD. Pulmonary rehabilitation programs offer supervised exercise and education for those with breathing problems.

CHAPTER

Pneumonia

Ashish Kumar Prakash, Reena Verma, Anand Jaiswal

INTRODUCTION

The word "pneumonia" almost always refers to a syndrome which is due to acute infection usually bacterial (may also be other microorganism), characterized by clinical and/or radiographic signs of consolidation of a part or parts of one or both lungs. Pneumonitis is sometimes used as a synonym for pneumonia, particularly when inflammation of lung has noninfectious etiology such as chemical, radiation, or interstitial. Pneumonia can be classified as anatomical and etiological given in (**Table 1**). Here we will provide a glimpse of acute pneumonia in adults. The most common causes of pneumonia with acute presentation are viruses, pneumococcus, and mycoplasma. In India, apart from those we can also get *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Legionella pneumophila*, or others as a causative agent for community-acquired pneumonia (CAP).

TABLE 1: Classification of pneumonia.

Basis	*Types*
Anatomical location	• Lobar • Multilobar • Segmental • Subsegmental • Bronchopneumonia
Etiological (microbiological)	• Bacterial • Viral • Fungal • Parasitic • Chemical (e.g., lipoid) • Physical (ionizing)
Empiricist's	• Community-acquired pneumonia (CAP) • Hospital-acquired pneumonia (HAP) or nosocomial pneumonia • Ventilator-associated pneumonia (VAP) • Aspiration pneumonia • Immunocompromised host pneumonia
Behaviorist's	• Easy pneumonia (responds to early treatment) • Difficult pneumonia (fails to do so)
Clinician's perspective	• Typical pneumonia • Atypical pneumonia

CLASSIFICATION OF PNEUMONIA

The main challenge in the emergency department (ED) for emergency physician is identifying the cause of the infection for pneumonia so that appropriate antibiotic treatment can be started at earliest apart from making the diagnosis of pneumonia. Patients with higher risk of mortality (i.e., hospitalized inpatients) are most beneficial with this strategy. At the time of the ED assessment, the initial therapy with antibiotics is empiric because microbiological testing results are not available. Thus, it is important to classify pneumonia to facilitate the decision-making process with regard to the institution of empiric antibiotics. *The traditional classification of pneumonia expressed as the terminology of typical or atypical pneumonia*. The *typical pneumonia* most commonly caused by *Streptococcus pneumoniae*, and clinically presents as high fever, rigors, cough with rust-colored sputum, and laboratory findings of leukocytosis. Microbiology revealed gram-positive encapsulated diplococci. The classic chest radiograph [chest X-ray (CXR)] appearance in this setting is lobar consolidation. *Streptococcus pneumoniae* is responsible for approximately 60% of CAP. The clinical presentation of *atypical pneumonia* is more gradual onset, dry cough, in healthy and ambulatory individuals. Often no organisms identified on microbiology on Gram stain because most commonly they did not have cell walls. The CXR appearance, more often an interstitial pattern. *Mycoplasma, Legionella,* and *Chlamydophila* are the most commonly described atypical organisms. The main challenge in classifying the pneumonia in typical and atypical is that in clinical practice the overlapping of presentations of these infections whereby a pneumococcal infection may present with an interstitial pattern on CXR and atypical clinical symptoms and vice versa.

So, in ED a more practical classification of pneumonia is needed to implement in which environmental contact combined with host factors is considered, so that likely offending agent can be identified. The pneumonia can be

classified broadly into four categories: CAP; hospital-acquired pneumonia (HAP); healthcare-associated pneumonia (HCAP); and ventilator-associated pneumonia (VAP). This practical classification of pneumonia is helpful for the emergency physician in implementing the appropriate empiric treatment. Thus, emergency physician should focus not only on the symptoms of pneumonia but also take history about setting in which the pneumonia is acquired, any recent travel or animal exposures along with any host risk factors that could predispose to certain types of infection and also predict patient outcome.

Community-acquired pneumonia is defined as an acute infection of the pulmonary parenchyma, contracted outside the hospital, with clinical symptoms of pneumonia along with the presence of an infiltrate on CXR. The diagnosis of CAP requires that a patient should not be hospitalized or in a nursing home in the previous 14 days. *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, *Chlamydophila* species, and viruses are the most common pathogens implicated in the development of CAP. A new respiratory infection that develops after >48 hours of hospital admission is HAP. Another group of patients in which repeated or multiple hospitalization is required includes patients undergoing dialysis or chemotherapy, chronic wound care or home intravenous antibiotics care, the immunocompromised patient population, and patients from nursing home facilities, so parenchymal infections in these patients hospitalized for 2 or more days in the previous 90 days is termed as HCAP. If pneumonia that is diagnosed >48 hours of patient intubation and mechanical ventilation in the intensive care unit (ICU) is termed as VAP. Schematic view of this classification of pneumonia and the most common pathogenic organisms associated with infection is provided in **Figure 1**. Predominately gram-negative bacteria are responsible for the latter three classes (HAP, VAP, and HCAP). Acinetobacter is a pathogen associated with VAP specifically, and particularly higher morbidity and mortality is seen with the three encapsulated bacteria (*S. pneumoniae*, *Klebsiella*, and *H. influenzae*) infections.

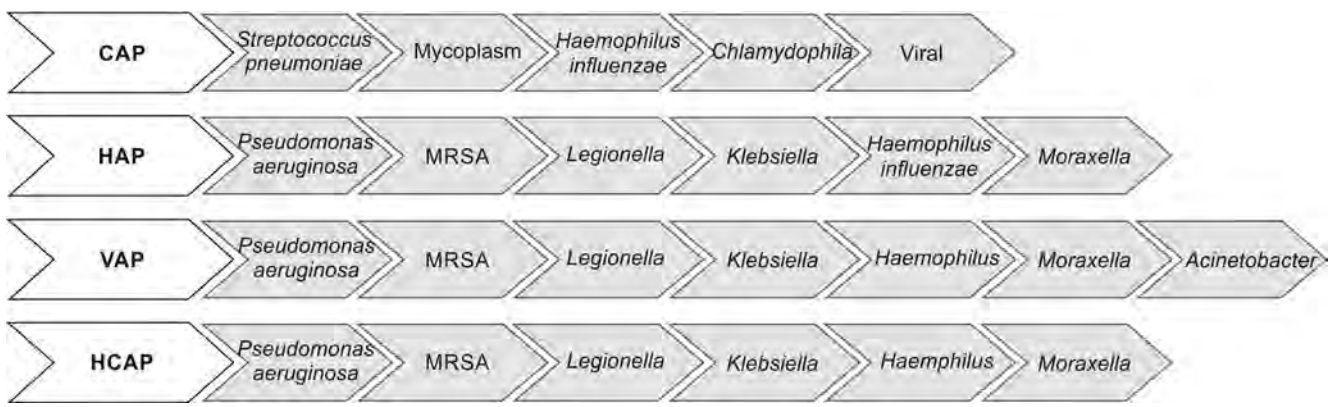
Patient suffering from chronic illness such as lung, heart, or kidney disease, sickle cell anemia, or diabetes having greatest risk of pneumococcal pneumonia. *Klebsiella*, *Legionella*, and *methicillin-resistant Staphylococcus aureus* (MRSA) infections are associated with high mortality. The clinical symptoms of pneumonia caused by various agents are often overlap so approach of antibiotic treatment of pneumonia in the ED is mostly empiric. The typical cardiovascular reaction to fever is tachycardia. Certain pneumonias due to *Legionella*, *Mycoplasma*, and tularemia may be associated with fever and relative bradycardia (Faget sign). Yellow fever, typhoid fever, brucellosis, and Colorado tick fever are the other infections associated with this clinical sign.

PATHOPHYSIOLOGY

Pneumonia is an alveolar infection that occurs due to defective and compromise innate immune system, and lower airway and alveoli unable to clear a pathogen from the respiratory tract. Lung parenchyma further damaged by local inflammatory factors and cytokines and lead to systemic inflammation, which causes secondary symptoms such as fever, chills, and fatigue. Due to the inflammatory response at histologic level, red and grey hepatization of lung tissues and congestion occurs and may resolve with minimal fibrosis. Mechanics and physiology of the lung also altered, decreased compliance of the lung and shunt occurs due to pus in the parenchyma, which increases the work of breathing and worsens hypoxemia and tachypnea—the most important bedside clinical features of severe pneumonia for emergency physicians. All ages group across the spectrum of health are affected by CAP. Specific patient subgroups are affected by certain organisms. Any condition like cigarette smoking causes risk of decreased mucociliary clearance and cough, conditions such as cerebral vascular accidents, esophageal disorders, and neuromuscular disorders lead to aspiration. Pneumonia is difficult to recognize in old age and dehydration, underlying cardiopulmonary disease, or structural lung disease.

CLINICAL EVALUATION

For typical pneumonias, cough, fever, and chest pain are the common presentation with which the patients come to the ED. Cough may be with expectoration whitish to greenish; rarely patients can have hemoptysis. Mucopurulent sputum



(CAP: community-acquired pneumonia; ED: emergency department; HAP: hospital-acquired pneumonia; HCAP: healthcare-associated pneumonia; MRSA: methicillin-resistant *Staphylococcus aureus*; VAP: ventilator-associated pneumonia)

FIG. 1: Practical classification of pneumonia for ED. (Viral includes influenza A and B, adenovirus, respiratory syncytial virus, and parainfluenza).

is mostly found with bacterial pneumonia. Patients may present only with high-grade sudden onset of fever, which is continuous, but many a times patients have already taken antipyretics for that. Chest pain can be pleuritic or dull aching in nature. Atypical presentation may also occur such as poor oral uptake, nausea, vomiting, diarrhea, change of mental status, or disorientation. This is more common in elderly patients. For clinician's perspective and management point of view in emergency it is very important to distinguish between atypical and atypical pneumonia (**Table 2**). Most of the time it is radiologically decided in Triage whether, it is typical and or atypical pneumonia. This is very important to differentiate between them and to decide about antibiotics and to add other supportive medicine. On general physical examination the patients are febrile with tachycardia and tachypnea. Sometimes relative bradycardia is also found in atypical pneumonia with *Mycoplasma, Legionella, Chlamydia psittaci, Francisella tularensis,* and *Mycoplasma pneumoniae*.

There are a few signs which can indicate serious illness or severe pneumonia such as cyanosis, nasal flaring, use of accessory muscles of respiration leading to intercostal or supraclavicular indrawing, respiratory rate >30 breaths/minute, heart rate >125 bpm, hypotension, and altered level of consciousness. In emergency, it is very important to detect pneumonia clinically and till X-ray and CT chest is done. Antibiotics first dose (to hit early and hard) can be given empirically. Though in modern era the medical science is more and more inclined towards investigations, but clinical examination and history taking is always very important either in emergency or in outpatient department (OPD). The important clinical signs the can give clue for consolidation in lung (may be absent):

- *Inspection*: While examining the respiratory system properly we may get decreased movement and tachypnea.
- *Palpation*: Tactile vocal fremitus (TVF) which is basically an increased vibration felt from the examining clinician's hand when patient is asked to say repeatedly sound like "*ek-do-teen*". It is very important to compare symmetrical areas on both side of chest. This is due to increased sound conduction at the consolidation side/lobe.
- *Percussion*: Dull note can be elicited if there is large lobar consolidation.
- *Auscultation*: Crackles or crepitation are most common findings in pneumonia. If lobar consolidation is there on auscultation with stethoscope, we may get:
  - Bronchial breath sound—harsh high-pitched inspiratory and expiratory sounds with a clear pause between them and has distinctive character
  - Vocal fremitus—audible TVF
  - Whispering pectoriloquy—whispered voice clearly transmitted to chest wall
  - Bronchophony—spoken voice is unduly loud and intense
  - Egophony—spoken voice has nasal quality like "bleating of goat"

TABLE 2: Differentiating features of typical and atypical pneumonia.

	Typical pneumonia	***Atypical pneumonia***
Microorganism	Mostly bacterial may be virus	Viral bacterial fungal protozoal
Signs and symptoms	Fever cough may be present and bulk sputum with productive cough	Fever, headache, sore throat, and upper respiratory tract also involved. Sweating and myalgia are common. Sputum is mild or absent produces nonproductive cough
Lab parameters	Raised WBC, ESR, CRP, and procalcitonin	ESR and CRP may be raised rest may be normal
Aggravating factors	Nonspecific	Air-conditioned environment, especially air-condition are not maintained
Presence of extrapulmonary symptoms and hypoxia	Rare	Yes
Treatment	Mainly antibiotics	To be given as per cause and other supportive management

(CRP: C-reactive protein; ESR: erythrocyte sedimentation rate; WBC: white blood cell)

DIAGNOSTIC APPROACH

Radiology

Chest X-ray is always advisable for patients with clinical suspicion of pneumonia. We most commonly see the patchy consolidation mainly confined to the lobes with air bronchogram or interstitial infiltrates as nonhomogeneous opacity and or cavity. If CXR is not informative, then we may have to ask for chest CT to rule out mass, effusion, cavity, etc. Computed tomography, i.e., CT chest is only advisable in case of nonresolving pneumonia or clinical worsening. Radiology either CT or X-ray may be helpful in differentiating between typical and atypical pneumonia (**Table 3**). Ultrasound of chest is also useful for detection of pleural effusion or pneumonia with parapneumonic effusion.

Microbiology

Sputum Gram stain and cultures are advice for all admitted patients. The sputum Gram stain is very useful for directing the choice of initial therapy but needs to be performed on a good quality sample and by a skilled microbiologist. The Infectious Diseases Society of America (IDSA) now recommends sputum and blood culture in patients with severe disease as well as in all inpatients who is on empirically treatment for MRSA or *Pseudomonas aeruginosa*. Sputum for acid-fast bacilli (AFB) should be obtained for nonresponders as per Revised National Tuberculosis Control Programme (RNTCP) guidelines. US Food and Drug Administration (FDA) has also approved some newer test that include polymerase chain reaction (PCR) (multiplex PCR) for detecting atypical organism such as *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* as well as 14 respiratory tract viruses. We can use it for sputum as well

TABLE 3: Radiologic differentiating features of typical and atypical pneumonia.

	Radiologic features of typical pneumonia	***Radiologic features of atypical pneumonia***
Features	• Consolidation • Typical air bronchogram • Bronchopulmonary segment. • May be lobar or multilobar infiltration not seen in perihilar region and localized centrally within the lobes and not toward the periphery. Any lobes can be affected	Often reflects a primary infection before features of atypical pneumonia develops. This phase is also called occult pneumonia. Infiltration begins in peripheral region and spread to periphery and not restricted to lobes. Lower lobes are predominantly affected. However other lobes are also involved. There may be ground glass opacities and interstitial shadow
Schematic presentation		X-ray/CT		
as for other respiratory samples such as bronchial washings and endotracheal secretions. These tests are rapid, sensitive, and specific.

Hematological

Total and differential leukocyte count (TLC and DLC) is of great value in dealing with pneumonia patients. In bacterial pneumonia, it is usually raised with neutrophilic predominance. It is also used for monitoring treatment response. Other important hematological tests apart from routine liver and renal function test are C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and serum procalcitonin. CRP and ESR has good prognostic role and serum procalcitonin is of diagnostic value for bacterial pneumonia. Procalcitonin guidance for antibiotic had a great impact and it was found that there was reduction in antibiotic exposure without an increase in mortality or treatment failure. Most of the time procalcitonin is able to differentiate between viral and bacterial infection and is very useful. But the sensitivity of procalcitonin for detection of bacterial infection ranges from 38 to 91%. There is a need of clinicoradiological correlation of this test to justify withholding antibiotics from patients with CAP having normal procalcitonin value. The role of procalcitonin to determine for initial antibacterial therapy is not recommended. Apart from these tests, urinary pneumococcal antigen and blood cultures are also of good diagnostic utility. Blood culture is only recommended for hospitalized patients (severe and patient on empiric treatment for MRSA or *Pseudomonas aeruginosa*) and not for patients who need treatment on OPD basis.

Serologic Testing

In the ED serologic testing for CAP, e.g., for *Chlamydia* species, *Legionella*, and some fungi are useful only from a retrospective perspective because they usually require both acute and convalescent serum titters. For influenza and respiratory syncytial virus (RSV) rapid antigen tests are also available. These serological tests may be useful as an adjunctive ED test for infection control purposes for hospital inpatients and as an aid in decision making regarding family and contact prophylaxis. For *Streptococcus pneumoniae* and *Legionella pneumophila* urinary antigen tests (UATs) are commercially available. In patients with more severe illness, these tests have the highest diagnostic yield. These antigen tests are rapid, simple to use, and have high specificity in adults.

Ultrasonography

Bedside ultrasonography has been used extensively in the ED for diagnosis of pulmonary conditions including pneumonia. In the diagnosis of radio-occult (negative CXR) pleural-pulmonary lesions bedside lung ultrasonography has been shown to be 96% sensitive and 96% specific. For the diagnosis of emergency pulmonary conditions, bedside lung ultrasonography is an ideal tool, with the benefit of the absence of radiation.

HOSPITAL ADMISSION DECISIONS

Assessment of the severity of illness is important for diagnostic and treatment decisions for pneumonia. These assessments of illness by scoring system affect the decision between inpatient and outpatient treatment and ICU admission versus admission to a general ward.

Scoring Systems

Two scoring systems can assist the emergency physician in the identification of patients who may be candidates for outpatient treatment: CURB-65 is a severity of illness score and the pneumonia severity index (PSI) is a prognostic model (**Table 4**). These objective criteria should be used along with physician judgment in clinical decision making. Patient compliance to oral medication and outpatient social support systems should be considered. The PSI uses a two-step approach to risk assessment. Patients who are considered as low risk, recommended for outpatient management. Patient's age 50 years, without significant comorbid conditions, and who have no red flags on physical examination are considered as low-risk patient. Patients are classified into categories based on age, comorbid illness, abnormal physical examination findings, and laboratory abnormalities who do not meet these low-risk criteria.

These scores are helpful in decreasing the admission rates and healthcare costs. However, the scoring system does not consider dynamic observation of patients over time, the ability to take oral medications, home supports, and access to follow-up.

CURB-65 is a more simplified tool that uses five criteria to determine patients at lower risk for adverse events. These criteria are confusion; uremia [blood urea nitrogen (BUN) >7 mmol/L]; respiratory rate (>30 breaths/minute); blood pressure (60 mm Hg diastolic); age of 65 years or greater.

Direct admission to an ICU or high-level monitoring unit is recommended for patients with either of the major criteria

TABLE 4: Comparison of CURB-65 and PSI scoring system.

CURB-65	*PSI (pneumonia severity index)*
• Confusion +1 • Blood urea nitrogen >7 mmol/L +1 • Respiratory rate >30 +1 • Systolic blood pressure <90 mm Hg • Diastolic blood pressure <60 mm Hg +1 • Age >65 +1	• Age • Female -10 • Nursing home resident +10 • Neoplastic disease history +30 • Liver disease +20 • Congestive heart failure +10 • Cerebrovascular disease +10 • Renal disease +10 • Altered mental status +20 • Respiratory rate >29 +20 • Systolic blood pressure <90 +20 • Temperature <35.5°C or >39.9°C +15 • Pulse >124 +10 • pH <7.35 +30 • Blood urea nitrogen (BUN) <29 +20 • Sodium <130+20 • Glucose <13.8 +10 • Hematocrit <30% +10 • Partial pressure of oxygen <60 +10 • Pleural effusion on X-ray +10

or with three of the minor criteria. *Major criteria are invasive mechanical ventilation or septic shock with the need for vasopressors*. **Table 5** shows the minor criteria for sever CAP.

TREATMENT OF PNEUMONIA

The initial approach to the pneumonia patient by a clinician either in emergency or in OPD is to access the severity, send the investigations (radiology and microbiology as discussed), and start the empirical treatment (**Table 6**). As per Indian guidelines the approach for pneumonia as depicted in algorithm (**Flowchart 1**). To assess the severity of pneumonia there are various scoring systems [CURB-65, CRB-65, SMART-COP, SMRT-CO, and American Thoracic Society-Infectious Diseases Society of America (ATS-IDSA) criteria] which can help us to decide regarding admission (ICU or ward) and OPD management. The most used is CURB-65 (**C**onfusion, **U**rea >7 mmol/L, **R**espiratory rate >30 breaths/minute, **B**lood pressure (systolic <90 mm Hg or diastolic <60 mm Hg), age >**65** years).

After empiric therapy we must follow-up the patients and if there is no response to the therapy within after 48–72 hours they should be re-evaluated. Once the culture report is available, the pathogen targeted therapy, if not started earlier can be started. To chase the culture report is very important for escalation or de-escalation of antibiotics. The first and foremost treatment of pneumonia is antibiotic but other supportive care also needs to be addressed like:

- Antipyretics
- Clear the airway
- Oxygen therapy, if needed
- Adequate hydration and nutrition
- Evaluate for ICU care
- Need to be seen for requirement of ventilator (noninvasive or invasive)

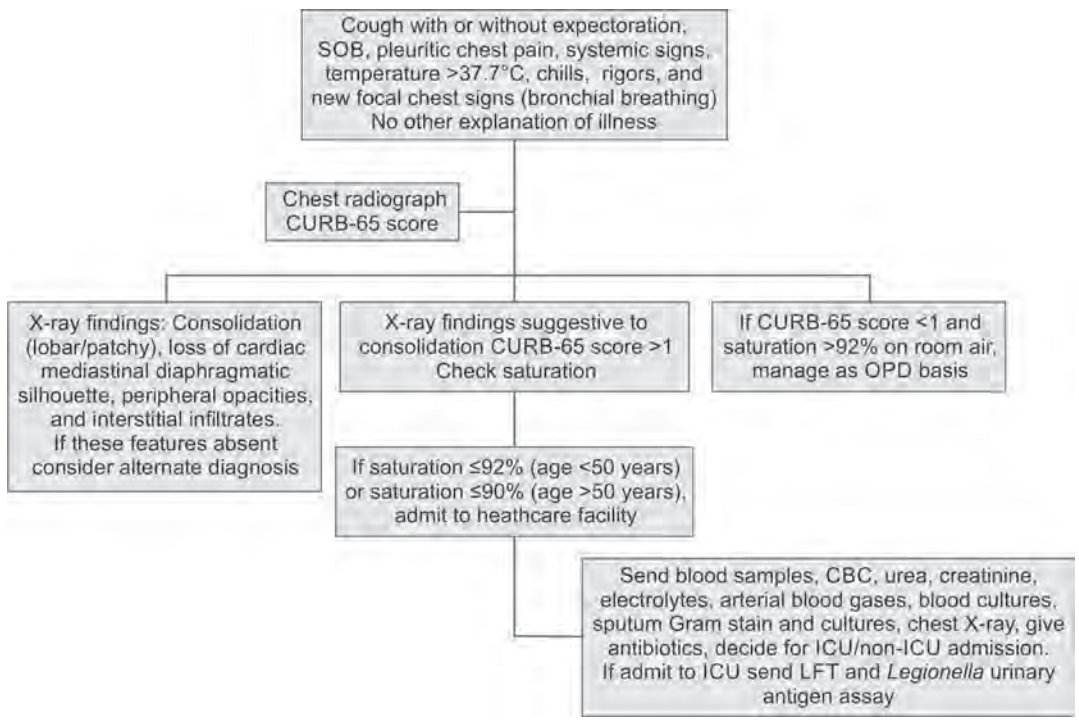
In emergency, oxygen supplement has very important role when respiratory failure (RF) is there. RF may range from mild to severe and is of different types. It is very important to understand and diagnose [on basis of arterial blood gas (ABG), oxygen saturation (SpO_2), etc.] the type of RF that would help in management.

- *Type 1 (hypoxemic)*: Arterial partial pressure of oxygen (PaO_2) < 60: Failure of oxygenation
- *Type 2 (hypoxia with hypercapnic)*: Arterial partial pressure of carbon dioxide ($PaCO_2$) >45: Failure to exchange or remove carbon dioxide and decreased alveolar minute ventilation, which is often accompanied by hypoxemia.
- *Type 3 (perioperative)*: Which is because of increased atelectasis due to low functional residual capacity (FRC) in the setting of abnormal abdominal wall mechanics that may results in type I or type II RF and can be ameliorated by anesthetic or operative technique, posture, incentive

TABLE 5: Minor criteria for severe CAP.

Physical examination	*CXR*	*Laboratory*
• Respiratory rates • Blood pressures require aggressive fluid and vasopressors • Hypoxemia PaO_2/FiO_2 ratio <250 • Mental status-confusion • Hypothermia temperature <36°C	Multilobar infiltrates	• Leukopenia: WBC <4,000 cells/mm^3 • Thrombocytopenia platelets counts <100,000 cells/mm^3

(CAP: community-acquired pneumonia; FiO_2: fraction of inspired oxygen; PaO_2: arterial partial pressure of oxygen; WBC: white blood cell)



Cough with or without expectoration, SOB, pleuritic chest pain, systemic signs, temperature >37.7°C, chills, rigors, and new focal chest signs (bronchial breathing) No other explanation of illness
Chest radiograph CURB-65 score
X-ray findings: Consolidation (lobar/patchy), loss of cardiac mediastinal diaphragmatic silhouette, peripheral opacities, and interstitial infiltrates. If these features absent consider alternate diagnosis
X-ray findings suggestive to consolidation CURB-65 score >1 Check saturation
If CURB-65 score <1 and saturation >92% on room air, manage as OPD basis
If saturation ≤92% (age <50 years) or saturation ≤90% (age >50 years), admit to heathcare facility
Send blood samples, CBC, urea, creatinine, electrolytes, arterial blood gases, blood cultures, sputum Gram stain and cultures, chest X-ray, give antibiotics, decide for ICU/non-ICU admission. If admit to ICU send LFT and *Legionella* urinary antigen assay

(CBC: complete blood count; ICU: intensive care unit; LFT: liver function test; OPD: outpatient department; SOB: shortness of breath)

FLOWCHART 1: Algorithm for approach to pneumonia in emergency department.

spirometry, postoperative analgesia, and attempts to lower intra-abdominal pressure.

- *Type 4 (shock)*: It is basically due to cardiovascular instability, among patients who are intubated and ventilated in the process of resuscitation for shock. Goal of ventilation is to stabilize gas exchange and to unload the respiratory muscles, lowering their oxygen consumption.

Mostly type 1 RF is managed by oxygen supplement or high-flow nasal cannula (HFNC) and patients with type 2 RF will require positive pressure ventilation support [continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and noninvasive ventilation (NIV)]. Failure to respond to any of this supportive management will lead to intubation and mechanical ventilation regardless of type of RF.

Oxygen supplement ⇔ HFNC ⇔ NIV ⇔ Mechanical ventilator

The treatment of RF is oxygen supplement. There are different modalities for oxygen supplement for managing hypoxia in pneumonia (**Table 7**) and various new emerging oxygen supplement equipment are coming to help patients of hypoxia in emergency and delivering FiO_2 in different rate (**Table 8**). Following are the modalities:

- *Nasal cannula*: It is an open device to deliver oxygen, but has low-flow and low-oxygen concentration. It is the simplest and cheapest way to deliver oxygen in hypoxic patients. Domiciliary oxygen can be provided and not much technical speciality is required. The FiO_2 delivery depends upon minute ventilation and amount of entrained room air, hence difficult to control its oxygen delivery accurately. The other limitation is that it does not increase the FiO_2 significantly in severe RF patients demanding more oxygen. High oxygen flow through nasal cannula rather leads to drying of the nasal mucosa and patient discomfort. Nasal prong is mainly used for relatively stable patients.
- *Venturi masks*: This device is used to deliver controlled and accurate amount of FiO_2. To deliver precise fraction of oxygen, variable oxygen concentration with color coding is there (aperture of different sizes). These masks supply oxygen through a jet-mixing device which causes a controlled entrainment of air and precise oxygen concentrations from 24 to 50% is delivered. This may be helpful in chronic obstructive pulmonary disease (COPD) patients who require controlled oxygen to prevent CO_2 narcosis.

TABLE 6: Initial empiric antimicrobial therapy for CAP.

Outpatient	*No comorbidities or risk factors for MRSA or Pseudomonas aeruginosa*: Amoxicillin or doxycycline or macrolide (if local pneumococcal resistance is 25%)
	With comorbidities: Combination therapy with amoxicillin/clavulanate or cephalosporin and macrolide or doxycycline OR monotherapy with respiratory fluoroquinolone
In Patient	*Non-ICU (nonsevere)*: A beta-lactam + macrolide OR respiratory fluoroquinolone
	ICU (severe): Pseudomonas not suspected: A beta-lactam plus either azithromycin or a fluoroquinolone
	Pseudomonas not suspected but patient allergic to beta-lactam: A fluoroquinolone and aztreonam
	Pseudomonas suspected: An antipneumococcal, antipseudomonal beta-lactam (piperacillin–tazobactam, cefepime, imipenem, or meropenem plus ciprofloxacin or levofloxacin 750 mg; or the above beta-lactam plus aminoglycoside and azithromycin. Or the above beta-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone (in penicillin-allergic patients use aztreonam instead of the beta-lactam)
	If MRSA is suspected, add vancomycin or linezolid
	India being a TB prevalent country fluoroquinolone are not recommended for empiric treatment
	Add MRSA or *P. aeruginosa* coverage and obtain cultures/nasal PCR to allow de-escalation or confirmation of need for continued therapy (if prior respiratory isolation of same)

(CAP: community-acquired pneumonia; MRSA: methicillin-resistant *Staphylococcus aureus*; PCR: polymerase chain reaction; TB: tuberculosis)

TABLE 7: Modalities to manage respiratory failure in pneumonia.

Modalities	***O_2 supplement***	***HFNC***	***Positive pressure***	***Mechanical ventilation***
Delivery methods	• Nasal cannula • Facemask • Venturi mask	Optiflow	• BiPAP • CPAP • AVAP • NIV	Mechanical ventilator
Intubation requirement	Noninvasive	Noninvasive	Noninvasive	Invasive
Respiratory failure	Type 1	Mainly type 1	Mainly type 2	Any type
Given at	Domiciliary, emergency, IPD, HDU, and ICU	Emergency, IPD, HDU, and ICU	Emergency, IPD, HDU, and ICU	ICU only
Contraindication	Can be given under strict monitoring particularly in COPD patients (may cause CO_2 narcosis)	Noncooperative patients	• Noncooperative patients • Copious secretion • Neck fracture	Not such

(AVAP: average volume assured pressure; BiPAP: bilevel positive airway pressure; COPD: chronic obstructive pulmonary disease; CPAP: continuous positive airway pressure; HDU: high dependency unit; HFNC: high-flow nasal cannula; ICU: intensive care unit; IPD: inpatient department; NIV: noninvasive ventilation)

- *Reservoir face masks*: It is high flow, high oxygen concentration, open device designed to minimize entrainment of air in patients with high inspiratory flow demand. These masks include a reservoir bag that is full of 100% oxygen. When the patient take breathe, effort generating a flow higher than the wall circuit can deliver, the reservoir of oxygen will be emptied to minimize entrainment of room air. The bag should be partially inflated throughout the respiratory cycle. It is used in severely sick patients with high oxygen demand.
- *Resuscitation bag-mask-valve unit*: It is used when patients required high oxygen. It needs high oxygen flow of around 15 L/min. Because of high oxygen demand, it is difficult to apply domiciliary (mostly used in hospitalized and sick patients with high oxygen demand). It causes minimized entrainment of room air when used with good facemask seal.
- *Noninvasive positive pressure ventilation (NPPV)*: Positive pressure ventilation to increase the tidal volume is used here. It gives ventilatory assistance along with controlled oxygen using a tight-fitting facemask called interface. Here the interface between the patient and the ventilator is used without intubating the patient, hence called noninvasive. It is very useful device in order to avoid or prevent intubation in selected patients.
- *High-flow nasal cannula*: Basic principle is depicted in **Figure 2**. The physiological effect of HFNC is:
  - Increased fraction of inspired oxygen (FiO_2)
  - Gas inlet flow prevents secondary room air entrainment
  - Provides anatomic oxygen reservoirs using nasopharynx and oropharynx
  - Washing out of airway dead space
  - Development of a CPAP effect
  - Decreases atelectasis
  - Improvement in pulmonary ventilation perfusion
  - Decreases work of breathing: Counteracts intrinsic positive end-expiratory pressure (PEEP)

TABLE 8: Various oxygen delivery system and delivered fraction of inspired oxygen (FiO_2).

FIG. 2: Basic principle—high-flow nasal cannula (HFNC).

- Greater patient comfort
- Warmed and humidified nasal oxygen can be better tolerated, especially with flows >6 L/min.

SPECIAL TREATMENT CONSIDERATIONS

Timing of Antibiotics

This is the traditional teaching for ED physician that the first antibiotic dose should be administered while the patient is still in the ED, especially in the special population. For patients admitted through the ED, studies suggested early antibiotic timing improves the outcomes. Early antibiotic treatment has been shown to decrease length of hospital stay but does not seem to shorten the time to clinical stability. However, there is insufficient evidence to establish an overall benefit for patients with CAP without severe sepsis in mortality or morbidity from antibiotics administered in <8 hours from ED arrival.

Transition from Parenteral Antibiotics to Oral Antibiotics

Parenteral antibiotics are started initially for treatment in most hospitalized patients. Once the patient has become clinically stable and has shown clinical improvement, oral antibiotics can be started. Criteria for clinical stability include temperature <37.8°C, heart rate <100 bpm, respiratory rate <24 breaths/min, systolic blood pressure >90 mm Hg, room air oxygen saturation of >90%, and normal mental status. Oral antibiotics should be started after assessing the patient for ability to ingest oral medications, with normal functioning gastrointestinal tracts.

Duration of Treatment

As per evaluation of few controlled trials the optimum duration of antibiotic therapy in either inpatients or outpatients with CAP are for 7–10 days or longer. Duration of treatment should be a minimum of 5 days and before discontinuation of treatment patient should be afebrile for 48–72 hours. The patient should not have any signs of clinical instability at the time of discontinuation of treatment.

Noninvasive Positive Pressure Ventilation

In patients with pneumonia, NPPV does not decrease overall duration of overall hospitalization or in-hospital mortality, except in the patients with pneumonia and underlying COPD. NPPV associated with a significant reduction in respiratory rate, need for endotracheal intubation, and duration of ICU stay, generally well-tolerated and safe. However, other studies have failed to show benefit of NPPV, patients eventually requiring intubation in patients with hypoxic RF. Hence, the routine use of NPPV in patients with severe pneumonia, with the exception of patients with underlying COPD is not recommended because of these conflicting data. Cautious trial of NPPV for refractory hypoxemia in patients with severe pneumonia is recommended by ATS and the IDSA.

Role of Steroid: Hypotensive and Fluid-resuscitated Patients with Severe Pneumonia

In addition to antimicrobials and symptomatic care, corticosteroids being the most important and widely debated as CAP treatment adjuncts and should be considered. Steroids may reduce the frequency of acute respiratory distress syndrome (ARDS) and decrease the length of illness by attenuating the inflammatory response. Steroids reduce the need for mechanical ventilation and rate of ARDS by 5% as per systematic review and meta-analysis. Despite this evidence in favor of steroids, there are many high-quality studies showing no benefit. The case for adjunctive steroids is stronger in severe CAP. Steroids trial should be given in patients with vasopressor-dependent shock and selectively in patients with severe CAP and evidence of inadequate cortisol response. Another important treatment adjunct in hospitalized patients is early induction of physical therapy.

Diffuse Bilateral Pneumonia and Acute Respiratory Distress Syndrome

Mortality is extremely high for patients with severe diffuse bilateral pneumonia or ARDS. Significant reduction in mortality with the use of low tidal volume ventilation (6 mL/kg ideal body weight) is revealed by ARDS net trial, known as lung protective ventilation strategy. The ATS therefore has made a level 1 recommendation that patients with diffuse bilateral pneumonia or ARDS should be mechanically ventilated with low tidal volumes.

Nonresponding Pneumonia

A clinical syndrome in which clinical symptoms of pneumonia do not improve or worsen despite an initial 10 days of antibiotic therapy or in which radiographic opacities fail to resolve within 12 weeks considered as nonresolving pneumonia. Mortality is greatly increased among nonresponding patients as compared with patients who initially respond to treatment. Overall mortality as high as 49% has been reported for nonresponding hospitalized patients with pneumonia. Nonresponse to antibiotics in pneumonia requires either a transfer to a tertiary level of care, further diagnostic testing, or a change in treatment. Most common cause of apparent treatment failure is inadequate host response. Patient who are most likely to be nonresponders are older than 65 years, those with COPD, diabetes, alcoholism, or those who are undergoing immunosuppressive therapy.

Long-term Host Effects

Patients should be informed about the usual course of illness in CAP on discharge. Fevers typically resolve within 3 days of initiating antibiotics. In previously healthy adults with pneumococcal pneumonia, 80% of patients will still have fatigue and 50% will have dyspnea 1 week after presentation. Overall, patients improve clinically much faster than radiographs clear. Primary care providers should ensure that after a pneumonia diagnosis, patient should receive aspirin and statin if they are eligible as excess cardiovascular risk has been observed for 5–10 years after infection likely due to the fact that systemic inflammation destabilizes coronary plaques and produces a procoagulant effect.

PREVENTION

Smoking cessation is the most important measure to reduce a patient's risk of CAP in the primary care setting because

tobacco use interferes with immune system and lung function. Children and all healthy adults over the age of 65 years should receive vaccination against *S. pneumoniae* and *H. influenzae*. Adults 65 years and older should be given 13-valent pneumococcal conjugate vaccine (PCV13) and the 23-valent pneumococcal polysaccharide vaccine (PPSV23) should be given at least 1 year later, important for patients with COPD in whom pneumococcal vaccine has been shown to reduce the likelihood of CAP and exacerbations of COPD. Influenza vaccines should be given yearly to all eligible patients. Finally, frequent hand washing should be encouraged to patients and providers alike, primarily to prevent spread of respiratory viruses.

SUMMARY

The challenge for the emergency physician is to recognize and diagnosis pneumonia which is a common disease presentation to the ED, initiate early and appropriate empiric antibiotic therapy, risk stratify patients with respect to severity of illness, and recognize indications for admission. Apart from initiating the empiric antibiotics in ED for pneumonia he should be vigilant regarding respiratory isolation and droplet precautions, but also the environment in which the pneumonia was contracted and the host factors that may implicate risk for a particular microorganism. Bacterial and viral pathogens both are responsible for CAP. Essential information to clinically diagnose CAP is obtained by history, physical examination including vital signs and saturation of peripheral oxygen, and chest radiographs results. Past medical history for risk factors that predispose to drug-resistant pneumonia is essential to take from the patient. Emergency physician need to be aware of risk factors for pneumonia and also the nonresponding pneumonia, in order to use the appropriate empiric broad spectrum antibiotics. Blood cultures should be collected before administering antibiotics and sputum cultures in ED in severe CAP when applicable. To determine the most appropriate disposition for a patient of CAP, PSI, and CURB-65 risk stratification tools should be used routinely. Underlying comorbidities of the patient, the clinical likelihood of deterioration, and the access to outpatient follow-up should also be taken in the account during the disposition, apart from the severity of the presenting symptoms. In ED, careful severity assessment includes screening for occult sepsis with a serum lactate is a crucial step of CAP management and should be followed by early antibiotics and fluid resuscitation when indicated. Emergency physician should know latest antimicrobial treatment guidelines for both outpatient and inpatient CAP, which will continue to change as resistance patterns in respiratory pathogens evolve. To prevent the respiratory infections in children and adults hand washing, mask, social distancing, and vaccination must be encouraged.

88
CHAPTER

Pneumothorax

Bhawana Sharma, Devendra Richhariya

INTRODUCTION

A pneumothorax is defined as the accumulation of air in the pleural space with secondary collapse of the surrounding lung. It must be distinguished from bulla or air cysts within the lung. Pneumothoraces can be divided into spontaneous pneumothorax and traumatic pneumothorax. Spontaneous pneumothorax is subclassified as either primary spontaneous pneumothorax (PSP) or secondary spontaneous pneumothorax (SSP) (**Table 1**). PSP occurs without a precipitating event in a person with no clinical evidence of lung disease. Many of these individuals have occult lung disease with subpleural blebs on computed tomography (CT) scans. Complication of underlying lung disease, most often chronic obstructive lung disease (COPD) gives rise to SSP. Blunt (nonpenetrating) or penetrating trauma disrupting the lung, bronchus, or esophagus causes traumatic (or nonspontaneous) pneumothorax. A subcategory of traumatic pneumothorax is iatrogenic pneumothorax, which occurs as a consequence of diagnostic or therapeutic maneuvers (i.e., thoracentesis, insertion of a central venous catheter, surgery, or mechanical ventilation).

TABLE 1: Etiological classification of pneumothorax.

Primary spontaneous: No underlying lung disease	Subpleural bullae formation → smoking causes elastic fiber dysfunction → influx of neutrophils and macrophages, inflammation induced → obstruction of small airway → rise in alveolar pressure and air leak into lung interstitium
Secondary spontaneous: Underlying lung disease	• Chronic obstructive pulmonary disease (COPD) • Asthma • Cystic fibrosis • Interstitial lung diseases and connective tissue disease • Carcinoma • Catamenial: Female 30–40 years, history of pelvic endometriosis, and thoracic endometriosis related to menstruation
Traumatic: Due to blunt and traumatic chest injuries	• Due to blunt and traumatic chest injuries • Fall from height • Dashboard injury and steering wheel injury • Road traffic accident
Iatrogenic: Due to diagnostic and therapeutic procedure	• Transthoracic needle aspiration or biopsy • Thoracentesis • Closed pleural biopsy • Transbronchial biopsy • Subclavian or jugular vein catheterization • Mechanical ventilation • Cardiopulmonary resuscitation • Nasogastric tube placement • Tracheostomy • Liver biopsy

PATHOPHYSIOLOGY

The pleural space has negative pressure during the entire respiratory cycle. This negative pressure is due to elastic recoil capacity of lung (collapsing nature) and the tendency of chest wall to expand. The negative pressure at the apex is more than the base, and this pressure difference keep the alveoli more distended in this region. Whenever a communication develops between an alveolus and the pleural space, air will move from the alveolus into the pleural space (due negative pressure difference) until there is equalization of pressure or the communication is sealed. As a consequence pneumothorax enlarges and lung becomes smaller resulting in reduction of vital capacity of the lung and partial pressure of oxygen (PaO_2). Total lung capacity, functional residual capacity, and diffusing capacity are also reduced. The reduction in arterial PaO_2 appears to be caused by low ventilation perfusion (Va/Q) ratios, anatomic shunts, and, occasionally, alveolar hypoventilation. If perfusion to the collapsed lung is preserved, there is an increase in pulmonary shunt and substantial hypoxemia. If perfusion to the collapsed lung is reduced by hypoxic vasoconstriction, hypoxemia may be minimal. In general, pneumothoraces occupying <25% of the hemithorax are not usually associated with significant shunts. Under normal circumstances, despite

the degree of pneumothorax; hypoxemia tends to abate within 24 hours, presumably because of redistribution of pulmonary blood flow. In tension pneumothorax (mechanical ventilation, resuscitation, and trauma), the intrapleural pressure is more than the atmospheric pressure during entire expiration and inspiration. The collapsed lung produces hypoxia and reduced venous return due to compression of atria decreases the cardiac output and resulting in hypotension.

CLINICAL FEATURES

The clinical presentation depends on degree of lung collapse and underlying lung pathology. Patient of pneumothorax may be asymptomatic or may be critically ill. Clinical manifestations are unreliable indicators of the size of the pneumothorax. The patients may present with chest pain, dyspnea, cyanosis, sweating, and tachycardia. Clinical examination may reveal pulsus paradoxus, respiratory distress, and tracheal deviation (to opposite side). There may be hyperresonance on percussion and auscultation may reveal ipsilateral decreased/absent breath sounds. Presence of chest pain and respiratory distress accompanied by tachycardia, tachypnea, and hypotension indicates tension pneumothorax. Rarely there may be cyanosis and altered level of consciousness. In emergency department, clinical evaluation should be the main determinant of the management strategy.

PRIMARY SPONTANEOUS PNEUMOTHORAX

Primary spontaneous pneumothorax is a primary process that occurs in the absence of underlying clinical or radiological lung disease. However, unrecognized lung disease may be present in most patients with a PSP and rupture of a subpleural bleb may result in the pneumothorax. The peak incidence is between the second and the third decade of life. Smokers are more likely to develop PSP. PSP develops secondary to a visceral pleural tear, which results from rupture of pleural blebs and bullae which usually located in apical area and partially communicated with the tracheobronchial tree. Several theories exist regarding the development of blebs and bullae in patients with PSP. The pathogenesis of bleb can be explained with alveolus air ruptured into the thin fibrous layer of visceral pleura where it accumulates forming cysts. Blebs may be congenital, acquired, or develop as a result of local inflammation, e.g., smoking or secondary to disturbed collateral ventilation. The formation of blebs may be associated with the weakening of the elastic fibers of the lung. Such process is caused by the imbalance between protease and antiprotease and oxidants and antioxidants, in which inflammatory cells (mainly neutrophils and macrophages) play a major role. This is supported by the fact that duration of smoking is associated with an increase in the risk of developing pneumothorax as compared to nonsmokers. There are various inflammatory changes in the distal airways occur in smokers which may lead to endobronchial obstruction of the small airways leading to over pressure in alveolar tissue and rupture of pulmonary parenchyma. The mechanisms of the formation of bullae are less clear than those of blebs, but the current evidence suggests possibility of regional damage to the apical portion of the lung. This damage is probably related either to ischemia or to the greater distensile forces of apical alveoli caused by more negative pleural pressure at the apices. Abrupt swings in atmospheric pressure also associated with high frequency of PSP.

SECONDARY SPONTANEOUS PNEUMOTHORAX

Secondary spontaneous pneumothorax associated with a wide variety of pulmonary diseases of either a focal or a diffuse variety of pulmonary diseases. Chronic obstructive pulmonary disease (COPD) is the most common cause associated with pneumothorax among all pulmonary diseases. Secondary to appropriate prophylaxis, the role of acquired immunodeficiency syndrome (AIDS) and *pneumocystis carinii* pneumonia infection is declining as a major etiology of SSP. The peak incidence is at 60–65 years of age. Development of SSP depends on two mechanisms: (1) Hyperexpansion of the distal airspace due to the obstruction of inflamed airways, or (2) Visceral pleural tear due to underlying inflammatory parenchymal process such as necrotizing pneumonia.

CATAMENIAL PNEUMOTHORAX

This is a SSP. It is a rare syndrome of recurrent pneumothorax in women occurring within 72 hours of the onset of the menses. It is important to recognize the catamenial pneumothorax since the management is distinct from other forms of spontaneous pneumothorax. The peak incidence is 30–40 years of age. The pathogenesis of catamenial pneumothorax remains obscure. The first hypothesis is that air enters through a diaphragmatic defect to the peritoneal cavity then escapes into the thoracic cavity during menstruation (though not demonstrated in majority of cases). Diaphragmatic defect may present as congenital defect or may be acquired by breakdown of diaphragmatic endometrial implants. The second hypothesis is the presence of focal implant of endometrial tissue on pleural surface,and pneumothorax occurs due to swelling of this focal implant during hormonal changes of menses. The third hypothesis is increased serum level of prostaglandin F2 (PGF2), known to exist in menstruating women, causes vascular and bronchial damage.

TENSION PNEUMOTHORAX

This is a pneumothorax in which intrapleural pressure more than the atmospheric pressure during most of the respiratory cycle. It is considered as a medical emergency since acute deterioration in cardiopulmonary functions occurs.

Incidence

Tension pneumothorax develops in association with a spontaneous pneumothorax in 1–2% of cases, mainly with traumatic penetrating lung injury and barotrauma secondary to mechanical ventilation.

Pathogenesis

The basis of tension pneumothorax depends on the development of a condition of a unidirectional flow of air from injured pulmonary parenchyma into the pleural space in such a way that a “check-valve” mechanism result. Initially during

expiration only, pleural pressure is positive but later pressure becomes positive throughout the entire respiratory cycle with increasing accumulation of air. Circulatory collapse may follow, mainly as a result of the reduction in oxygen delivery due to severe hypoxemia secondary to the development of a large shunt in the involved collapsed lung. Reduction in cardiac output and systemic blood pressure will follow later.

Pneumothorax and Air Travel

The exact incidence of pneumothorax during commercial air travel is unknown, but seems to be exceedingly rare. The main factor that might predispose patients to pneumothorax during air travel is the expansion of the trapped air due to the reduction of barometric pressure according to Boyle's law. Noncommunicating pulmonary blebs and bullae will enlarge as the air expands and could rupture. Aircraft maintain a "cabin altitude" <8,000 feet at the highest operating altitude (usually 22,000–44,000 feet), which is achieved by pressurizing the cabin. Such pressurization will not only maintain an acceptable PaO_2 in the cabin, but it will also reduce the risk of spontaneous pneumothorax, as trapped gas within the lungs expands by only 38% at a cabin altitude of 8,000 feet compared to 400% at 35,000 feet. Based on the current available data, air travel may be contraindicated in patients with severe bullous emphysema, large congenital pulmonary cysts, or a prior spontaneous pneumothorax in the preceding 30 days.

RADIOLOGICAL EVALUATION OF PNEUMOTHORAX

Chest X-ray, an expiratory film, is more sensitive method in diagnosing the pneumothorax (**Fig. 1A**). Confirmation can be done by demonstrating the thin (<1 mm thick) visceral pleural line displaced away from the chest wall. Lateral decubitus film is also helpful in identifying a small pneumothorax. Large, thin-walled, and air-containing bulla should be differentiated from pneumothorax. Generally, in pneumothorax, pleural line is oriented in convex fashion towards the lateral chest wall, whereas in large bulla, pleural line is usually concave. In doubtful conditions, CT scan of the chest is helpful in differentiating the two conditions. An estimation of the percentage of lung volume lost due to pneumothorax is also the part of radiological evaluation of pneumothorax. **Accurate pneumothorax size calculations are best achieved by CT scanning.** For clinical purposes, an approximation of the % collapse can be made from the following equation:

% Collapse = [(D-d)/D × 100] When (D and d) are the average diameter of the chest wall and lung.

% Collapse = 4.2 + [4.7 × (A + B + C) another formula can also be used for estimation of % collapse **(Fig. 1B).**

MANAGEMENT OF PNEUMOTHORAX

Management of pneumothorax mainly consists of: (1) Remove the air from the pleural space to allow re-expansion of the collapsed lung, (2) Reduce the likelihood of recurrence.

General Physiology

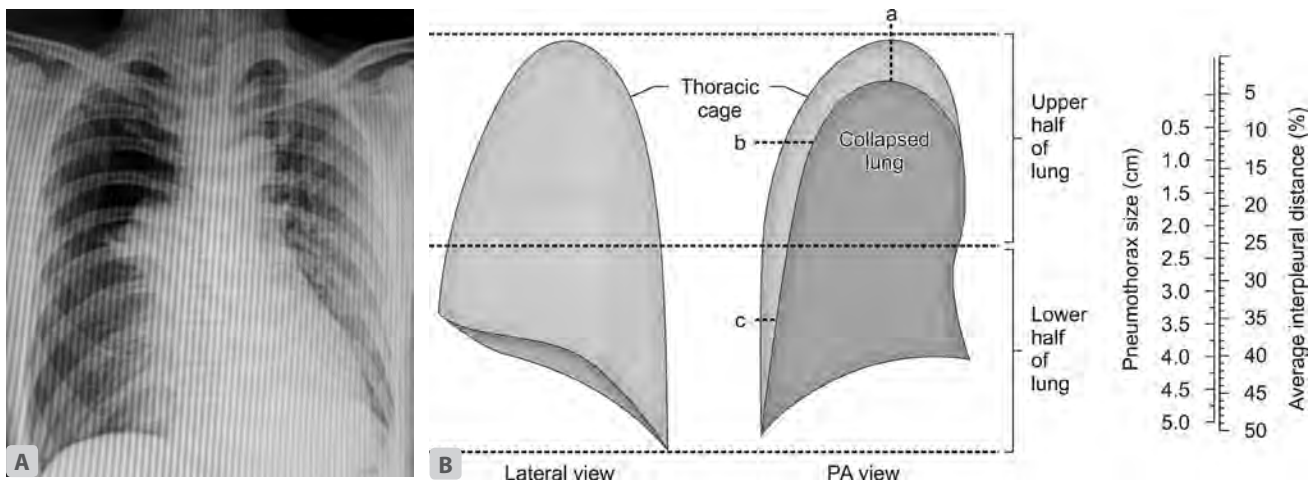
Air in the pleural space nitrogen (N_2), oxygen (O_2), carbon dioxide (CO_2), and water (H_2O) will slowly equilibrate with tissue gases. Oxygen and CO_2 will be absorbed and the remaining N_2 will have a small pressure gradient between pleural gas and tissue gas, mainly capillary blood. Nitrogen in the pleural space will then be absorbed slowly (secondary to pressure gradient) at a rate of approximately 1.25% per 24 hours, and so lung expansion will take place gradually. This means that a 30% pneumothorax will need 24 days to resolve spontaneously.

Simple Observation

A simple observation is a reasonable option when the following criteria are met: (1) Small PSP (<15–20%), (2) Healthy and asymptomatic patient, and (3) No evidence of progression of the pneumothorax.

Oxygen Supplementation

A high concentration of fraction of inspired oxygen (FiO_2) will simply widen the nitrogen gradient between the pleural space and the capillary blood thus allowing the rapid absorption of the pleural gas. This is achieved by getting a higher O_2 tension in the blood, leading to a reduction in the blood nitrogen



FIGS. 1A AND B: (A) Showing right side pneumothorax; (B) Quantification of pneumothorax size on chest radiograph using intrapleural distances at three locations: (a) the apex of collapsed lung to cupola, (b) the midpoint of the upper half of collapsed lung to chest wall, and (c) the midpoint of the lower half of collapsed lung to chest wall.

tension, and so widening the nitrogen gradient between the blood and pleural space. Based on this simple physics, pleural space air absorption can be increased by fourfold to sixfold. Oxygen administration should be considered for any patient admitted for observation and treatment of pneumothorax.

Catheter Aspiration

Catheter aspiration should always be considered for the initial treatment if PSP is exceeding 15–20% of the value of the hemithorax. It is successful in avoiding tube thoracostomy in 65% of such cases. If the catheter aspiration method is chosen, air should be aspirated using a 50 mL syringe attached to a stopcock, until a resistance is felt, which indicates lung expansion. If no resistance is felt after 4 L of air has been aspirated, a persistent leak is present and tube thoracostomy is indicated. Catheter aspiration does not reduce the incidence of recurrence of spontaneous pneumothorax.

Tube Thoracostomy

Tube thoracostomy is indicated for patients with SSP of >15–20% of the hemithorax value. It is also indicated for patients with PSP who have severe shortness of breath or chest pain, are hypoxic, or failed catheter aspiration. Finally,it is also indicated for traumatic as well as mechanical ventilation induced pneumothorax. Following placement, the thoracostomy tube is connected to a one-way valve or a chest drainage system, which has two basic components. A water seal chamber, which functions as a one-way valve, consists of a tube submersed under water to prevent air entry into the negative-pressured pleural cavity. When pleural pressure becomes positive and exceeds the height of the submersed tube (usually 2 cm), air can escape. The second component is the suction control chamber, which provides a controlled amount of suction. Generally speaking, suction should be reserved for patients in whom expansion does not take place within 24 hours. The tube is left in place until lung expansion is complete and the air leak is closed. At this point, the tube is clamped for 12–24 hours and the patient is observed for recurrence by chest X-ray. If the lung remains expanded, the tube is removed. Failure of tube thoracostomy is considered to be the inability to expand the lung fully or the presence of a persistent air leak after 7 days of tube placement (in the absence of positive pressure mechanical ventilation). The thoracostomy tube (without pleurodesis) does not reduce the incidence of recurrent spontaneous pneumothorax.

Chemical Pleurodesis

Intrapleural administration of a chemical to produce adhesion of the visceral and parietal pleura is a therapeutic option in selected cases of pneumothorax. Properly applied, it can decrease the recurrence rate of spontaneous pneumothorax. Chemical pleurodesis, however, is not effective for the closure of bronchopleural fistula. Tetracycline was considered as the sclerosing agent of choice due to its efficacy, ease of administration, low cost, and lack of significant side effects. In a prospective randomized trial, tetracycline reduced the recurrence rate to 25% compared to the tube thoracostomy rate of 41%. In several other studies, tetracycline reduced the recurrence rate further to 9–16%. Different studies have documented a dose response relationship. The proposed mechanism of action is the release of cytokines [interleukin 6-8 (IL 6-8) and tumor necrosis factor], which are markers of inflammatory response that attract neutrophils to the pleural space causing pleural symphysis. Tetracycline is no longer available for clinical practice and doxycycline has been used as an alternative. A number of other sclerosing agents have also been utilized including bleomycin, aerosolized talc, and talc slurry. Aerosolized talc has the lowest reported recurrence rate (4–6%) and is highly efficacious in achieving pleurodesis in both persistent SSP and recurrent PSP. Despite its efficacy, its application needs a thoracoscopic procedure under local or general anesthesia and special surgical skill. Talc slurry has recently gained much interest, and it might be proven to be the sclerosing agent of choice. Preliminary data indicates that talc slurry has a high success rate. In a randomized prospective trial of 96 patients, pleurodesis with talc slurry resulted in the lowest recurrence rate of 8%, compared to 13% with tetracycline and 31% with simple tube drainage. The major concern with talc slurry is the reported association with acute respiratory distress syndrome (ARDS). This complication is probably dose related and occurred when high doses (>10 g) of talc were used. Liberal use of analgesia is usually indicated for severe pain, which is the most common side effect of chemical pleurodesis.

Thoracotomy

Thoracotomy is the most effective treatment modality for preventing recurrent pneumothorax, with a recurrence rate of 0.6–2%. The advantages of surgical management are controlling the air leak, decreasing the recurrence rate, and addressing any underlying lung pathology that may have contributed to the pneumothorax. Surgical pleurodesis can also be performed, if indicated. The indications for thoracotomy and surgical management of pneumothorax are as following: (1) Large (>50% minute ventilation) air leak for over 24 hours with proper drainage. (2) Continued symptoms due to persistent air leak. (3) Recurrence of pneumothorax with failure or contraindication to chemical pleurodesis. (4) Pneumothorax accompanied by hemorrhage, loculated effusion, or empyema. (5) Recurrent contralateral pneumothorax. (6) Simultaneous bilateral pneumothorax (single-side procedure). (7) Pneumothorax following previous pneumonectomy. (8) Treatment of initial episode in patients with high-risk occupation (for example, pilots). Recently, video-assisted thoracic surgery (VATS) has been introduced as a possible alternate to thoracotomy. A recurrence rate of 5% has been reported for VATS compared to conservative therapy either by observation or tube thoracostomy. Recent data has shown that, irrespective of the presence of blebs or bullae, drainage and hospitalization time are shorter and complications and recurrence are much lower in patients treated with VATS when compared to conservative therapy with either first time or recurrent spontaneous pneumothorax.

INTERCOSTAL CHEST DRAIN INSERTION

Intercostal chest drains are inserted into the pleural or mediastinal spaces to remove abnormal collections of air, blood, pus or fluid and in many acute and chronic conditions, especially when respiratory function is compromised. The procedure is usually performed by surgeons and chest physicians, but every emergency physician should be well versed with the technique of insertion of chest drain. Insertion of an intercostal chest drain are indicated for appropriate lung re-

expansion in pneumothoraces, complicated parapneumonic effusions or empyema, hemothoraces, bedside pleurodesis, and following cardiothoracic surgery or thoracoscopic procedures (**Table 2**). Absence of informed consent or patient cooperation is the only absolute contraindication for tube thoracostomy. Relative contraindications include uncorrected coagulopathy (e.g., patients with international normalized ratio >1.5–2 or with a platelet count <50,000/μL). Chest tube insertion should be avoided over an infected skin area. Once the indication is ascertained, follow the preparation and equipment checklist to arrange all necessary requirements at the bedside (**Table 3**).

TABLE 2: Indications and contraindications for intercostal chest drain insertion.

Indications	• Pneumothorax (in any ventilated patient, tension pneumothorax, persistent or recurrent pneumothorax, large secondary pneumothorax, and malignant pleural effusion) • Empyema and complicated pleural effusion • Traumatic hemopneumothorax • Post-chest surgery
Contraindication	• Coagulopathy • Dense lung adhesions • Diaphragmatic hernia

TABLE 3: Checklist—Preparation and equipment for intercostal chest drain.

Preparation	• Identify the correct patient and side of insertion • Review the radiology and indication for procedure • Explain the procedure and obtain informed consent • Arrange for equipment • Secure intravenous line • Mild sedation may be required if patient is apprehensive • Monitoring of vitals and oxygen saturation during the procedure
Equipment required	• Sterile gown and gloves • Sterile drapes • Suture set • Sterile gauze swabs • Syringes and needles of various sizes • Local anesthetic • Scalpel and blade (No. 11) • Betadine • Local anesthetic—lignocaine 1% or 2% • Suture—silk No. 1 on cutting needle • Instrument for blunt dissection (e.g., curved clamp) • Chest drains • Connecting tubing • Closed drainage system (including sterile water for underwater seal) • Dressing material (Tegaderm)

Chest Tube Types and Sizes

The chest tubes or catheters are basically classified according to size and method of insertion. Various materials such as polyvinyl chloride, polyethylene, and silicone are used for making the chest tubes, and commercially available in straight, angled, or coiled at the end ("pig-tail") with numbers of holes on the sides and tip and with radiopaque strip. According to the Poiseuille's law (liquids) and the Fanning equation (gases), internal diameter and length of chest tubes determine the air or liquid flow rate through the drain. The size of a chest tube means its outer diameter and is displayed in "French" (F) and 1 F corresponding to one-third millimeter. Thus, a 12 F tube is 4 mm in diameter. Chest tube sizes usually range between 8 F and 36 F. A general distinction is made between small-bore chest tube (SBCT) and large-bore chest tube (LBCT). SBCT can be defined as 14 F or less, and LBCT as >14 F, some authors also prefer to consider a group of medium-bore tubes (16–24 F). Based upon expert opinion, use of chest tubes ≥20 F is recommended in the following situations: (1) there is significant risk of air leak, as in traumatic pneumothorax or bronchial dehiscence; (2) iatrogenic pneumothorax from barotrauma (mechanical ventilation); (3) hemothoraces; and (4) postoperative drainage of the chest cavity. Estimation of size of chest tube according to the age can be estimated with the help of **Table 4**.

- Spontaneous uncomplicated pneumothorax: 16–22 Fr (small bore)
- Unstable patient, bronchopleural fistula, or mechanical ventilation: 24–28 Fr
- Complicated pneumothorax or hemothorax (trauma): 32 Fr (large bore) or larger
- Pediatric: 4 X (age/4 + 4)
- For Seldinger technique of insertion: 14 Fr

Techniques for Chest Tube Placement

Small-bore chest tube (14 F or less) or medium-bore chest tubes (MBCT) are typically placed using the Seldinger technique, whereas LBCT (>24 F) can be inserted by blunt dissection or the trocar technique (**Figs. 2A** and **B**). Because of the ease of insertion and increased patient comfort, the Seldinger technique has become the most widespread method of tube placement. Conversely, the trocar technique is obsolete and should be avoided. It significantly increases the risk of misplaced drains and organ perforation. Advantages and possible complications of the procedure should be explained to the patients, written informed consent should be obtained, except in emergency situations. A recent chest radiograph should be obtained and evaluated before starting the procedure.

The first step involves positioning the patient according to the location chosen for drain insertion.

Most comfortable position for chest tube insertion is supine position with arm abducted and placed by side. If patient is breathless or can not lie supine, upright position leaning over pillow/cardiac table or lateral decubitus position is preferred (**Fig. 3A**). Chest drains are usually inserted in the triangle of safety, which is defined anteriorly by the fold of pectoralis major, posteriorly fold of latissimus dorsi, and inferiorly by a line drawn downward from nipple, which usually corresponds to 5th or 6th intercostal space in the midaxillary line. Clean a large area appropriately with Betadine and drape with sterile

TABLE 4: Chest tube size for age.

		Pneumothorax	*Pleural fluid*	*Empyema*	*Hemothorax*
Neonate/newborn	<5 kg	8–14 Fr	8–14 Fr	8–14 Fr	14–20 Fr
Infants/children	5–10 kg	8–14 Fr	8–14 Fr	12–18 Fr	18–24 Fr

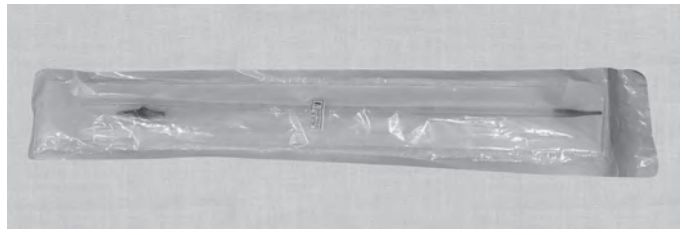

FIG. 2B: Intercostal drain without trocar drain.

sheets. Aspirate and identify if air or fluid/blood can be aspirated. In case of loculated collections, ultrasonography is helpful to identify the site of insertion of drain. In cases of severe cardiomegaly and distorted thoracic anatomy, blind insertion of a chest tube through the *"triangle of safety"* is not safe. If air or fluid is not found, the insertion site should be changed. Infiltration of skin, subcutaneous tissue, chest wall muscles, and pleura are performed using generous amount of diluted local anesthetic. Up to 7 mg/kg of locally injected 1% lidocaine with epinephrine (1:100,000) can be used (up to 5 mg/kg if not using epinephrine). Stepwise approach is as follows (**Fig. 3B**). Skin incision is made parallel to the intercostal space (size 1–2 cm) at the marked site. Blunt dissection of subcutaneous tissues is done with a blunt artery forceps up to intercostal muscles. Insert the finger to explore the tract created and feel for the intercostal space. Enter the pleural cavity using a blunt artery forceps (guarded by fingers) at the upper border of the lower rib (this avoids injury to the neurovascular bundle running at the lower border of each rib). One may encounter gush of air coming out (pneumothorax) or blood (hemothorax) or pleural fluid (effusion). Keep the blades of the artery forceps open so as to create the tract for chest drain. Insert the finger through the wound into the intercostal space to feel inside the pleural cavity and rule out underlying dense lung adhesions. This maneuver also allows the surgeon to feel for the tract which facilitates in the insertion of chest tube. The chest tube is held by blunt artery forceps just proximal to its tip and is inserted into the pleural cavity. Drain is directed toward apex in case of pneumothorax and toward base in case of fluids and then pushed into the pleural cavity for appropriate length. Successful drainage of pleural cavity can be achieved even if the tube is not placed at the ideal position. Drain manipulation and reposition should not be performed until the drain is functioning and draining the pleural cavity. The drain is then connected to closed underwater seal drainage system (**Fig. 4**). Look for the bubbling of air or column swing in the tubing. This confirms the presence of functioning tube in the pleural cavity. Fix the drain with the help of vertical mattress suture taken near the drain. The whole length of string is wrapped around the drain tightly and then tied (the same suture would be utilized to close the wound after drain removal). Extra stitch may be applied to avoid leakage from insertion site. Dressing is applied and drapes are removed. Check for any kink or leakage in the tubing. Provide adequate length of the tubing and avoid loop of tube on the floor.

Postprocedure Intercostal Drain Care

Not >1 L of fluid should be allowed to drain in case of massive pleural effusion, to avoid re-expansion pulmonary edema. The drain should be clamped and fluid drained intermittently (500 mL every few hours by releasing the clamp). Chest X-ray must be done following the procedure to ensure the correct position of the drain (**Fig. 5**). All holes of the drain should be inside the pleural cavity. The dressing should remain clean and dry, change if it gets soaked or spoiled. Adequate analgesia should be given to promote chest physiotherapy. The underwater seal bottle should be kept below the level of chest. Universal sterile precautions should be taken while changing the underwater seal bottle and should be done by a trained person. Chest drains should never be clamped, especially in patients with pneumothorax (clamping of drains in patients with air leaks can cause tension pneumothorax). Daily drainage chart should be maintained and hourly drainage should be recorded in patients of hemothorax

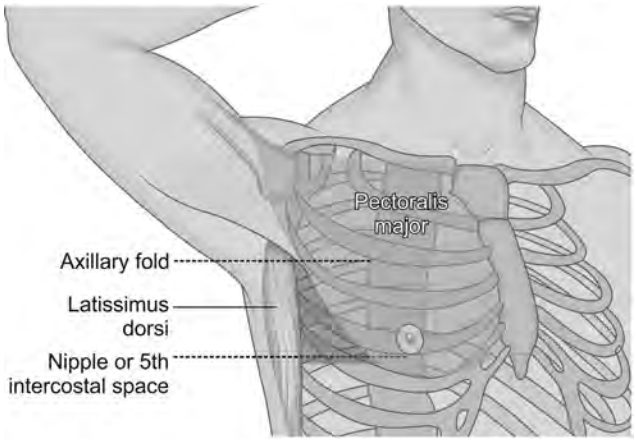

FIG. 3A: Position of the patient for chest drain insertion.

Underwater Seal Chest Drain System

Once a chest tube is in place, a chest drainage system is attached.

Single-chamber underwater seal chest drains (**Fig. 6A**), as the name suggests, single chamber/bottle is used in this system. The patient chest tube is submerged in the water about 2 cm which act as one-way valve. The air in the tube will bubble out and escape into the atmosphere when the patient's pleural pressure exceeds the level of water (i.e., >2 cm H_2O). With inhalation of the patient the negative intrapleural pressure will suck drain water up the tube, but no additional air can enter. Advantages of single-bottle drains are it is simple, cheap, and easily improvised from unrelated equipment, it is very useful for simple pneumothorax, there is usually no need for anything more sophisticated, and the fluid level (i.e., valve pressure) is

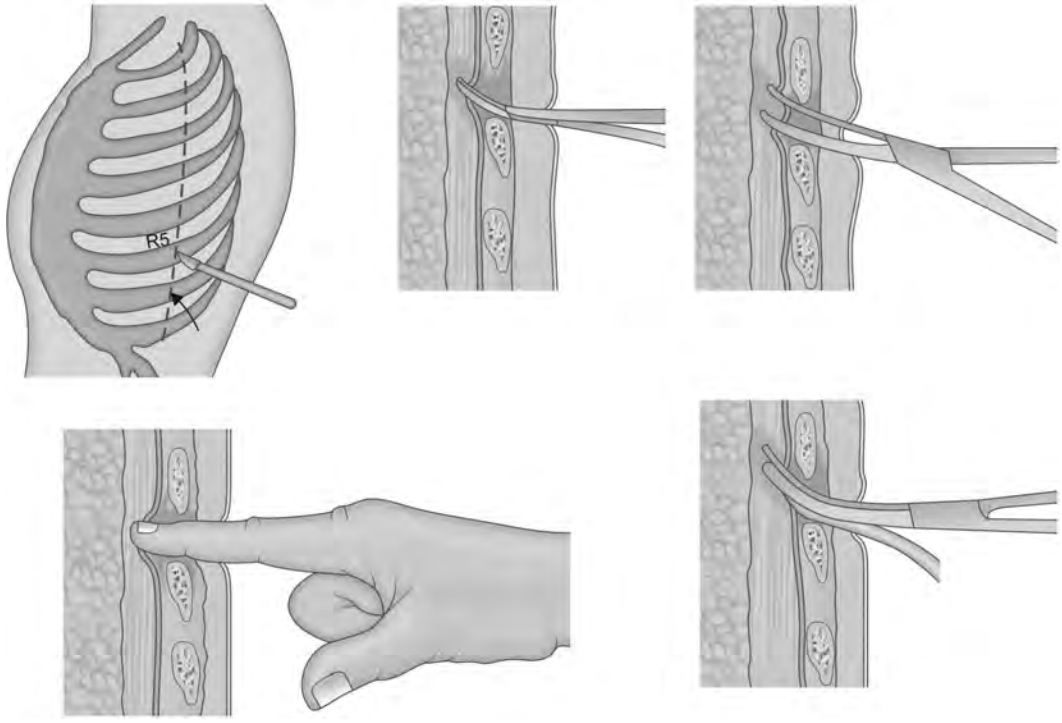

FIG. 3B: Stepwise approach.

FIG. 4: Underwater seal drainage system.

FIG. 5: Postintercostal drain procedure X-ray.

adjustable. The disadvantage of single-bottle system is that it is not suitable for pleural fluid drainage. Second, if pleural fluid goes enter the bottle, froth will form. Third, fluid may reflux into the patient's chest cavity. To remove the disadvantages of the single-bottle system another bottle or chamber is added in the system to make it *two-chamber underwater seal chest drains* (**Fig. 6B**). Fluid collection chamber is separated from the water seal chamber in this system. Pleural fluid can be collected in separate bottle without affecting the underwater seal to prevent the re-entrainment of air. Advantages of two-bottle system are consistent (low) resistance to air expulsion because of fixed underwater seal level, no development of froth as pleural fluid and water seal are separate. So, two-bottle system is used in pneumothoraces as well as drainage of pleural fluid. Two-bottle system has disadvantages of being less efficient in draining the air cavities, and without suction the drainage is less efficient. To overcome this problem *three-chamber underwater seal drain* (**Fig. 6C**) is developed which is similar to two-bottle seal but another chamber is added to help regulate the suction pressure. Advantages of the three-chamber drain: Pressure of the suction can be adjustable which protects the pleural cavity from the unmoderated effects of wall suction. Three-bottle system is effective for both pneumothorax and pleural fluid. There is virtually no chance that pleural drain fluid will reenter the chest cavity with a sudden decrease in intrathoracic pressure. Disadvantages of three-bottle system includes continuous frothing, its complexity, and in case of suction failure or occlusion two-chamber system will be blocked and chances of re-expansion of the pneumothorax. To overcome this situation one may add forth bottle for safety to make it *four-chamber underwater seal drain* (**Fig. 6D**). This system is different with addition of *another* underwater

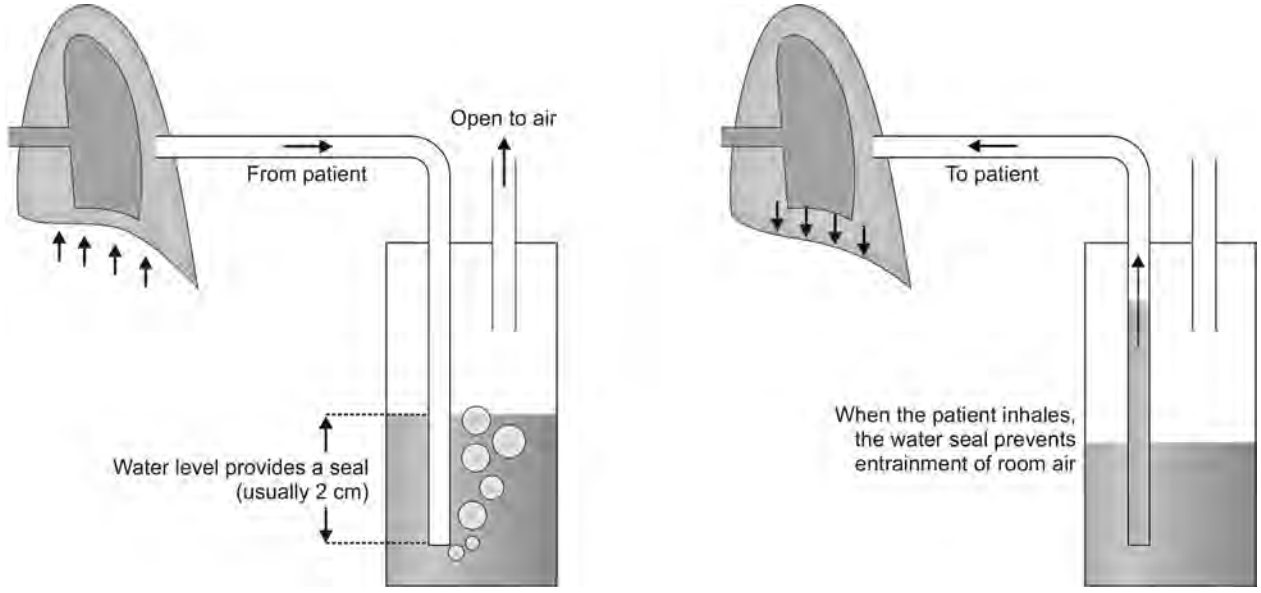

FIG. 6A: Single-chamber underwater seal drain.

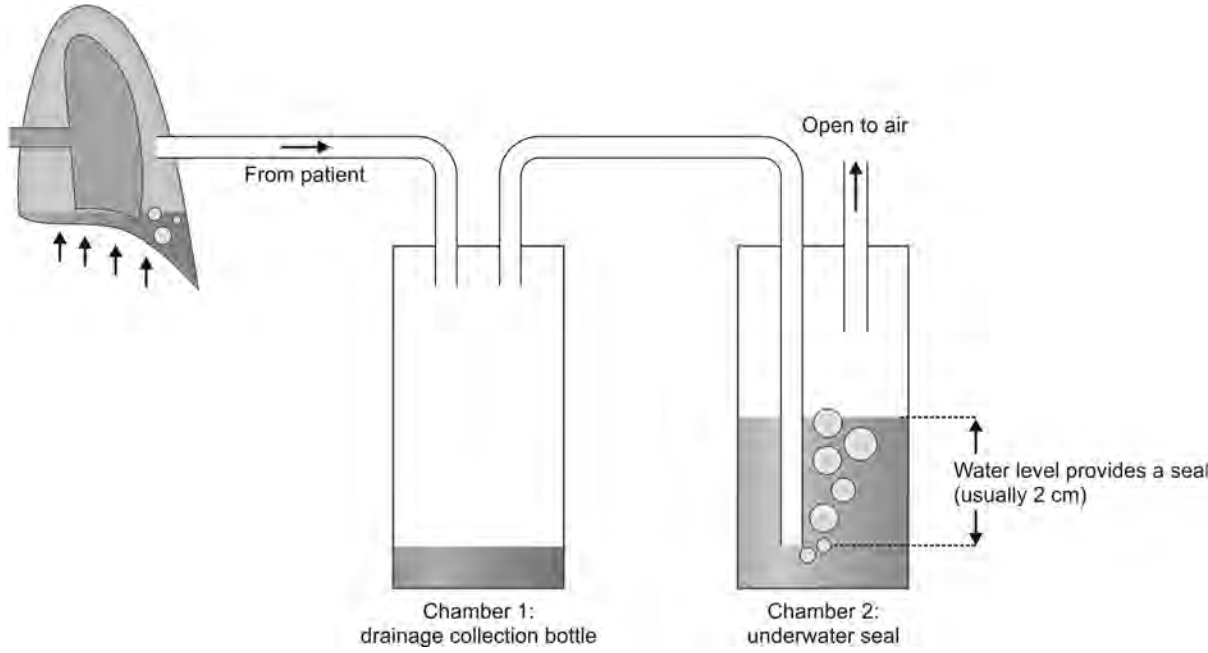

FIG. 6B: Two-chamber underwater seal drain.

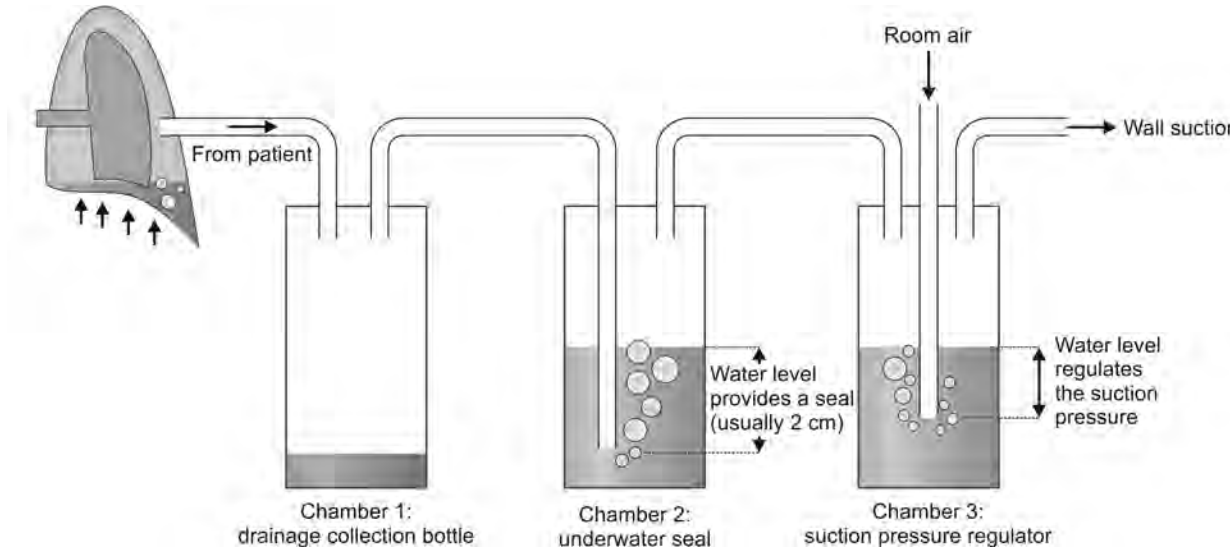

FIG. 6C: Three-chamber underwater seal drain.

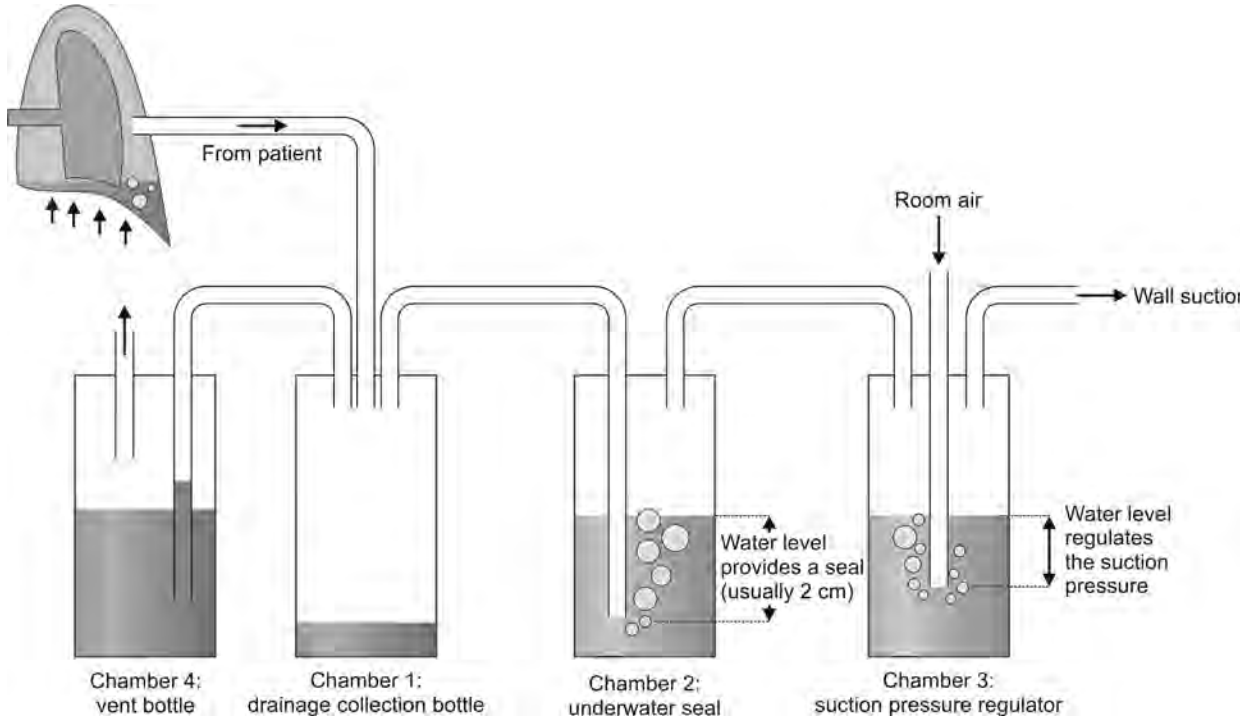

FIG. 6D: Four-chamber underwater seal drain.

seal, and not connected from the wall suction and vented to the room air. In case of sudden suction failure, it protects the patient from pneumothorax. In normal circumstances, with adequate suction, the underwater seal prevents the air from the fourth chamber from entering the rest of the system.

Intercostal Chest Drain removal

Chest drain can be removed, if: (1) Chest X-ray shows complete lung expansion (resolution of pneumothorax/hemothorax or pleural effusion). (2) No air leak (ask the patient to cough and look for air bubbling at the underwater seal). (3) Daily drainage should be <200 mL/day (should not be blood). Once the decision for drain removal is taken, take the help of an assistant and maintain aseptic precautions while removing the drain. Clean the wound and tubing with Betadine. Cut the distal end of the suture and untie. Explain the procedure to the patient and ask the patient to do inspiration and expiration on instruction. Ask the assistant to hold the ends of suture. Ask the patient to hold the breath at the peak of expiration and pull the drain out while the assistant pull the ends of suture

to tighten the knot thereby sealing the wound as soon as the drain is pulled out. Ask the patient to resume breathing as the knot is tied. Extrastitch may be applied to secure an air tight closure. Sterile dressing is applied. Check the integrity of the removed drain (especially for pigtail catheters). Chest X-ray is done 2 hours after drain removal to rule out pneumothorax. Symptomatic large pneumothorax needs drain reinsertion otherwise observation with serial chest X-rays is required for small asymptomatic pneumothorax which resolves spontaneously. For drain reinsertion always make a separate incision. Never use the previous drain site for drain reinsertion even if the drain is inadvertently pulled out.

Complications Related to Intercostal Chest Drain Insertion

The complications rate mainly depends on operator experience, the size of the tube, and use of imaging to guide insertion. Fewer complications appear when experienced operators insert under image guidance. The most frequent immediate complications include pain, inability to place the drain, and vasovagal syncope, while delayed complications included pain, blockage of drain, dislodgment of tube, and subcutaneous emphysema. With large-bore chest drain (LBCT ≥20 F) commonly reported complications are malposition, drain blockage, organ injuries, and empyema. Re-expansion pulmonary edema is a rare, but potentially serious complication of the treatment of pneumothorax by pleural drainage. The major risk factors are the duration of collapse prior to the attempts of re-expansion (>3 days) and the rapidity of the re-expansion, especially if suction is applied. The pathogenesis of re-expansion pulmonary edema is not clear, but may be related to increased pulmonary capillary permeability secondary to the vascular damage following prolonged collapse, perhaps compounded by increased capillary blood flow due to re-expansion. Re-expansion pulmonary edema is usually self-limited and management is supportive. In high-risk patients, staged lung expansion and avoidance of active suction, if possible, should be considered in order to minimize the risk of this complication. Complications related to chest drain insertion are summarized in (**Table 5**).

TABLE 5: Complications of intercostal chest drain insertion.

Insertion-related complications	• Malposition of the chest tube • Hemothorax, lung injury (laceration and bronchopleural fistula) • Diaphragm injury • Cardiac and great vessel injuries • Esophageal injury • Thoracic duct injury (chylothorax) • Injury to abdominal organs (stomach, liver, spleen, and bowel)
Infectious complications	• Chest tube site infection • Empyema • Necrotizing chest wall infection
Mechanical complications	• Tube dislodgment • Tube kinking • Tube occlusion • Arrhythmias • Phrenic nerve palsy • Horner's syndrome
Miscellaneous complications	• Pain • Inadvertent drain removal (inadequately secured chest tube) • Subcutaneous emphysema • Re-expansion pulmonary edema • Retained catheter fragment • Chest wall arteriovenous fistula • Procedure tract metastases (mesothelioma)

PNEUMOMEDIASTINUM (MEDIASTINAL EMPHYSEMA)

Presence of air in the mediastinum is termed as pneumomediastinum and also known as mediastinal emphysema. Presence of air into the mediastinum without an obvious causative factor is termed as spontaneous pneumomediastinum and secondary pneumomediastinum when a causative factor is identified, e.g., operative procedure, viscous perforation, infection, or trauma. Pneumomediastinum can be observed in a significant percent of patients in whom no causative factor is identified. Acute exacerbation of asthma and COPD with excessive coughing may lead to pneumomediastinum.

Pathophysiology

Laenek in 1827 first described the pneumomediastinum. Possible explanation for pneumomediastinum is the abnormal sudden increase of pressure in the mediastinum, creating low and negative pressure in the pleural cavity, causing air to dissect in between the mediastinal structures, which support the mediastinal organs. The situation can also be arisen by a dramatic decrease in intravascular pressure and that further create relative pressure gradient in the perivascular spaces. Subcutaneous emphysema may also occur as the air may dissect to the neck, upper abdomen, or the skin via the loose alveolar fat tissue. Pneumothorax or pneumoperitoneum can also occur once air passes the pleura or peritoneum.

Incidence

The pneumomediastinum is not a common entity, but many authors believe that the occurrence of pneumomediastinum is more frequent than initially thought due to underdiagnosis. Infrequently the pathology may not be identified on the chest radiograph and consequently related symptoms may be attributed to musculoskeletal pain or other insignificant causes.

Clinical Presentation

The main presenting symptom is chest pain, usually retrosternal, radiating to the neck or the back. The pain is acute and sudden onset, or follows exacerbations of underlying pathology such as asthma. Other frequent symptoms include dyspnea, coughing spells, neck pain, emesis, or dysphagia, which however may

be attributed to the possible underlying disease. In cases of spontaneous pneumomediastinum no complain is usually reported and no inducing factor may be found. With diagnosed pneumomediastinum, subcutaneous emphysema can be detected in 70% of patients. Other clinical features depending on underlying pathology include rhinolalia (nasally sounding voice), hoarseness of voice, and swelling of neck. Most patients generally remain well appearing, but in some patient clinical evaluation may reveal tachycardia, tachypnea, or anxiety. A specific sign with an infrequent appearance should be sought for, known as the Hamman's sign. It is the presence of mediastinal crunch or click present on auscultation over the cardiac apex and the left sternal border synchronous with the heartbeat. Accumulation of a significant amount of air in the mediastinum, causing vessel or tracheal obstruction is considered as malignant pneumomediastinum and gives rise to features suggestive of tamponade and decreased venous return.

Diagnosis

Plain anterior chest film is helpful in diagnosing the pneumomediastinum, showing lucent streaks, bubbles of air outlining mediastinal structures, and visible mediastinal pleura (**Fig. 7**). If chest X-ray is inconclusive, chest CT scan should be considered to confirm the diagnosis, also helpful in assessing the extent of the pneumomediastinum (i.e., mild, moderate, or severe). CT chest can also be performed in suspicious cases and to identify causative factors or pathologies as routine diagnostic modality. CT chest can also differentiate pneumomediastinum and pneumopericardium (air within the pericardium and not on the prepericardial fat). CT chest can also reveals presence of pneumothorax which can be missed on a plain chest X-ray in cases with severe subcutaneous emphysema. Bronchoscopy, esophagoscopy, or esophagography are not routinely required.

Management

Pneumomediastinum is generally known as a benign clinical condition with good prognosis. Once the significant pathology is excluded, the pneumomediastinum treatment is directed toward symptom relief. After diagnosis patient can be hospitalized for next 24 hours for observation. Strict bed rest is advised with symptomatic treatment for pain. Antianxiety drugs and coughing suppressant, antitussives can be added. Oxygen administration should be added as this increases the gas absorption. Any underlying pathology such as asthma or COPD should be treated and controlled adequately. In the rare instances of missed esophageal/pulmonary trauma, significant amount of air accumulated in the mediastinum which can cause important air leak and the simple pneumomediastinum may progress to a tamponade and airway compression. In such cases, decompression, VATS, or even thoracotomy may require. Extensive subcutaneous emphysema or pneumothorax is the other complication of pneumomediastinum which may require skin incisions and chest tube drainage. Respiratory compromise may occur if air can dissect in the retropharyngeal and retroperitoneal space. Rarely air can dissect between the mediastinum and the upper spine causing free air in the spinal canal and the condition is called pneumorrhachis.

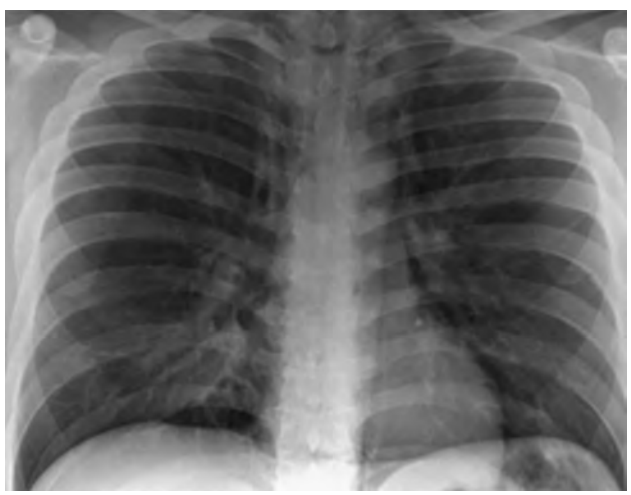

FIG. 7: Chest X-ray showing mediastinal emphysema.

SUBCUTANEOUS EMPHYSEMA

Subcutaneous emphysema is a condition when air gets into the tissues, accumulated under the skin and in the soft tissues, and on palpation gives crepitus. This frequently seen in the soft tissues of the chest wall or neck, but other parts of the body can also involve. Various diseases process can give rise to subcutaneous emphysema such as blunt or penetrating trauma, pneumothorax, barotrauma, infection, malignancy, or can develops as a complication of surgical procedures. The most common and visible sign and symptom of subcutaneous emphysema is swelling around the neck accompanied with pain in the chest. Other clinical features include mild sore throat, neck pain, swallowing difficulties, dyspnea, wheezing, and feeling of distension. Most of the cases present with minimal symptoms, no specific treatment is required. Condition becomes severe, stressful, and life-threatening if it involves the deeper tissues of the thoracic outlet, chest, and abdominal wall, can lead to high airway pressure, severe respiratory acidosis, ventilator failure, pacemaker malfunction, airway compromise, and tension phenomena due to restriction of full lung re-expansion. Subcutaneous emphysema can be diagnosed by physical examination (crepitation on palpation) and radiological studies indicating air in the involved area. Subcutaneous emphysema often presents a management dilemma. Management of subcutaneous emphysema includes identifying and removal of the offending cause of the subcutaneous dissection of air. Subcutaneous incisions, needles, drains, or cervical mediastinotomy are the modalities of treatment used in clinical practice. Two infraclavicular incisions may be an option when these interventions do not relieve increasing respiratory distress.

SUMMARY

Pneumothorax can occur in various clinical settings. It is classified as primary and secondary pneumothorax. Small PSP often requires no intervention, while a SSP almost always

requires drainage because of the high risk of recurrence and complications. In an emergency situation, one should believe more on clinical findings rather than waiting for X-ray, and immediate treatment is required. Management of pneumothorax is summarized in **Table 6**. Pneumomediastinum is considered as uncommon condition when air leaks into the mediastinum as a result of physical trauma or other pathologic situations and detected in mediastinum on chest X-ray. Clinical features may include breathlessness, hoarseness of voice, and subcutaneous emphysema mostly affecting neck, face, and chest. On auscultation "crunching" sound can be heard timed with the cardiac cycle (Hamman's crunch). The diagnosis can be confirmed by doing CT scan of the thorax. Pneumomediastinum may also present with cardiac tamponade like symptoms due to increased intrapulmonary pressure on venous flow to the heart. Most of the pneumomediastinum are treated conservatively as the tissues in the mediastinum will slowly resorb the air of the cavity.

TABLE 6: Summary—treatment of pneumothorax.

Primary spontaneous pneumothorax	***Secondary spontaneous pneumothorax***
Small pneumothorax: • Provide oxygen and observation in emergency department • Repeat chest X-ray after 24 hours if no further increase in size, then no further management only follow-up in outpatient department (OPD) *Large pneumothorax*: • Hospitalization • Chest tube insertion • If expansion of lung and no air leak • Remove chest tube and repeat chest X-ray after 24 hours • If stable then no further management • If large pneumothorax or air leak then surgical intervention needed	*Small/large pneumothorax*: • Hospitalization • Oxygen inhalation • Chest tube insertion *Surgery*: In patients with persistent air leak, recurrent pneumothorax, spontaneous hemothorax professions such as pilots and divers *Chemical pleurodesis*: Only be used if a patient is either unwilling or unable to undergo surgery. Rate of success is low with chemical pleurodesis

89 CHAPTER

Pleural Effusion, Lung Empyema, and Cavitary Lung Lesions

Laxman Bhusal, Rabin Bom

PLEURAL EFFUSION

The term effusion means escape of a fluid from anatomical vessels by rupture or exudation. Pleural effusion means presence of excessive amount of fluid in the potential space between the visceral and parietal pleura. There are many causes that results in pleural effusion (**Table 1**), e.g., congestive heart failure (CHF), malignancy, pneumonia, and pulmonary embolism. Tuberculosis is most common cause in the developing world. Other causes that can lead to pleural effusion include viral infections, cirrhosis, nephrotic syndrome, uremia, ovarian hyperstimulation syndrome, collagen vascular diseases, myxedema, and intra-abdominal conditions.

Pathophysiology of Condition

Pleural fluid is secreted from parietal pleura and absorbed by visceral pleural microcirculation and lymphatics of parietal pleura. When there is excessive production of pleural fluid or decreased reabsorption then pleural effusion occurs. Normally there is 0.1–0.2 mL/kg body weight fluid present in pleural space which is clinically insignificant. Pleural effusions are mainly divided into two groups— (i) transudates and (ii) exudates—according to composition of the pleural fluid. Transudate is ultrafiltrate of plasma, containing low amount of protein. A transudative effusion develops due to an increase in hydrostatic pressure or decrease in oncotic pressure within the pleural microvessels. This results from imbalance between hydrostatic and oncotic pressure between pleural microvessels. Most common cause of transudate is CHF. Exudates contains relatively high amount of protein. Any pulmonary or pleural process leading inflammation can cause exudative effusion. Most common cause for exudative effusion is parapneumonic effusion. Parapneumonic effusion is caused due to intense pleural inflammatory reaction to infection of adjacent lung. Exudative effusion can also occur due to malignant conditions, inflammatory conditions in the abdomen like pancreatitis or subphrenic abscess. Pleural adhesion may occur due to fibrinous tissue left behind after reabsorption of exudative effusion.

Massive effusion (>1.5–2 L) is usually caused by malignancy but also can occur in heart failure and other volume load conditions. Pleural fluid is considered as an exudate if one or more of the following conditions are met (Light's Criteria):

- Pleural fluid protein level/serum protein level exceeds 0.5.
- Pleural fluid lactate dehydrogenase (LDH) level/serum LDH level exceeds 0.6.
- Pleural fluid LDH level exceeds two-thirds of the upper limit of normal for the serum LDH level.

Clinical Presentation

Most of small pleural effusions are asymptomatic. Patient complains of pleuritic pain, pain over shoulder. Dyspnea usually does not occur until the volume of pleural fluid is at least 500 mL in adults. Physical finding varies depending on amount of pleural effusion. Pleural frictional rub may be only finding in isolated pleurisy. Signs of cardiopulmonary compromise may be present in massive effusions.

Red Flags (Concerning Features)

- Respiratory rate >30 breaths/min
- Heart rate >120 beats/min
- Blood pressure <90/60 mm Hg
- Hemorrhagic pleural effusion

Evaluation

History: Patient complains of fever, pleuritic chest pain, and dyspnea.

Physical examination: Oxygen saturation may be decreased in moderate-to-severe pleural effusion. Patient may feel difficulty in speaking or completing sentences. High respiratory rate in moderate-to-severe pleural effusion. Unequal movement of chest wall may be noticed in severe pleural effusion. Decreased breath sounds or bronchial breathing sound on auscultation. Dullness on percussion over pleural effusion side. Orthopnea is present; patient can be seen seated with tripod position. Tachycardia is seen in

TABLE 1: Causes of pleural effusion.

Transudates	• Congestive heart failure • Cirrhosis with ascites • Nephrotic syndrome • Hypoalbuminemia • Myxedema • Peritoneal dialysis • Glomerulonephritis • Superior vena cava obstruction • Pulmonary embolism
Exudates	*Infections:* • Bacterial pneumonia • Bronchiectasis • Lung abscess • Tuberculosis • Viral illness • Fungal infection • Parasitic infections
	Neoplasms: • Primary lung cancer • Mesothelioma • Pulmonary or pleural metastasis • Lymphoma
	Connective tissue diseases: • Rheumatoid arthritis • Systemic lupus erythematosus • Drug-induced lupus • Immunoblastic lymphadenopathy • Sjögren's syndrome • Wegener's granulomatosis • Churg–Strauss syndrome
	Abdominal or gastrointestinal disorders: • Pancreatitis • Subphrenic abscess • Esophageal rupture • Abdominal surgery • Diaphragmatic hernia • After liver transplant • Endoscopic variceal sclerotherapy
	Other conditions: • Pulmonary infarction • Uremia • Drug reactions • Postpartum • Chylothorax • Meigs' syndrome

moderate-to-severe cases of pleural effusion. Hypotension may be seen in severe pleural effusion. Pedal edema present in cases of fluid overload conditions such as CHF, nephrotic syndrome, cirrhosis, and malnutrition.

Investigations

Tests routinely performed on pleural fluid include the cell count and cell differential, pH, protein, LDH, and glucose. Additional commonly performed tests in selected patients include amylase, cholesterol, triglycerides, N-terminal pro-brain natriuretic peptide (BNP), creatinine, adenosine deaminase (ADA), gram and acid-fast bacillus (AFB) stain, bacterial and AFB culture, and cytology. Suspected patients with pleural effusion should undergo chest X-ray (**Figs. 1A** and **B**). Minimum of 200 mL of pleural effusion is required to be seen in upright chest radiograph. Less than 200 mL of pleural effusion can be noted in posterior costophrenic gutter on lateral projections. Chest ultrasound has replaced the lateral decubitus X-ray in the evaluation of suspected pleural effusions and as a guide to thoracentesis (**Fig. 2**). Sonographically, pleural effusion appears hypoechoic fluid above the diaphragm. Curvilinear probe is used to visualize pleural effusion in mid axillary line. Hemothorax and pyothorax appears heterogeneous in ultrasound. A significant pleural effusion is large enough to produce a pleural fluid strip >10 mm wide on lateral decubitus radiographic views or by ultrasound. CT scan is gold standard for pleural effusion, it can detect as little as 3–5 mL of pleural effusion (**Figs. 3A** and **B**). CT scan helps in differentiating between pleural and parenchymal cause for pleural effusion.

Diagnostic thoracentesis is done if available with help of ultrasound to reduce the complications. This fluid should be sent for culture and biochemical analysis. Light's criteria to identify exudative pleural effusion are 98–99% sensitive wile specificity is 65–86%. Most transudates have absolute total protein concentrations below 3.0 g/dL (30 g/L). Tuberculous pleural effusions virtually always have total protein concentrations above 4.0 g/dL (40 g/L). Pleural fluid LDH levels above 1,000 IU/L (with upper limit of normal for serum of 200 IU/L) are characteristically found in empyema, rheumatoid pleurisy, and pleural paragonimiasis, and are sometimes observed with malignancy. A pleural fluid of pH < 7.3 is associated with parapneumonic effusions, malignancies, rheumatoid effusions, tuberculosis, and systemic acidosis. A pH < 7.0 strongly suggests empyema or esophageal rupture and is generally taken to be an indication for tube thoracostomy. A low pleural fluid glucose concentration [<60 mg/dL (3.33 mmol/L), or a pleural fluid/serum glucose ratio < 0.5] narrows the differential diagnosis of the exudate. If there is neutrophil predominance then it suggests parapneumonic, pulmonary embolism, or pancreatitis in origin. If there is lymphocytic predominance then it favors towards cancer, tuberculosis, or postcardiac surgery.

Measurement of ADA may be helpful to distinguish between malignant and tuberculous pleurisy when an exudative effusion is lymphocytic, but initial cytology and smear and culture for tuberculosis are negative. The level of ADA is typically >35–50 U/L in tuberculous pleural effusions.

In case of nonbloody tap, bloody fluid suggests trauma, neoplasm, or pulmonary infarction. If the hematocrit of the pleural fluid exceeds that of the peripheral blood by 50%, the effusion is, by definition, a hemothorax. In case of suspicion of malignancy fluid should be submitted for cytologic examination.

FIGS. 1A AND B: (A) X-ray suggestive of mild pleural effusion on left side of chest indicated by arrow; (B) X-ray suggestive of massive pleural effusion on left side of lung.

Treatment

Treatment is started with systematic approach starting from airway-breathing-circulation. If dyspnea is present oxygen is supplemented. Most pleural effusions do not require emergent drainage. Indications of therapeutic thoracentesis in emergency are: (1) Massive effusions (>1.5 L), (2) Respiratory and circulatory collapse in which condition draining the pleural effusion stabilizes the patient, (3) Pyothorax, (4) Recurrent pleural effusion in oncology patient where patient gets symptomatically better after thoracentesis. Relative contraindications of thoracentesis include coagulopathy and bleeding disorders. For risk of potential pneumothorax ultrasound-guided thoracentesis can be performed.

Following thoracentesis, a chest radiograph should be obtained to evaluate for iatrogenic pneumothorax. Depending on laboratory result of thoracentesis antibiotics are used. In developing countries, tuberculosis is common so antitubercular medicine are initiated as per national tuberculosis guidelines. In case of pyothorax, broad-spectrum antibiotics are initiated until culture and sensitivity results and then narrowed down. If pleural effusion is due to systemic cause such as cardiac, liver, and renal causes, then those are treated first.

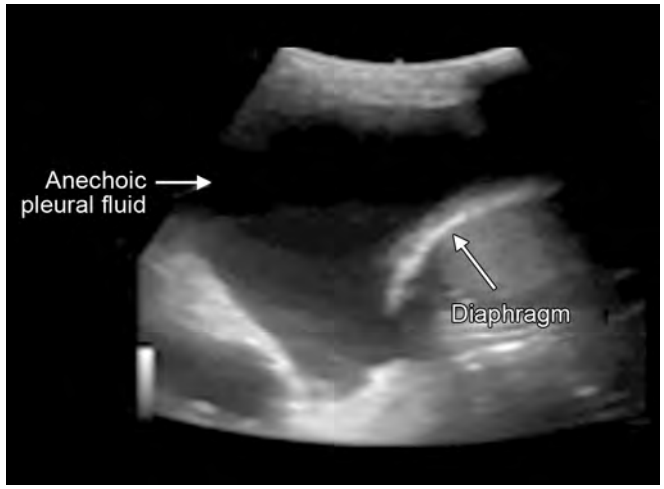

FIG. 2: Ultrasound suggestive of pleural effusion above diaphragm.

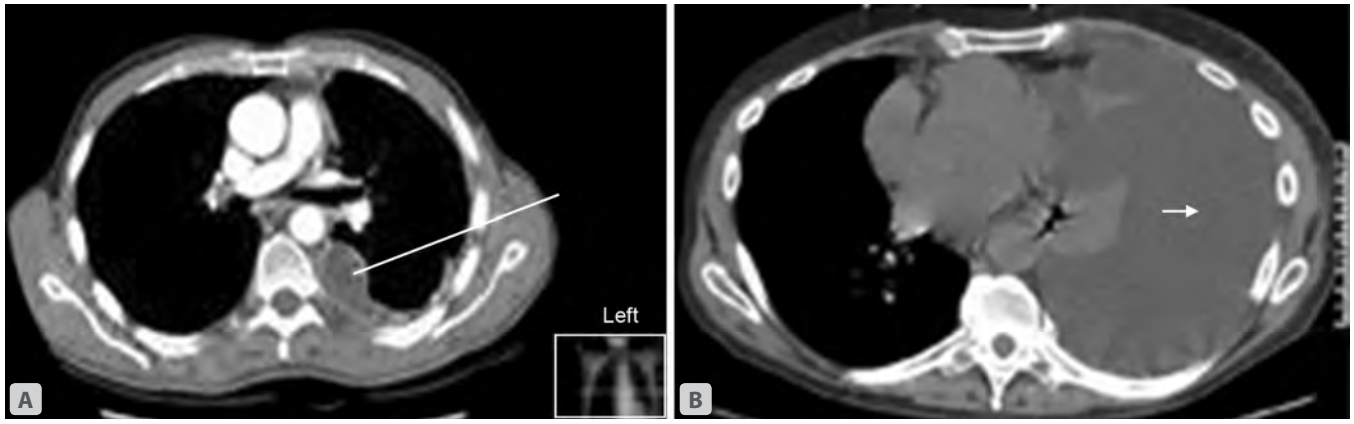
Disposition

Patients with pleural effusion who are having unstable respiratory and hemodynamic condition are admitted to hospital. Viral pleuritic or pleural effusion, minimal effusion after surgery or postpartum resolves spontaneously within few days. Pleural effusion that develops on background of cardiac failure responds well to diuretics. Patients with parapneumonic



FIGS. 3A AND B: (A) CT scan suggestive of left-sided mild pleural effusion; (B) CT scan suggestive of massive pleural effusion of left side of lung.

effusion due to community-acquired pneumonia should be admitted to hospital as it increases morbidity and mortality. Empyema develops in 5–10% of parapneumonic effusion. Early surgical drainage is treatment of choice. Malignant pleural effusion indicates disseminated stage of cancer. Recurrent drainage may be required for symptomatic relief. These patients may get relieved by pleurodesis or pleuroperitoneal shunts.

LUNG EMPYEMA

An empyema refers to a collection of pus within the pleural space, which can develop when pyogenic bacteria, fungi, parasites, or mycobacteria invade the pleural space, either from an adjacent pneumonia or from direct inoculation (e.g., from blunt trauma) or other source. Empyema that develops from an adjacent pneumonia is a subclass of a complicated parapneumonic effusion. Empyema is pus in pleural cavity (**Figs. 4A** and **B**).

Causes

Bacterial pneumonia with a parapneumonic effusion is the most common precursor, seen in about 60% of empyema patients (**Table 2**). Other causes of empyema up to 40% may be secondary to a nonpneumonic process, such as systemic infection with hematogenous spread or abdominal etiology (**Table 3**).

Pathophysiology of Condition

Most empyema is due to underlying pneumonia. They develop in three stages. Patient can present at any stage of development.

1. *Simple or uncomplicated parapneumonic effusion*: Pleural effusion with exudative nature without evidence of microorganisms or infection.
2. *Complicated parapneumonic effusion and empyema:* When bacterial invasion across the damaged pleural mesothelium stimulates an inflammatory response resulting in fibrin deposition and loculations within the pleural space. Here exudative fluid with high white cell counts is noted. If frank pus is noted then it is termed as empyema. Empyema can present independently of pneumonia (e.g., empyema due to esophageal rupture, blunt or penetrating chest trauma, and hematogenous spreads).
3. *Chronic organization:* Pleural fluid begins to organize. Fibrinous pleural covering starts to form and may encase the lungs impairing lung functions.

Clinical Presentation

Patient is suspected for empyema if symptoms of pneumonia do not resolve with the therapy. Symptoms of pneumonia are fever, cough, dyspnea, chest pain, and malaise. Onset may be insidious, patient appears chronically ill, weight loss, anemia, and night sweats.

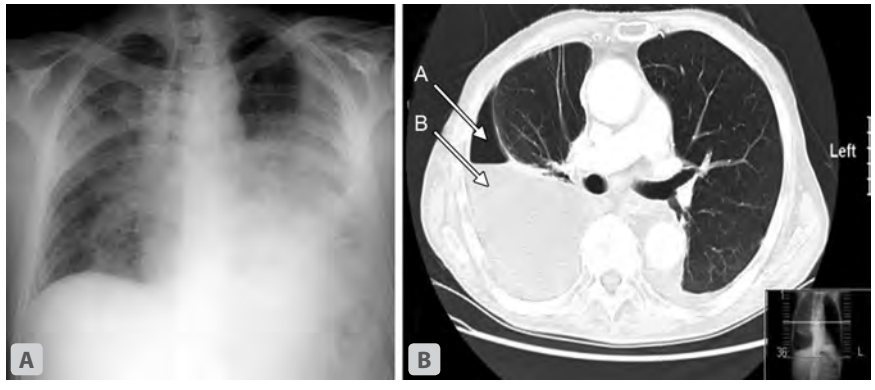
Physical examination includes decreased breath sounds, dullness to percussion, decreased tactile fremitus, and occasionally frictional rub. Patient with pneumonia deteriorating or not getting better with antibiotic is feature of concerns.

Diagnosis

Diagnosis is done by aspiration of pleural fluid by thoracentesis preferably with ultrasound guidance. At least one of following finding should be present: Positive Gram stain or culture, pleural fluid glucose < 40 mg/dL, pH <7.2, and LDH > 1,000 IU/L. Patients need to have following investigations: Chest X-ray and ultrasound of lungs, if loculated effusion CT scan of chest may be required. Complete blood count (CBC), serology, pleural fluid analysis (protein and LDH), Gram stain, AFB stain, culture, and sensitivity are done.

Treatment

Main treatment of empyema is drainage and antibiotics. Analgesics like nonsteroidal anti-inflammatory drugs (NSAIDs) should be used for pleuritic pain. Ultrasound-guided drainage of small empyema and chest tube thoracentesis relieves symptoms. Antibiotics should be used on background of clinical presentation and results of diagnostic studies. Antibiotics should cover both aerobic and anaerobic pathogens. Antibiotic with beta-lactamase activity like piperacillin-tazobactam or ampicillin-sulbactam, a carbapenem, or clindamycin should be used. For anaerobic pathogens, second- or third-generation cephalosporin plus metronidazole, a carbapenem, or a beta-lactam aminopenicillin with beta-lactamase activity should be used. For methicillin-resistant *Staphylococcus aureus* (MRSA)



FIGS. 4A AND B: (A) Empyema on left side of lung; (B) CT scan suggestive of pleural empyema.

TABLE 2: Causative agents of empyema.	
Bacteria	• *Streptococcus pneumoniae*, microaerophilic streptococci (e.g., *S. anginosus and S. intermedius)* • Anaerobes*: Fusobacterium* species, *Prevotella* species, *Peptostreptococcus* species, and *Bacteroides* species • *S. aureus* • Atypical bacteria: *Legionella, Mycoplasma,* and *Chlamydia* species • Mycobacteria
Fungal	Rare <1% mostly *Candida*

TABLE 3: Common organism in empyema and associated pathology.	
Pathology	***Organism***
Pneumonia	• *Streptococcus pneumoniae* • *Staphylococcus aureus*
Pneumonia (unimmunized with Haemophilus influenzae type B vaccine)	*H. influenzae*
Lung abscess	Mixed oropharyngeal anaerobes
Aspiration pneumonia	*S. aureus*
Recent thoracotomy	Gram-negative bacilli
Chest trauma	• *S. aureus* • Gram-negative bacilli
Contiguous abdominal infection	• Gram-negative bacilli • Anaerobes
Esophageal rupture	Mixed oropharyngeal organisms
Postprocedure	• Methicillin-resistant *S. aureus* • *Pseudomonas*
Hospital-acquired empyema	• Methicillin-resistant *S. aureus* • *Pseudomonas*
Pneumonia in the setting of human immunodeficiency virus	• Tuberculosis • Fungal infections

vancomycin is used. Intravenous antibiotic should be used until clinical and radiological improvement then switched to oral agents. Fibrinolytics (streptokinase, urokinase, etc.) helps to drain better in loculated empyema. One-third of patients treated with antibiotics and chest tube drainage need surgical drainage.

Disposition

Patients are admitted to hospital until clinical and radiological improvement is noted. Chest tube should be removed when the lung is fully reinflated and there is <200–300 mL of noninfected fluid output in 2 hours.

CAVITARY LUNG LESIONS

When there is confined space within lung which contains air, fluid, solid material, or combination of the three then it is known as cavitary lesion. These lesions are surrounded by a wall, usually of varied thickness. Some authors have tried to make this distinction by defining cysts as being air-containing spaces surrounded by a thin (4 mm or less) wall and cavities at least 5 mm thick. Cavitary lesions may be single or multiple and may be accompanied by multiple nodules, parenchymal scarring, and loss of volume (as in tuberculosis), pneumonia (as in lung abscess), or pleural disease.

Causes

Cavities are frequent manifestations of a wide variety of pathological processes involving the lung. Presence of a cavity helps the clinician to focus the diagnostic evaluation (**Table 4**). Viral infection like coronavirus disease-2019 (COVID-19) can also cause cavitary lesions in lung.

Pathophysiology of Condition

Most lung abscesses arise as a complication of aspiration pneumonia and are caused by species of anaerobes that are normally present in the gingival crevices. Pneumonitis arises first but, based upon the usual mixture of organisms, progresses to tissue necrosis after 7–14 days. This necrosis results in lung abscess and/or an empyema in the form of suppurative necrosis (pyogenic lung abscess), caseous necrosis (tuberculosis), ischemic necrosis (pulmonary infarction. In case of infectious diseases, cavitation represents the outcome of complex interactions between host and pathogen. Lung abscesses are usually polymicrobial infections. Malignant processes may cavitate because of treatment-related necrosis, internal cyst formation, or internal desquamation of tumor cells with subsequent liquefaction. Fluid within a cavitary lesion may be thin and serous (resembling pleural fluid), thick and purulent, or bloody, and it may contain necrotic lung tissue, blood cloths, or foreign material (e.g., fungal hyphae).

TABLE 4: Causes of cavitary lung lesions.		
Infectious	Bacterial	• Anaerobic abscess • Aerobic abscess • Infected bullae • Tuberculosis • Actinomycosis • Pleural empyema
	Fungal	• Coccidioidomycosis • Histoplasmosis • Blastomycosis • Aspergillosis • *Cryptococcus*
	Parasitic	*Echinococcus*, *Entamoeba histolytica, amebiasis,* and *Paragonimus westermani*
Neoplastic	• Bronchogenic carcinoma (squamous cell carcinoma or adenocarcinoma) • Metastatic cancer (colorectal or renal) • Lymphoma or Hodgkin's disease	
Inflammatory	• Sarcoidosis • Wegener's granulomatosis	
Other	Foreign body aspiration	

Clinical Presentation

Patient presents with fever, cough with purulent sputum, and shortness of breath, malaise, pleuritic chest pain, anorexia, nausea, and vomiting. At later stages hemoptysis and weight loss.

Differential Diagnosis of Cavitary Lung Lesions

Many different diseases present as cavitary pulmonary nodules. The spectrum of diseases ranges from acute to chronic infections, chronic systemic diseases, and malignancies. Knowledge of common and uncommon radiological findings in correlation with relevant clinical history and findings is necessary to make the right diagnosis and recommend the correct follow-up. Infections which may be caused by several groups of microorganisms, e.g., *S. pneumoniae, S. aureus, and Klebsiella,* include pulmonary abscess, septic emboli, *Mycobacterium tuberculosis* infection, nontuberculous mycobacterial infections, aspergillosis, systemic disease such as granulomatosis and polyangiitis, rheumatic nodules, sarcoidosis, and malignancies are considered among differential diagnosis.

Investigations

Once history and physical examination is done following investigations should be sent:

Complete blood count and chest X-ray (**Fig. 5**) initially help to come to conclusion. Chest CT scan helps to delineate the lesions (**Figs. 6A** and **B**). Routine Gram stain and aerobic culture of expectorated sputum for aerobes should be performed, ideally before antibiotics have been started. Serology if not done prior. Baseline of liver function test (LFT) and renal function test (RFT) will guide during course of treatment. Sputum culture and AFB stain for tuberculosis. Blood cultures in case of bacterial infection. Tumor markers may be necessary if malignancy is suspected. Examiner must be vigilant to look for primary source of tumor.

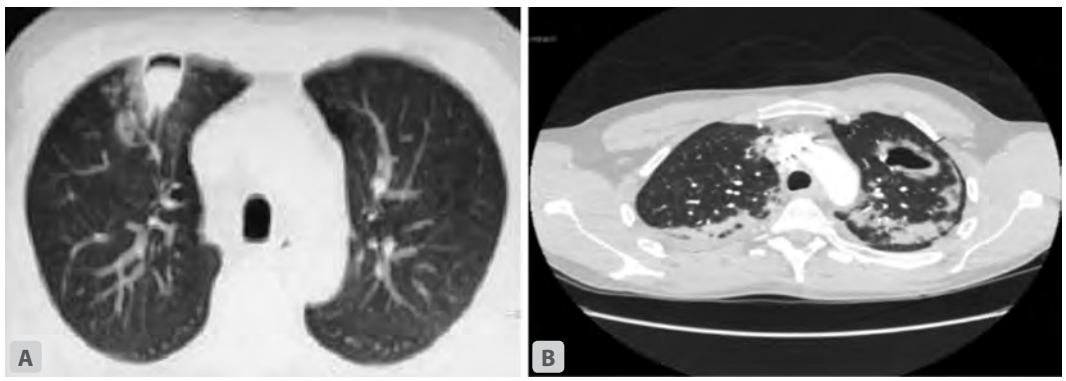
Treatment

Treatment modality depends on clinical presentation of patient to health center. If patient is in respiratory and hemodynamic distress then patient is managed in emergency. Airway, breathing, and circulation problems are addressed and managed. Patient is started on broad-spectrum antibiotics till culture report arrives. Empiric regimens should penetrate the lung parenchyma and target both strict anaerobes and facultatively anaerobic streptococci. Drugs that are reasonable to use are any combination of a beta-lactam–beta-lactamase inhibitor [e.g., ampicillin-sulbactam 3 g intravenously (IV) every 6 h] or a carbapenem (e.g., imipenem and meropenem). The duration of the antibiotic should be prolonged until the chest radiograph shows a small and stable residual lesion or is clear. If infection is due to tuberculosis then antitubercular medication are started according to national tuberculosis guidelines. Surgical drainage is must if there is cyst along with pus in thoracic cavity (empyema thoracis). The usual indications are failure to respond to medical management suspected neoplasm or hemorrhage. If infection is due to fungal etiology then antifungal are initiated. Antiparasitic medications for cavitary lesions caused by parasites. Cardiovascular and thoracic surgery and oncological consultation for cavitary lesions caused by malignancy.

Disposition

Patients with cavitary lung lesions who appear sick must be admitted to hospital. They must be managed with intravenous

FIG. 5: Chest X-ray of patient with cavitating staphylococcal pneumonia.



FIGS. 6A AND B: (A) Computed tomography (CT) of immunocompromised patient with invasive aspergillosis; (B) CT scan of the chest with contrast opacity in the left upper lobe with cavitation.

medications. Patients who are stable and ambulatory without comorbid conditions can be managed on outpatient basis.

SUMMARY

Tuberculosis is the most common cause of pleural effusion in developing countries. Chest radiograph will detect pleural effusion >200 mL. Ultrasound is more sensitive in detecting small amount (as much 50 mL) of pleural effusion. Chest CT is gold standard for minimal pleural effusion. Therapeutic thoracentesis is indicated for relief in acute respiratory and cardiovascular compromise. Diagnostic thoracentesis helps to distinguish between transudative and exudative nature of effusion.

Lung empyema required drainage for proper treatment along with management of underlying cause like pneumonia with antibiotics. Antibiotics with both aerobic and anaerobic coverage should be used. Intravenous antibiotics should be used until clinical and radiological improvement is seen.

Cavitary lesions of lungs are caused by diverse group of pathological agents. Knowledge about causative agents of cavitary lesions, clinical features, and radiological patterns helps in coming to diagnosis and management.

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2)

90 CHAPTER

Devendra Richhariya, Bhawana Sharma

INTRODUCTION

Humans and animals are affected by large group of virus family—coronaviruses. In rare instances, animal coronavirus infect people and spread between them such as Middle East respiratory syndrome (MERS) and severe acute respiratory syndrome (SARS). The outbreak of coronavirus was first noticed in Wuhan city in Hubei province of China in mid-December, 2019. The World Health Organization (WHO) (under International Health Regulations) has declared this outbreak as a "Public Health Emergency of International Concern (PHEIC)" on 30th January 2020. The WHO subsequently declared coronavirus disease-2019 (COVID-19) as a pandemic on 11th March, 2020. About 213 countries and the territories are affected due to COVID-19. More than 90% of COVID-19 cases are outside China.

Available evidence shows that coronavirus [SARS coronavirus 2 (SARS-CoV-2)] is a zoonotic source (bat origin). Coronavirus is related to the SARS virus. It is an enveloped ribonucleic acid (RNA) and probably uses the angiotensin-converting enzyme 2 (ACE2) receptor for cell entry. ACE2 mostly present in the lung alveolar epithelial cells, cardiac myocytes, and vascular endothelial cells

Person-to-person transmission is the main source and cause of spreading of infection. Respiratory droplets are released when infected person sneeze, cough, or speaks. These droplets contain viable viruses and infect surface also, and when any person comes in to contact of infected surface and touches his/her nose/eyes/face infections spreads. As per current evidence infectivity period starts 2 days prior to onset of symptoms and remain up to 8 days. Median incubation period is of 5 days. Various issues such as period of infectivity of a person and role of preclinical and asymptomatic period in transmission are still under research.

The SARS-CoV-2 infection (COVID-19) is primarily an upper respiratory tract infection and small proportion of cases can progress to severe systemic involvement such as acute respiratory distress syndrome (ARDS), sepsis and septic shock, and multi-organ failure including acute kidney injury and cardiac injury.

Autopsy studies done mostly in European countries and China reveal endothelial damage of pulmonary vasculature followed by extensive alveolar and interstitial inflammation due to SARS-CoV-2 infection. These changes result in COVID-19 vasculopathy, pulmonary intravascular coagulopathy, hypercoagulability, ventilation perfusion mismatch, and refractory ARDS. ARDS-induced hypoxemia may also activate the coagulation cascade.

DEFINITION OF CASES AND CLINICAL FEATURES

Suspected Cases

- Patient with acute respiratory illness (fever and at least one sign/symptom of respiratory disease, e.g., cough and shortness of breath), a travel history/residence in a location of endemic area during the 14 days prior to symptom onset
- A patient with any acute respiratory illness who comes in contact with a confirmed or probable COVID-19 case in the last 14 days prior to symptom onset
- A patient with severe acute respiratory illness need hospitalization and clinical presentation not fully explain the alternative diagnosis

Probable Cases

Coronavirus disease 2019 testing is inconclusive or could not be done for any reason in any suspected cases.

Confirmed Cases

Irrespective of signs and symptoms laboratory confirmation of the COVID-19 cases.

CLINICAL FEATURES

Common Generalized Features

Fever, cough, fatigue, shortness of breath, expectoration, myalgia, rhinorrhea, sore throat, and diarrhea are common generalized features. Before onset of symptoms, loss of smell and taste also reported by some patient.

Atypical symptoms such as fatigue, reduced alertness, reduced mobility, diarrhea, loss of appetite, delirium, and absence of fever are reported in elderly and immuno-compromised individuals.

Children may have fewer/mild symptom (fever and cough) than adult. Few cases may progress to severe disease, especially in individual who are elderly and associated with risk factors such as diabetes, hypertension, cardiac disease, chronic lung disease, cerebrovascular disease, chronic kidney disease, immune suppression, and cancer.

Pulmonary Features

Mild cold like symptom is seen in majority of the COVID-19 infected patient. Symptoms appear 2–14 days of exposure, mostly dry cough, fever, and sore throat. The most common complications seen in COVID-19 patients are pneumonia (15%), shortness of breath, and desaturation of blood oxygen level which needs hospitalization. About 5% of severely symptomatic patient may need advanced organ support therapy including intubation and mechanical ventilation in intensive care unit. Extrapulmonary manifestations are summarized in **Table 1**.

TABLE 1: Extrapulmonary features of COVID-19.

Cardiac manifestation	• Coronary artery disease • Acute cardiac injuries • Arrhythmias (atrial arrhythmia is common) • Heart failure • Cardiogenic shock • Cardiac tamponade • Myopericarditis
Neuromuscular manifestation	• CNS—headache, dizziness, confusion, delirium, stroke ataxia, and seizures • PNS—taste, smell, vision impairment, and neuropathy • Skeletal muscle—myopathy and raised CPK level
GI manifestation	• Anorexia • Nausea and vomiting • Abdominal pain • Abnormal liver function test • Detection of virus in stool
Renal manifestation	• Raised blood urea nitrogen • Proteinuria • Hematuria • Acute kidney injury
Ocular manifestations	• Watery eyes, increased secretions, chemosis, and conjunctivitis
Hematologic manifestation	• COVID-19 is considered as hypercoagulable state and increase risk of venous thromboembolism • Pulmonary embolism • Deep vein thrombosis and catheter-related thrombosis • Thrombocytopenia
Psychiatric manifestation	Anxiety, depression, panic/somatic attack, post-traumatic stress, and suicidal tendency
Skin manifestations	Maculopapular exanthem, papulovesicular rash, urticaria, and painful papule petechiae

(CNS: central nervous system; COVID-19: coronavirus disease-2019; PNS: peripheral nervous system)

SEVERITY CLASSIFICATION OF SARS-CoV-2, INVESTIGATIONS AND SUGGESTED TREATMENT

Progression of illness due to SARS-CoV-2 is classified in to three categories (**Table 2**) which corresponds to distinct clinical findings, treatment response, and complications. Initial stage is categorized as mild at the time of inoculation with asymptomatic or mild clinical features. Diagnosis at this stage includes respiratory sample, polymerase chain reaction, serum testing for SARS-CoV-2 immunoglobulin G (IgG) and immunoglobulin M (IgM), chest imaging, complete blood count, and liver function tests. Complete blood count may reveal a lymphopenia and neutrophilia without other significant abnormalities. Treatment at this stage is primarily targeted toward symptomatic relief. Antiviral therapy, such as remdesivir, may prove beneficial, may reduce duration of symptoms, minimize contagiousness, and prevent progression of severity. Prognosis and recovery is excellent if disease is in this stage. Next progressive stage is moderate category in which virus multiply, localized inflammation in the lung, and established pulmonary disease. Clinical features are fever, cough, and breathlessness associated with pulmonary infiltrates and ground-glass appearance in X-ray and CT scan of the chest. Markers of systemic inflammation may be elevated. Patient should be admitted in hospital and observed closely. Judicious use of anti-inflammatory therapy and corticosteroids may be beneficial if hypoxia persists or requirement of oxygen therapy increases. Few patients may progress into severe categories with extensive pulmonary involvement and extrapulmonary manifestation. Systemic inflammatory markers are elevated in moderately sever/severe categories. Inflammatory cytokines and biomarkers such as interleukin-2 (IL-2), IL-6, IL-7, granulocyte colony-stimulating factor, macrophage inflammatory protein-1α, tumor necrosis factor-α, C-reactive protein, ferritin, and D-dimer are significantly elevated in severe category patients. Troponin and N-terminal pro B-type natriuretic peptide can also be elevated. Severe COVID-19 patients are at higher risk of thrombosis due to low blood flow (induced by both vasoconstriction and stasis) together with endothelial injury and hypercoagulability. The incidence of venous thromboembolism [deep vein thrombosis (DVT) and pulmonary embolism (PE)] is more due to excessive thrombin generation and imbalance of pro- and anticoagulant factors. Stroke is also common in critically ill COVID-19 patient. Disseminated intravascular coagulation (DIC) is not a common complication of COVID-19. Pathophysiology for COVID-19-related systemic microthrombosis is summarized in **Figure 1**. Experimental therapies such as favipiravir, remdesivir, tocilizumab (TCZ) (targeting cytokine storm), and plasma therapy can be offered. Suggested investigations in each category are summarized in **Table 3**. Suggestive treatment options which are under research are summarized in **Tables 4** and **5**.

CT CHEST IN SARS-CoV-2—CORRELATION WITH DISEASE SEVERITY

Reverse transcription-polymerase chain reaction (RT-PCR) assay is used for definitive diagnosis of COVID-19. Though this is accurate laboratory test while in clinical practice sensitivity range from 42% to 83% and depend on symptom duration,

TABLE 2: Classification of clinical severity of SARS-CoV-2.

Categories	*Clinical presentation*	*Clinical parameters*
Mild	• Mild upper or lower respiratory tract infection with mild symptoms of fever, cough, sore throat, nasal congestions, malaise, headache, loss of taste or smell, mild gastrointestinal symptoms (nausea, vomiting, and diarrhea) • Clear sensorium	• No oxygen dependency • No respiratory distress • Room air SpO_2 >95% • No hypotension • No multi-organ involvement
Moderate	• Moderate lower respiratory symptoms • Dyspnea • Worsening vomiting/diarrhea • Fever confusion/drowsiness • Unusual symptoms: Febrile encephalopathy, CVA, and MI	• Oxygen dependency/±respiratory distress • Tachypnea, RR >24 breaths/min • SpO_2 <93% on room air • No hypotension • No multi-organ involvement
Severe	• Severe lower respiratory infection • Sever pneumonia • Dyspnea • Worsening nausea vomiting • Fever confusion drowsiness • Unusual symptoms: Febrile encephalopathy, CVA, and MI	• Oxygen dependency/±respiratory distress • Tachypnea, RR >30 breaths/min • SpO_2 <95% on supplemental oxygen on 10 L/min, HFNC (FiO_2 50%), NIV (FiO_2 50%, and EPAP 6) • Presence of hypotension • Shock and multi-organ involvement • Septic shock persisting hypotension in spite of volume resuscitation requiring vasopressor to maintain MAP > 65

(CVA: cerebrovascular accident; EPAP: expiratory positive airway pressure; FiO_2: fraction of inspired oxygen; MAP: mean arterial pressure; MI: myocardial infarction; NIV: noninvasive ventilation; RR: respiratory rate; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2; SpO_2: oxygen saturation)

TABLE 3: Baseline laboratory investigations for SARS-CoV-2.

• Real-time or conventional RT-PCR test is recommended for diagnosis. • SARS-CoV-2 antibody tests are not recommended for diagnosis of current infection with COVID-19.	
Mild cases	• Complete blood count, electrolytes and ECG • If risk factors present other tests should be included e.g., LFT, KFT, PT/INR, CRP, LDH, D-dimer, lactate, blood group, arterial blood gas, ECHO, Trop I
Moderate and severe cases	Arterial blood gases, complete blood count, ferritin, fibrinogen, LFT, KFT, PT/INR, CRP, LDH, D-dimer, lactate, blood group, ECHO, ECG, Trop I, X-ray chest, HRCT chest, and collect blood culture (prior to antibiotics)
Investigations which have prognostic value and indicative of risk of progression • *CRP > 100 • LDH > 245 • Trop I > ULN • D-dimer > 1,000 ng/mL* • *Ferritin > 300 µg/L • IL-6 > 70 (10 times of ULN)*	
Baseline investigations to be repeated 48–72 hours in moderate and severe cases	

(COVID-19: coronavirus disease-2019; CRP: C-reactive protein; CT: computed tomography; ECG: electrocardiogram; ECHO: echocardiogram; HRCT: high-resolution computed tomography; IL: interleukin-1; KFT: kidney function test; LDH: lactic dehydrogenase; LFT: liver function test; PT/INR: prothrombin time/international normalized ratio; RT-PCR: reverse transcription-polymerase chain reaction; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2; Trop I: troponin I; ULN: upper limit of normal)

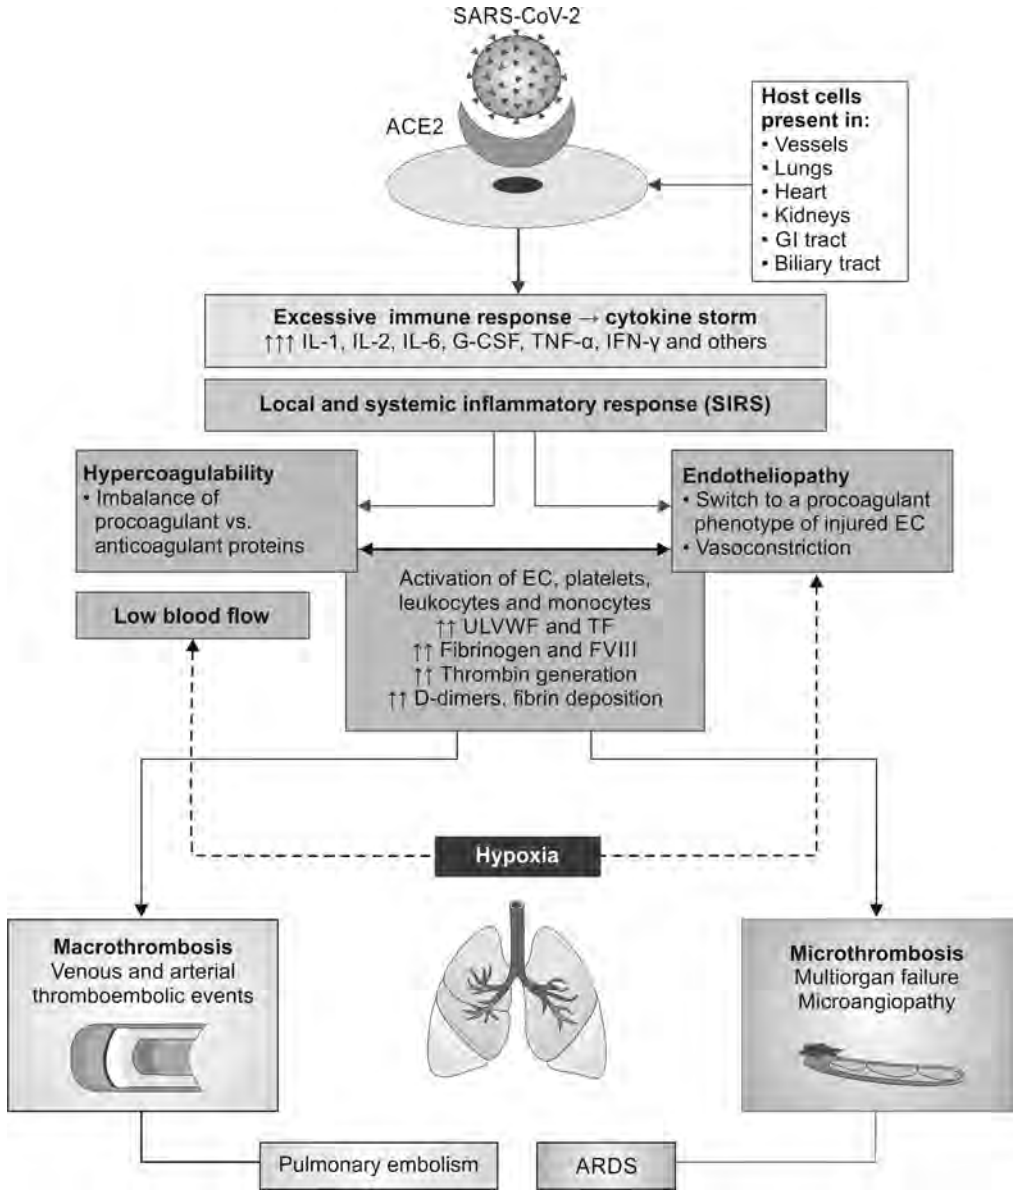
viral load, and test sample quality. RT-PCR assay results takes hours or days to come which causes pressure on observation or holding area where patient are observed before being sent to COVID ward. In view of this role, CT chest is evolving in COVID-19 for clinical workup and decision making.

The main hallmark of COVID-19 pneumonia manifests as bilateral ground glass opacities with or without consolidative areas, with a predominant peripheral, lower lobe, and posterior anatomic distribution. Some CT findings of COVID-19 overlap with some other viral disease but have some specific findings which are not seen in other disease. COVID-19 Standardized Reporting Working Group of the Dutch Radiological Society chose the term COVID-19 Reporting and Data System (CO-RADS) to standardized assessment scheme for pulmonary involvement of COVID-19. The CO-RADS provides suspicion of pulmonary involvement (category-1 very low to category 5 very high) in SARS-CoV-2 infection (**Table 6**).

Computed tomography has a reported high sensitivity in patients infected by SARS-CoV-2, thus it is largely used to help patient management. In the current public health emergency, a highly sensitive test like CT allows to speed-up diagnostic workflow and establishes isolation at admission.

REMDESIVIR

Several potential treatments for coronavirus SARS-CoV-2 infection have emerged during the COVID-19 pandemic. Remdesivir is an antiviral prodrug and originally investigated for the treatment of Ebola virus infection and considered a treatment for COVID-19 because it was known to have activity against coronaviruses that undergoes intracellular metabolism to form a pharmacologically active nucleoside triphosphate metabolite. This competes with adenosine triphosphate (ATP) for incorporation into nascent RNA chains by SARS-CoV-2 RNA-dependent RNA polymerase, delaying chain termination during replication of viral RNA. It is used for the treatment of COVID-19 pneumonia requiring supplemental oxygen in adults and adolescents (aged ≥12 years with body weight



(ACE2: angiotensin-converting enzyme 2; ARDS: acute respiratory distress syndrome; COVID-19: coronavirus disease-2019; EC: endothelial cell; FVIII: factor VIII; G-CSF: granulocyte colony-stimulating factor; GI: gastrointestinal; IFN: interferon; IL: interleukin; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2; SIRS: systemic inflammatory response syndrome; TF: tissue factor; TNF: tumor necrosis factor; ULVWF: ultralarge von Willebrand factor)

FIG. 1: Pathophysiology for thrombosis in critically ill patients with COVID-19. SARS-CoV-2 aggression on the host cells through ACE2 receptors, the excessive immune response-induced cytokine storm, the local and systemic inflammatory response responsible for an endothelial damage and a hypercoagulability state, leading to both systemic and macro- and microthrombosis.

≥40 kg). The recommended dose regimen comprises a loading dose of 200 mg by intravenous infusion, followed the next day by 100 mg once daily by intravenous infusion for a total of at least 5 days and maximum for 10 days (similar dose recommended for older people). Remdesivir should not be prescribed for patients with severe renal impairment [estimated glomerular filtration rate (eGFR) <30 mL/min]. Its pharmacokinetics has not been evaluated in patients with renal or hepatic impairment. Its safety during pregnancy and in women who are breastfeeding is unknown.

Two clinical trials of remdesivir in COVID-19 have been published—one small study from China and the second is an international clinical trial [the Adaptive COVID-19 Treatment Trial (ACTT)]. The National Institute for Health and Clinical Excellence (NICE) review included these and an observational study (n = 53). Remdesivir significantly reduced the median time to recovery compared with placebo. In the China trial, serious adverse events were reported in 18% of patients treated with remdesivir and 26% assigned to placebo, but discontinuation was more frequent with remdesivir (12% vs. 5%). Adverse events resulted in treatment discontinuation in 9% of patients treated with remdesivir and 10% of those assigned to placebo.

TABLE 4: Suggested treatment guidelines for mild SARS-CoV-2.	
Mild cases	*(Asymptomatic to mild symptoms no oxygen therapy no X-ray/CT findings no rise of inflammatory markers, no risk factors)*
General measures in mild cases	1. Balanced diet 2. Adequate sleep 3. Breathing exercises 4. Remain physically active 5. Hot water gargles three times a day 6. Positive mood and outlook 7. In case of symptoms seek medical advice 8. Monitor saturation with pulse oximeter 9. Temperature monitoring and paracetamol as needed 10. Multivitamins, zinc, vitamin C, and vitamin D
When to seek medical attention	Immediate medical attention must be taken if serious signs or symptoms develop. These could include: 1. Difficulty in breathing and saturation <94% 2. Persistent pain/pressure in the chest 3. Mental confusion or inability to arouse 4. Developing bluish discolorations of lips/face 5. As advised by treating medical officer
When to discontinue home isolation	Patient under home isolation will end home isolation after 17 days of onset of symptoms (or date of sampling, for presymptomatic cases) and no fever for 10 days. There is no need for testing after the home isolation period is over.
During initial phase of pandemic various repurposed drugs are used in combination or alone, though their efficacy is not established: Hydroxychloroquine + azithromycin (in age <50 and no cardiac comorbidities) OR Hydroxychloroquine + doxycycline (in age >50 and no cardiac comorbidities) OR Doxycycline + ivermectin (any age with cardiac comorbidities) OR Only doxycycline (after 7 days of onset of symptoms) OR Favipiravir (contraindicated in hepatic/renal comorbidities and in pregnancy • *Tablet hydroxychloroquine 400 mg BD × 1 day followed by 200 mg BD × 9 days* • *Tablet azithromycin 500 mg OD × 1 day followed by 250 mg OD × 4 days* • *Capsule doxycycline 100 mg BD after food × 5 days* • *Tablet ivermectin 12 mg OD × 3 days* • *Tablet favipiravir 1,800 mg BD on day 1 followed by 800 mg BD × 8–14 days* • *In all regimen add antacid zinc, vitamin C, and vitamin D* • Strong recommendations against the use of chloroquine hydroxychloroquine with or without azithromycin in hospitalized or nonhospitalized patient • Strong recommendations against the use of lopinavir/ritonavir and other HIV protease inhibitors in hospitalized or nonhospitalized patient • There are insufficient data to recommend either for or against the use of ivermectin for the treatment of COVID-19. Further clinical trials are required on the role of ivermectin in treatment of COVID-19 • There are insufficient data to recommend either for or against the use of vitamin C and D and zinc for the treatment of COVID-19	

(COVID-19: coronavirus disease-2019; CT: computed tomography; HIV: human immunodeficiency virus; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2)

FAVIPIRAVIR

During worst hit pandemic COVID-19, repurposed drugs, already in use against other viral infections, have been introduced into quick service agent against the SARS-CoV-2 as discovery of a new and specific antiviral would involve a long timeline. One such drug is favipiravir, initially marketed as an anti-influenza agent in Japan and used in Japan for the management of emerging pandemic influenza infections in 2014. Favipiravir is administered as a prodrug. It has an excellent bioavailability (~94%), 54% protein binding, and a low volume of distribution. Within the tissue, it converts to the active form of drug by phosphoribosylation to favipiravir-RTP.

Influenza

Favipiravir inhibits 53 types of influenza viruses including seasonal strains A (H1N1), A (H3N2), and influenza B; the A (H1N1) pandemic virus; highly pathogenic avian influenza virus A (H5N1) isolated from humans.

TABLE 5: Suggested treatment guidelines for moderate-to-severe cases of SARS-CoV-2.

1. Asymptomatic to mild infection (no oxygen dependency) with CT evidence of disease and/or at high risk for deterioration with epidemiological risk factors present or elevated inflammatory markers
2. Moderate-to-severe infection (increasing oxygen dependency)

General measures and oxygen therapy	• Target SpO_2: 92–96% (88–92% in patients with COPD) • The device for administering oxygen (nasal prongs, mask, or masks with breathing/nonrebreathing reservoir bag) depends upon the increasing requirement of oxygen therapy. If HFNC or simple nasal cannula is used, N95 mask should be applied over it • Awake proning may be used as a rescue therapy • All patients should have daily 12-lead ECG • Follow CRP, D-dimer, and ferritin every 48–72 hourly (if available); CBC with differential count, absolute lymphocyte count, KFT/LFT daily • Add antacid, zinc, vitamin C, and vitamin D • Antibiotic as per local guidelines
Strongly recommended therapy (steroid)	Tablet dexamethasone 6 mg/day orally for 10 days OR IV dexamethasone 20 mg per day intravenous × 5 days followed by 10 mg per day IV × 5 days; titrate dose and duration to culmination of oxygen dependency OR IV methylprednisolone 2 mg/kg intravenous total dose in three divided doses for 7 days followed by 1 mg/kg for 5 days and then 0.5 mg/kg for 5 days (preferably within 48 hours of admission or if oxygen requirement is increasing and if inflammatory markers are increased) OR IV hydrocortisone 50 mg intravenous 6 hourly × 7 days followed by 50 mg IV 12 hourly × 4 days followed by 50 mg IV 24 hourly × 3 days *The UK RECOVERY trial has demonstrated mortality benefit with low dose dexamethasone in COVID-19 patients requiring oxygen.*
Low-molecular-weight heparin (LMWH)	• Association between COVID-19 infection and thromboembolism associated with inflammation and a prothrombotic state, with increases in fibrin, fibrin degradation products, fibrinogen, and D-dimers. In some studies, elevations in these markers have been associated with worse clinical outcomes • Prophylactic dose of UFH or LMWH (e.g., enoxaparin 40 mg per day SC)
Remdesivir (emergency use approval-experimental)	• Remdesivir is approved by the Food and Drug Administration (FDA) for the treatment of COVID-19 in hospitalized adult and pediatric patients (aged ≥12 years and weighing ≥40 kg) • IV remdesivir 200 mg intravenous day 1 followed by 100 mg IV daily for 4 days • Remdesivir may be considered in patients with moderate disease (those on oxygen) with none of the following contraindications: ○ AST/ALT > 5 times upper limit of normal (ULN) ○ Severe renal impairment (i.e., eGFR < 30 mL/min/m^2 or need for hemodialysis) ○ Pregnancy or lactating females ○ Children (<12 years of age)
Baricitinib	Janus kinase inhibitors: Baricitinib plus remdesivir is superior to remdesivir alone in reducing recovery time
Favipiravir (emergency use approval-experimental)	• Favipiravir is a pyrazinecarboxamide derivative that acts as an inhibitor of viral RNA-dependent RNA polymerase, causing chain termination and preventing RNA elongation • Tablet favipiravir 1,800 mg BD (9 tablets of 200 mg each BD) on day 1 followed by 800 mg BD (4 tablets of 200 mg each BD) for a total duration of 7–14 days.
Experimental therapies	
Targeting cytokine storm (tocilizumab)	• Indications: Special considerations before its use include: Presence of raised inflammatory markers (e.g., CRP, ferritin, and IL-6). Patients should be carefully monitored post tocilizumab for secondary infections and neutropenia. Active infections and tuberculosis should be ruled out before use. CT suggestive of active disease with radiological worsening + IL-6 >70 + rising serum ferritin/rising CRP/rising D-dimer/rising LDH + >48 h of steroids (dexamethasone 20 mg/day or methylprednisolone 80–120 mg/day or hydrocortisone 200 mg/day) • Dose: 6–8 mg/kg (maximum 400 mg at one time) given slowly in 100 mL NS over 1 hour; dose can be repeated once after 12–24 h, if needed
Plasma therapy	• May be considered in patients with moderate/severe disease who are not improving (oxygen requirement is progressively increasing) despite use of steroids. • Special prerequisites while considering convalescent plasma include: ○ ABO compatibility and crossmatching of the donor plasma ○ Recipient should be closely monitored for several hours post-transfusion for any transfusion-related adverse events ○ Use should be avoided in patients with IgA deficiency or immunoglobulin allergy • Dose: Dose is variable ranging from 4 to 13 mL/kg (usually 200 mL single dose given slowly over not <2 h

(CBC: complete blood count; COPD: chronic obstructive pulmonary disease; COVID-19: coronavirus disease-2019; CRP: C-reactive protein; CT: computed tomography; eGFR: estimated glomerular filtration rate; HFNC: high-flow nasal cannula; IgA: immunoglobulin A; KFT: kidney function test; LDH: lactic dehydrogenase; LFT: liver function test; RNA: ribonucleic acid; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2; SpO_2: oxygen saturation; UFH: unfractionated heparin)

TABLE 6: CO-RADS categories and suspicion of pulmonary involvement in COVID-19.

CO-RADS categories	*Level of suspicion*	*Interpretation*
0	Not interpretable	Scan not sufficient to interpret
1	Very low	Normal of noninfectious
2	Low	Typical for infection other than COVID-19
3	Equivocal	Feature symptom of COVID-19 but also other disease
4	High	Suspicious for COVID-19
5	Very high	Typical for COVID-19
6	Proven	RT-PCR positive for SARS-CoV-2

Typical features for pulmonary involvement of COVID-19

Obligatory features: Ground glass opacities, with or without consolidations, in lung regions close to visceral pleural surfaces, including the fissures (subpleural sparing is allowed) and multifocal bilateral distribution

Confirmatory patterns:

- Ground glass regions
- Unsharp demarcation, (half) rounded shape
- Sharp demarcation, outlining the shape of multiple adjacent secondary pulmonary lobules
- Crazy paving
- Patterns compatible with organizing pneumonia
- Thickened vessels within parenchymal abnormalities found in all confirmatory pattern

(CO-RADS: coronavirus disease 2019 Reporting and Data System; COVID-19: coronavirus disease-2019; RT-PCR: reverse transcription-polymerase chain reaction; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2)

Ebola

Favipiravir was one of the drugs shortlisted by WHO for trials during the Ebola virus outbreak in 2014. Apart from efficacy against influenza and Ebola viruses, favipiravir has been found to have therapeutic efficacy against arenavirus, bunyavirus, filovirus, West Nile virus, yellow fever virus, foot-and-mouth-disease virus, and Lassa virus including agents causing viral hemorrhagic fevers and encephalitis.

Role in SARS-CoV-2

To assess the efficacy of favipiravir in the management of COVID-19 various clinical studies have been performed all over the world. In spite of inconclusive results over its usefulness in COVID-19 patient, most countries, including India, using it in clinical dose of 1,800 mg bid on day 1, followed by 800 mg bid on days 2–14. Oseltamivir and ribavirin are not effective in the treatment of SARS-CoV-2. Repurposed antiviral drugs have all been introduced into treatment after rapidly conducted clinical trials. Furthermore, larger RCTs are urgently needed before this drug can be unreservedly recommended.

TOCILIZUMAB

Pathogenesis of COVID-19 is incompletely understood but evidence suggests the severity is associated with increased

TABLE 7: Indication for tocilizumab (TCZ) (clinical criteria and inflammatory markers).

Clinical criteria	
Grade I—mild disease—pneumonia without oxygen requirement	TCZ not required
Grade II—moderate disease—fever, no hypotension, fluid requirements and oxygen requirement, FiO_2 <40%	TCZ not required (send IL-6)
Grade III—new organ dysfunction, fluid and vasopressors requirements, FiO_2 >40%—(HNFC and NIV)	Send IL-6 consider TCZ
Grade IV life-threatening mechanical ventilation, high dose vasopressors	Send IL-6 and consider TCZ
Inflammatory markers—criteria for diagnosing cytokine release syndrome (CRS)	
• Ferritin 300 µg/dL with doubling time within 24 hours or 600 µg/dL • LDH >250 U/L • Raised D-dimer >1 mg/mL • CRP >150 • IL-6 (normal values <7) >10 times of ULN	

(CRP: C-reactive protein; FiO_2: fraction of inspired oxygen; HNFC: high-flow nasal cannula; IL-6: interleukin 6; LDH: lactic dehydrogenase; NIV: noninvasive ventilation; ULN: upper limit of normal)

inflammatory markers such as cytokines interleukins (IL-6 and IL-10), tumor necrotic factors, and chemokines. Cytokines release syndrome (CRS) is key pathophysiologic process behind sudden deterioration of COVID-19 patient and progression of diseases to ARDS and multi-organ failure (**Table 7**). TCZ is a monoclonal antibody against IL-6 receptors has been used in various studies with variable effects. TCZ can improve outcome by decreasing the need for mechanical ventilation and reduces the mortality though large sample size studies are required to evaluate its role in COVID-19 treatment.

CONVALESCENT PLASMA THERAPY IN PATIENTS WITH COVID-19

Anti-SARS-CoV-2 antibody containing plasma obtained from recovered patients who had confirmed COVID-19 is collected by apheresis devices and stored in blood banks. It may be an adjunctive treatment option to the antiviral therapy. The protective effect of convalescent plasma (CP) may remain for weeks and months. After the assessment of the donor, 200–600 mL of plasma can be collected with apheresis devices.

Mechanism of Action

Based on previous studies in other viral infections such as Ebola and respiratory syncytial virus, the mechanism of action is mainly viral neutralization. Though the exact mechanism of CP in COVID-19 has not been clearly established. The other mechanisms are antibody-induced cellular cytotoxicity, complement activation, and phagocytosis. Neutralizing antibody can provide control of viral load. Non-neutralizing antibodies may also contribute to prophylaxis and/or enhance recovery. The Food and Drug Administration (FDA) does not allow the use of CP for prophylaxis. The WHO advised using

CP when vaccines and antiviral drugs are not available in the treatment of critically ill patients with COVID-19.

Collection of Convalescent Plasma

All the steps are important and should be organized carefully and performed by expert healthcare workers.

Eligibility of Donor

According to the FDA, individuals fulfilling following criteria can be a donor.

- Recovered from COVID-19, blood donor tests were done, and suitable for donation.
- Evidence of COVID-19 documented by a laboratory test either by a diagnostic test (e.g., nasopharyngeal swab) at the time of illness, or a positive serological test for SARS-CoV-2 antibodies after recovery, if prior diagnostic testing was not performed at the time COVID-19 was suspected.
- Complete resolution of symptoms at least 14 days prior to donation.
- Male donors, or female donors who have not been pregnant, or female donors who have been tested since their most recent pregnancy and results interpreted as negative for human leukocyte antigen (HLA) antibodies.
- When measurement of neutralizing antibody titers is available, neutralizing antibody titers of at least 1:160 is recommended. A titer of 1:80 may be considered acceptable if an alternative matched unit is not available.

Evaluation of Donors before Donation

As RNA detectability is low in samples collected for RT-PCR before 7 days and during days 15–39, that is why coronavirus predonation screening should be supported by antibody detecting tests. Minimize the risk of transfusion-related acute lung injury (TRALI) by screening for HLA antibodies in pregnant females. The relationship between total anti-SARS-CoV-2 antibodies and neutralizing anti-SARS-CoV-2 antibodies is not clear. The antibody titer will differ according to the duration between the collection time and onset of infection. Seroconversion has been observed to occur between 8 days and 21 days after the onset of symptoms. Reports suggest that CP that is collected ≥14 days after resolution of symptoms contain high titer of antibodies. According to the FDA, neutralizing antibody titer should be at least 1:160 but a titer of 1:80 may be considered acceptable if an alternative matched unit is not available.

Convalescent Plasma Collection

Approximately 200–600 mL plasma can be collected with apheresis devices depending on total blood volume of the donor. The collected plasma volume (excluding the anticoagulant solution) should not exceed 750 mL for each procedure. CP is stored by freezing or applied within 6 hours without freezing. Freezing should be started within the first 6 hours after the apheresis process is completed. Barcoded products should be stored at or below –18/25°C in a separate storage cabinet. ABO blood group should preferably compatible. It is recommended that CP should have undergone pathogen inactivation process such as amotosalen + ultraviolet light; riboflavin + ultraviolet light; methylene blue; or a solvent/detergent may be used. It should be irradiated if it will be given to the patient without being frozen within 6 hours after plasma collection. The frozen plasma does not need to be irradiated.

Convalescent Plasma Dosage

One unit may be used for prophylaxis and one to two units for the treatment. The duration of efficacy of the antibodies is not known, but it is estimated to last in weeks to a few months. According to linear proportionality, 3.125 mL/kg of plasma with a titer of >1:64 would provide an equivalent immunoglobulin level to one quarter of 5 mL/kg plasma with a titer of 1:160.

Coronavirus disease 2019 is rarely symptomatic in pediatric age group. In pediatric population dose by weight should be used. In previous use of CP therapy in SARS, 5 mL/kg of plasma at a titer of 1:160 was used.

Patient Selection

The FDA suggests the following criteria for the use of CP:

- Laboratory confirmed COVID-19
- Severe or immediately life-threatening COVID-19
  - Severe disease is defined as one or more of the following:
    - Dyspnea
    - Tachypnea ≥ 30/min
    - Blood oxygen saturation ≤ 93%
    - Partial pressure of oxygen (PaO_2)/FiO_2 < 300
    - Lung infiltrates > 50% within 24–48 hours
  - The life-threatening disease is defined as one or more of the following:
    - Respiratory failure
    - Septic shock

Prophylaxis

The FDA does not allow the use of CP for prophylaxis. The new phase 2–3 trial is evaluating the use of postexposure prophylactic plasma in COVID-19 patients who have had close contact exposure but have not yet presented symptoms.

Risks associated with CP are following:

- Infection (bacterial or viral)
- Immunological reaction, e.g., serum sickness
- Nonhemolytic transfusion reactions (fever, tremors, and urticarial)
- Transfusion-associated circulatory overload and TRALI.

Transfusion-transmitted SARS-CoV-2 is theoretical specific risk of anti-SARS-CoV-2. Other theoretical risk of CP is an antibody-dependent enhancement (ADE). Antibodies that develop during a previous infectious disease caused by a different serotype may exacerbate clinical severity. One more theoretical risk of CP is attenuation of the development of a natural immune response, especially when administered for prophylaxis. Even though published studies are not prospective or randomized, until the development of vaccines or therapeutics, CP appears to be a safe and probably effective treatment for critically ill patients with COVID-19.

VACCINES FOR SARS-CoV-2

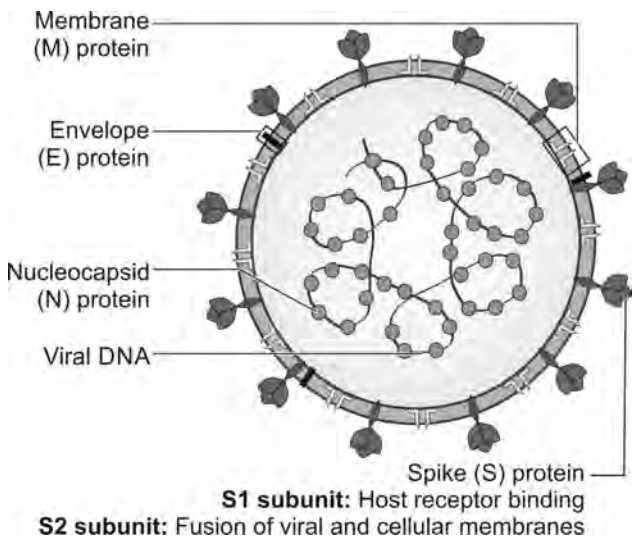
The COVID-19 SARS-CoV-2 is the disease caused by a novel beta coronavirus, first case reported in December 2019 in Wuhan (China) further spread globally and declared pandemic by March 11, 2020, at the time of writing, 23nd April 2021, there has been over 145 million people infected and more than 3

million deaths worldwide and 17 million cases and 187,000 death in India. COVID-19 (SARS-CoV-2) primarily a respiratory tract disease severity ranging from very mild fever, body ache, rhinorrhea to severe ARDS, and death. Nonrespiratory symptoms of SARS-CoV-2 are anosmia, diarrhea, rash, thromboembolic disorders, myocarditis, and vasculitis. The median incubation period is estimated to be 5 days with a majority developing symptoms by 11.5 days. The case fatality rate is highest in elderly (aged >70 years). Coronaviruses have a large (30 + kb) single-stranded positive sense RNA genome encased by a helical nucleocapsid (N) and an outer envelope comprised of matrix protein (M), envelope protein (E), and spike proteins (S) (**Fig. 2**). The S protein of SARS-CoV-2 is responsible for binding onto the ACE2 and entry into the cell which naturally occurs in a trimeric form, contains the receptor-binding domain (RBD). In SARS-CoV-2, S protein is a major target antigen for vaccine development and found to elicit neutralizing antibody.

During global pandemic setting, developing and scaling-up mass production of a vaccine rapidly is challenging because it requires coordination of many activities and in normal situation process is usually decade long, sequential process with preclinical testing, phased clinical trials, planned production, and distribution. In humans, live-attenuated viruses (e.g., measles, mumps, and rubella), inactivated viruses (e.g., inactivated polio vaccine), protein or polysaccharide conjugated subunit vaccines (protein: acellular pertussis and hepatitis B; polysaccharide conjugated: pneumococcus and meningococcus), and virus-like particles are used. With the advancement of new technology, vaccines composed of nucleic acid (DNA and RNA) and viral vectors and recombinant proteins are also developed over the last decade.

Recombinant Vaccines/Viral Vectors

One or more genes that encode a target antigen within an unrelated and engineered virus can be delivered by viral vector technology. The viral vector can be replication competent (live attenuated) or replication deficient. Viral vectors technology is used for developing vaccines for human immunodeficiency virus (HIV), Ebola, Zika, and Chikungunya, including adenovirus (Ad), measles virus (MV), vesicular stomatitis virus (VSV), alphaviruses, poxviruses, and herpesviruses allowing ability to stimulate cellular and humoral immunity.



(DNA: deoxyribonucleic acid; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2)

FIG. 2: Structure of SARS-CoV-2.

Nucleic Acid Vaccines

Antigen-encoding plasmid DNA or RNA, messenger RNA (mRNA), or viral replicons are used for developing nucleic acid vaccines. Once the nucleic acid enters in the cell, protein synthesis started and similar to natural infection humoral and cell-mediated immune response is expected to occur. The benefit of a nucleic acid platform-based vaccines is that it allows antigen manipulation easily and the speedy production. Nucleic acid, especially mRNA, are fragile and require an uninterrupted cold-chain process for transport and storage is one the disadvantages. Clinical trials are on various stages for SARS-CoV and MERS-CoV DNA vaccines.

SARS-CoV-2 VACCINES IN INDIA

Two vaccines (Covishield and Covaxin) approved by India's top drug regulator for emergency and restricted use against COVID-19 on 3 January 2021. *Covishield* vaccine is by the Oxford University-AstraZeneca with average efficacy of 70.4%. Covishield is developed by the world's largest vaccines manufacturer, the Serum Institute of India. Against COVID-19, *Covaxin* is India's first home produced vaccine developed by Bharat Biotech in collaboration with the Indian Council of Medical Research and the National Institute of Virology. The Lancet published Covaxin's phase I trial data on 21st January 2021, giving positive conclusion for safety and stating that it generates adequate immune response, with recommendation of further trials. Both vaccines work by priming the immune system with a SARS-CoV-2 spike protein and require two doses. Covishield uses a weakened version of adenovirus, while Covaxin uses an inactivated SARS-CoV-2 virus extracted from an asymptomatic patient. Characters of both vaccines are summarized in **Table 8**. From 16 January 2021 health ministry started India's huge immunization drive to vaccinate four priority groups: healthcare workers, people over 50, public workers, and those under 50 with comorbidities—with the former two groups to be inoculated first in an initial rollout to 30 million people. Till 23rd April 2021, 140 million people received vaccination in India. From 1st May 2021 Government of India (GOI) has started vaccination drive to all population over 18 years of age. Russia's Sputnik V vaccine is also given approval for emergency use and may prove crucial as the powdered version of the vaccine can be stored at refrigerator temperatures, making it more suitable for India's climate. India's biotech companies are also expected to produce 300 million doses of Russia's Sputnik V vaccine.

Indications

Active immunization for individuals ≥18 for COVID-19 prevention.

Precautions

If required, COVID-19 vaccine and other vaccines should be separated by an interval of at least 14 days. Interchangeability of vaccines is not permitted; second dose should be of the

TABLE 8: Characteristics of Covishield and Covaxin vaccine.

Indicators	*Covishield*	*Covaxin*
Type of vaccines	Recombinant vaccine based on viral vector technology	Whole virion inactivated coronavirus vaccine
No. of doses in each vial/ dose	• 10/0.5 mL each dose • Discard 4 hours of opening of vials	• 10/0.5 mL each dose • Discard 4 hours of opening of vials
Route	Intramuscular	Intramuscular
Shelf life	6 months	6 months
Course/schedule	Two doses/6–8 weeks apart	Two doses/6–8 weeks apart
Storage and transportation	+2°C to +8°C at all levels	+2°C to +8°C at all levels
Adverse events following immunization (AEFI)	• Injection site tenderness, headache, fatigue, myalgias, malaise, pyrexia, and chills • Paracetamol may be used for symptomatic relief	• Injection site tenderness, headache, fatigue, myalgias, malaise, pyrexia, chills, nausea, vomiting, dizziness, giddiness, and sweating • Paracetamol may be used for symptomatic relief

same COVID-19 vaccine which was administered as first dose. Vaccine should be administered with precaution in person with history of any bleeding or coagulation disorder.

Contraindications

A confirmed anaphylactic reaction to a previous dose of COVID-19 vaccine, immediate or delayed onset anaphylaxis or allergic reaction to vaccines or injectable therapies, pharmaceuticals products, food items, etc. COVID-19 vaccines are currently not recommended in pregnant or lactating women.

Temporary Contraindications (Differ for 4–8 Weeks)

- Active SARS-CoV-2 infection
- SARS-CoV-2 patients who have been given monoclonal antibodies or CP
- Acutely unwell or hospitalized patients due to any illness

OMICRON—NEW VARIANT OF SARS-COV-2

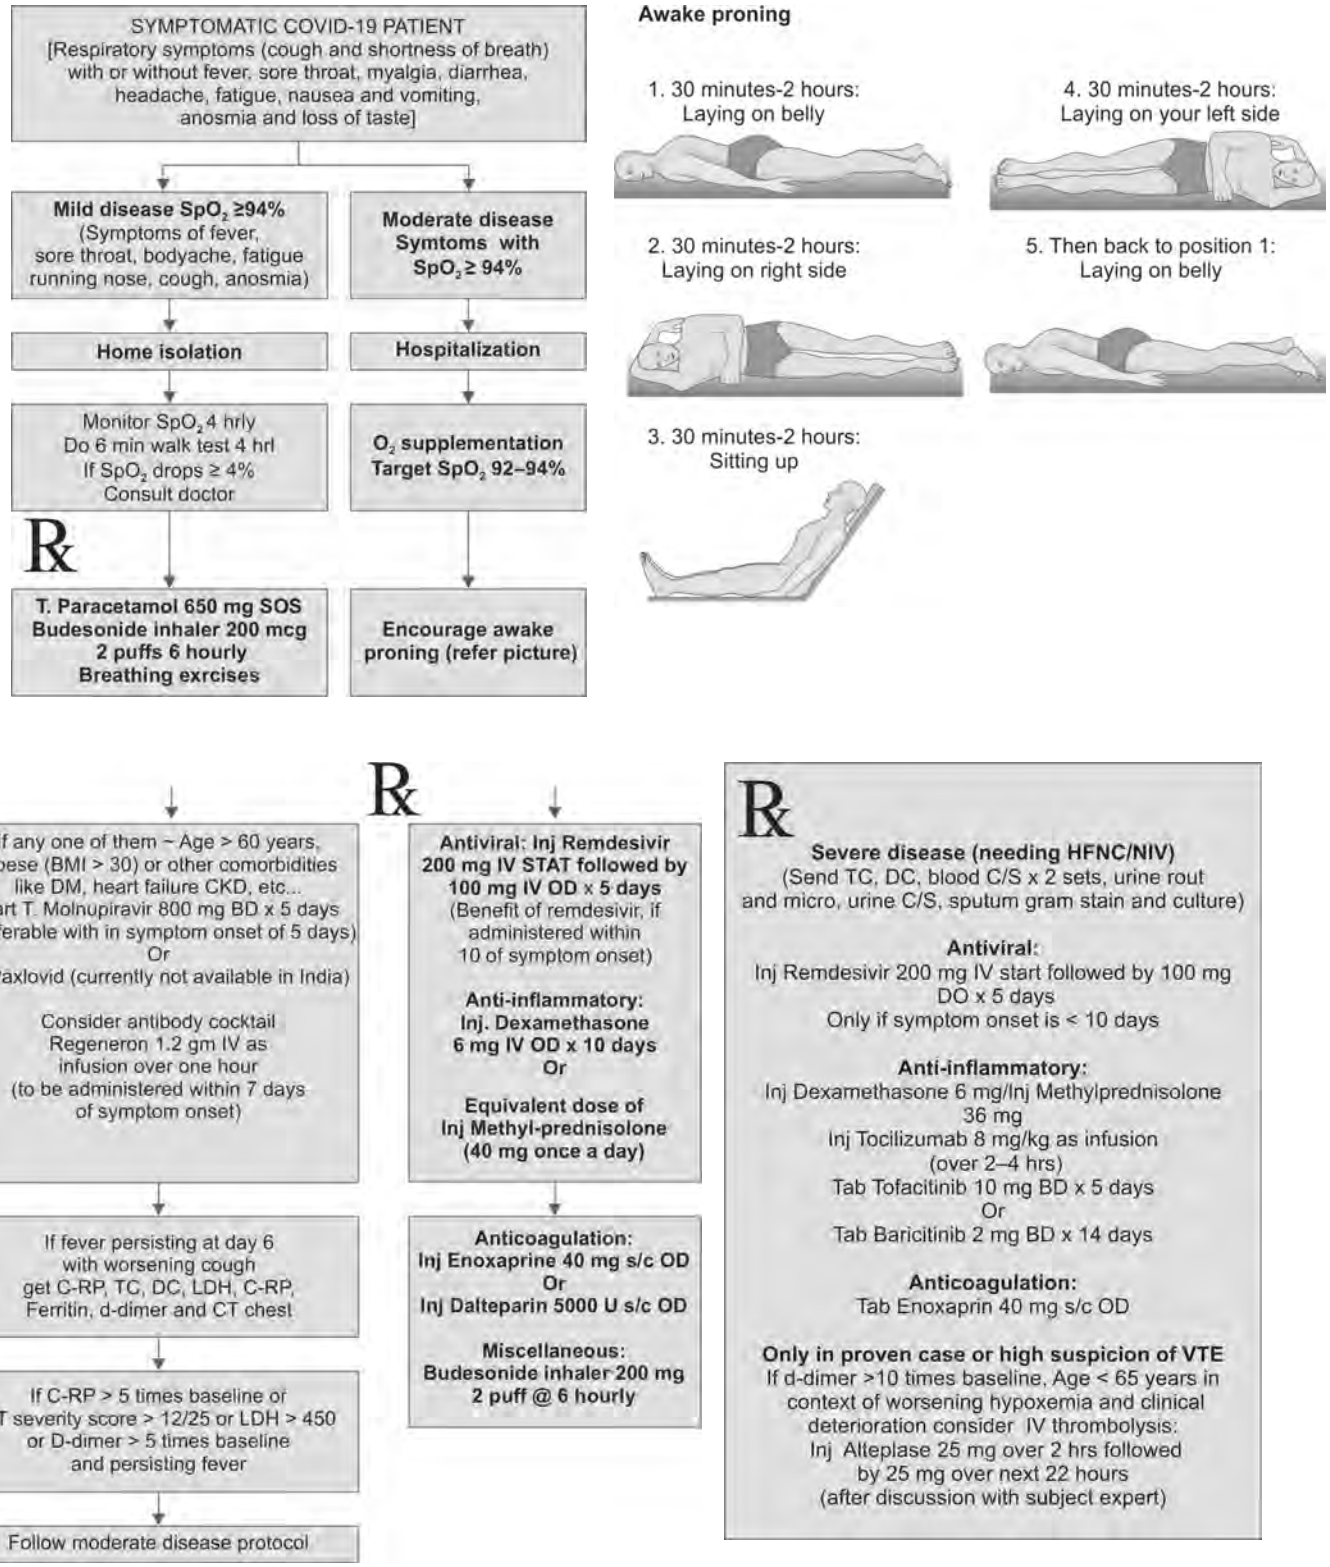
Mutation in spike protein region gives the variant the potential to develop an immune escape mechanism. The omicron variant has more than 30 mutations in spike protein region. This variant is a major cause of concern because most of the vaccines work by forming antibodies against spike proteins. Hence, vaccines have to be reviewed to check the possibilities of decreased efficacy of the existing COVID-19 vaccines. Structural changes have been observed in the omicron variant which is indicative of adherence to the same cellular receptors with an increase in affinity and transmission.

Oxygen and steroid still remain the promising drugs. Apart from Favipiravir which is described earlier in this chapter, two new promising drugs, Molnupiravir and Paxlovid, are investigational drugs for the treatment of SARS-CoV-2. Molnupiravir is an oral drug which inhibits the multiple RNA virus including SARS-CoV-2 and is most effective when used early. Paxlovid, a protease inhibitor, is an investigational drug which inhibits the viral replication at proteolysis (a stage that occurs before proteolysis).

The Drug Regulator of India approved two new covid vaccines, Covovax by the Serum Institute of India and Corbevax by Biological E, for restricted use in an emergency situation. The Drug Regulator of India also approved Molnupiravir, an oral drug, which has shown promising results in early use in the treatment of mild-to-moderate SARS-CoV-2 infection in an adult and reduces the risk of hospitalization and death.

SUMMARY

A large number of populations of world are affected by the COVID-19 pandemic. Various groups of drugs are proposed to treat the COVID-19, e.g., antivirals, antimalarials, and immunomodulators. Remdesivir (antiviral) shows promising results in the treatment of the COVID-19. Hydroxychloroquine (HCQ) also used extensively for the treatment of COVID-19. TCZ (immunomodulatory therapy) and plasma therapy can be used in moderate-to-severe disease to control the cytokine storm. Low-molecular-weight heparin is used in both prophylactic and therapeutic therapy. Adjunctive therapy, vitamin C, and vitamin D may be useful. Several vaccines are currently under trial and also given approval for emergency use in various countries. Current proposed management for COVID-19 is given in **Flowchart 1**.



SYMPTOMATIC COVID-19 PATIENT
[Respiratory symptoms (cough and shortness of breath) with or without fever, sore throat, myalgia, diarrhea, headache, fatigue, nausea and vomiting, anosmia and loss of taste]
Mild disease SpO2 ≥94%
(Symptoms of fever, sore throat, bodyache, fatigue running nose, cough, anosmia)
Moderate disease Symtoms with SpO2 ≥ 94%
Home isolation
Hospitalization
Monitor SpO2 4 hrly
Do 6 min walk test 4 hrl
If SpO2 drops ≥ 4%
Consult doctor
O2 supplementation
Target SpO2 92–94%
Rx
T. Paracetamol 650 mg SOS
Budesonide inhaler 200 mcg
2 puffs 6 hourly
Breathing exrcises
Encourage awake proning (refer picture)
Awake proning
1. 30 minutes-2 hours: Laying on belly
2. 30 minutes-2 hours: Laying on right side
3. 30 minutes-2 hours: Sitting up
4. 30 minutes-2 hours: Laying on your left side
5. Then back to position 1: Laying on belly
Rx
If any one of them ~ Age > 60 years, Obese (BMI > 30) or other comorbidities like DM, heart failure CKD, etc...
start T. Molnupiravir 800 mg BD x 5 days
(preferable with in symptom onset of 5 days)
Or
T. Paxlovid (currently not available in India)
Consider antibody cocktail
Regeneron 1.2 gm IV as infusion over one hour
(to be administered within 7 days of symptom onset)
Antiviral: Inj Remdesivir 200 mg IV STAT followed by 100 mg IV OD x 5 days
(Benefit of remdesivir, if administered within 10 of symptom onset)
Anti-inflammatory:
Inj. Dexamethasone 6 mg IV OD x 10 days
Or
Equivalent dose of Inj Methyl-prednisolone (40 mg once a day)
If fever persisting at day 6 with worsening cough
get C-RP, TC, DC, LDH, C-RP, Ferritin, d-dimer and CT chest
Anticoagulation:
Inj Enoxaprine 40 mg s/c OD
Or
Inj Dalteparin 5000 U s/c OD
Miscellaneous:
Budesonide inhaler 200 mg
2 puff @ 6 hourly
If C-RP > 5 times baseline or
CT severity score > 12/25 or LDH > 450
or D-dimer > 5 times baseline
and persisting fever
Follow moderate disease protocol
Rx
Severe disease (needing HFNC/NIV)
(Send TC, DC, blood C/S x 2 sets, urine rout and micro, urine C/S, sputum gram stain and culture)
Antiviral:
Inj Remdesivir 200 mg IV start followed by 100 mg DO x 5 days
Only if symptom onset is < 10 days
Anti-inflammatory:
Inj Dexamethasone 6 mg/Inj Methylprednisolone 36 mg
Inj Tocilizumab 8 mg/kg as infusion (over 2–4 hrs)
Tab Tofacitinib 10 mg BD x 5 days
Or
Tab Baricitinib 2 mg BD x 14 days
Anticoagulation:
Tab Enoxaprin 40 mg s/c OD
Only in proven case or high suspicion of VTE
If d-dimer >10 times baseline, Age < 65 years in context of worsening hypoxemia and clinical deterioration consider IV thrombolysis:
Inj Alteplase 25 mg over 2 hrs followed by 25 mg over next 22 hours
(after discussion with subject expert)

Criteria for discharge: Resolution of clinical symptoms, patient remaining asymptomatic for 3 days. No need for RT-PCR/CBNAAT/True-NAT before discharge. Post discharge ~ home quarantine × 10 days.

Ancillary measures: Normal feeding, no dietary restrictions. No role of maintenance IV fluids. Maintain blood glucose levels < 180 mg/dL. Patients on oxygen should always remain in propped up and prone position. Mandatory incentive spirometry every hour for 35–35 breaths. Maintain net-neutral fluid balance in patients on supplemental oxygen.

Disclaimer: There is no conclusive evidence of outcome benefit with the use of antiviral drugs and novel therapies. However, the suggestions made are derived from the prevailing trials published so far and collation of literature that has come out so far. These recommendations would change with the evolving evidence.

FLOWCHART 1: Proposed management algorithm for SARS CoV-2 (COVID-19) infection.

91
CHAPTER

Abdominal Pain

Roberta Petrino, Aldo Tua

INTRODUCTION

Abdominal pain is a very common symptom of presentation for patients admitted to the emergency department and represents a strong challenge for physicians and nurses involved in diagnosis and treatment. Incidence and clinical manifestations are both influenced by many demographic variables (age, gender, geography, etc.). Although in most of the cases it is not related to a serious disease, in some cases it can be the only symptom of a potential rapidly evolved situation.

ETIOLOGY

Many intra-abdominal disorders cause abdominal pain and also several extra-abdominal diseases can present with abdominal pain. Some of these are immediately life-threatening, requiring rapid diagnosis and surgery. The knowledge of abdominal anatomy and its innervation helps for differential diagnosis; however, a systematic and logical approach, with a careful medical history and clinical evaluation, is fundamental. Focused clinical history and physical examination are able to place a right diagnostic hypothesis in 80% of patients with abdominal pain There are some alert signs and symptoms that must always be taken into careful consideration because they probably underlie a serious condition. Often a definitive diagnosis is impossible in the emergency department but the emergency physician has always to identify and rule out life-threatening clinical conditions. These include ruptured *abdominal* aorta aneurysm (AAA), perforated viscus, mesenteric ischemia, and ruptured ectopic pregnancy. Other diseases (e.g., acute appendicitis, acute diverticulitis, severe acute pancreatitis, intestinal obstruction) are also serious and nearly as urgent. The emergency physician must correlate between the anatomical site of abdominal pain and the differential diagnosis (**Fig. 1**).

PATHOPHYSIOLOGY

The abdominal viscera are innervated by nociceptive fibers on the mesenteric surface and inside the wall of the hollow organs. These fibers are sensitive to both mechanical, mainly stretching, and chemical stimuli. They can produce dull, continuous, crampy, or violent pain.

The abdominal pain is divided into the following:

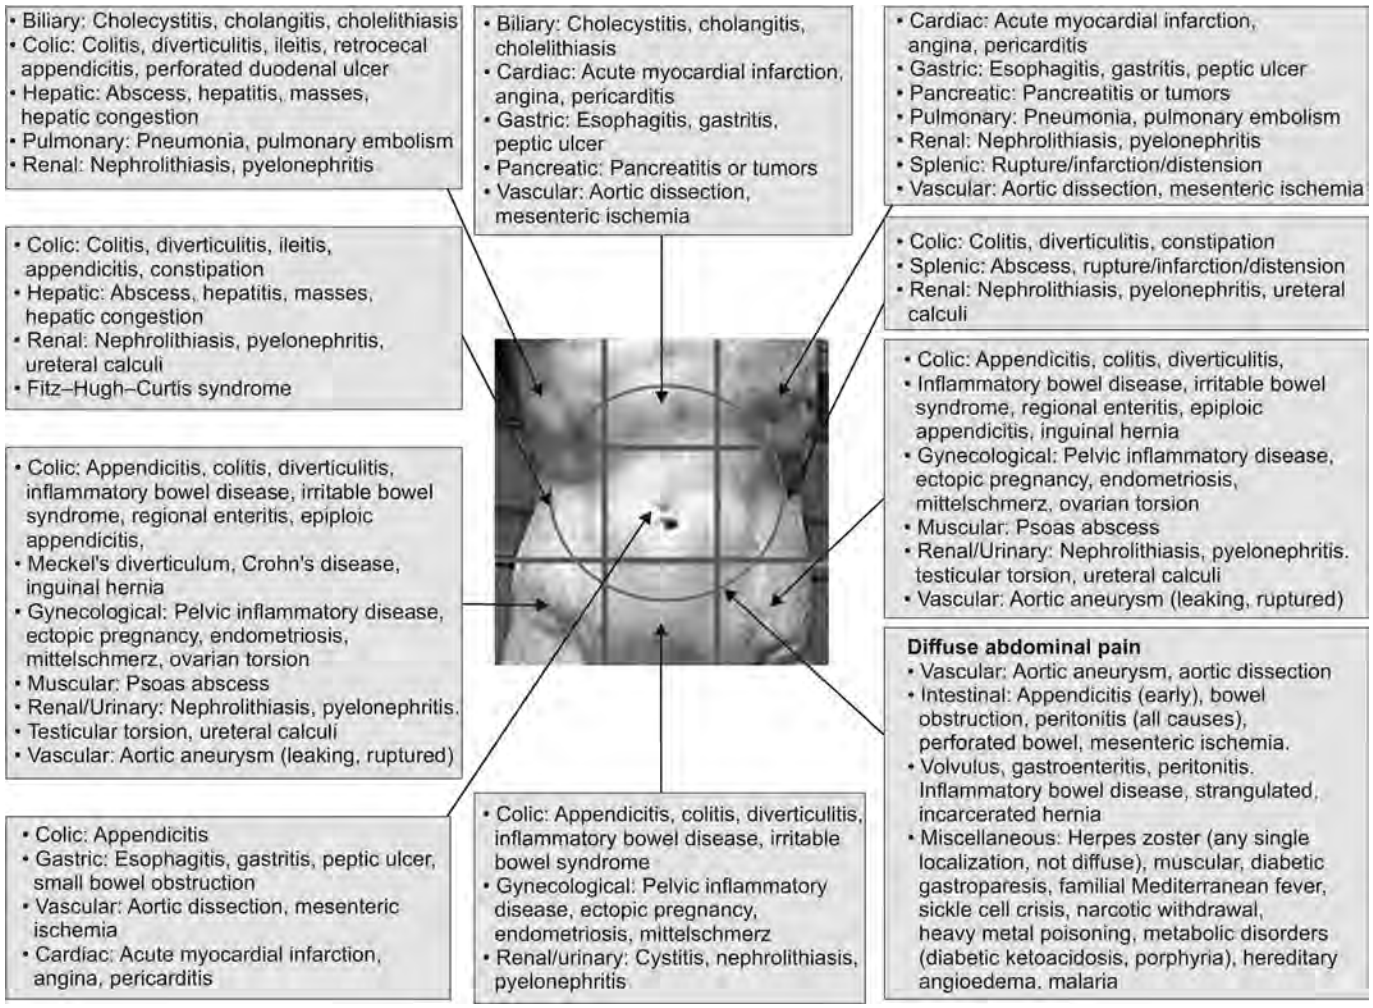
- *Visceral*: Usually secondary to stretching of hollow organs, twist or spastic contraction. It can be deaf and continuous or colic, often located in the median site, as visceral innervation is bilateral, and it corresponds to the dermatome relative to the involved organ. Therefore, for the organs located above the Treitz ligament, it will be epigastric; for those between the Treitz and the hepatic flexure of the colon, it will be umbilical; and for the most distal organs, it will be hypogastric.
- *Parietal*: It is usually acute, due to direct irritation of the peritoneum located above the involved organ. The parietal innervation is unilateral, so the pain will be well localized. Only when there is widespread involvement of the peritoneum, as for leak of gastric contents, blood, pus, or other, the pain will be extended to all of the abdomen. The peritoneal irritation may cause a reflex contracture of abdominal muscles whereby the abdomen will become stiff and untreatable. The irritant reaction to organic or chemical substances is different so that the peritonitic pain will be much more striking during gastric perforation with spreading of gastric acid than during colic perforation, with the leaking of stool or blood.
- *Referred*: It appears when the afferent fibers from an injured abdominal organ enter the spinal cord at the same level of somatic fibers coming from distant regions (e.g., the gallbladder pain can be referred to the right shoulder).

CLINICAL PRESENTATION

Clinical features of concern *(red flags)*, which are important for the emergency physician to know are, as follows:

- Signs of shock (e.g., tachycardia, hypotension, diaphoresis, confusion)
- Severe pain
- Signs of peritonitis
- Abdominal distention
- Attention to nonabdominal diseases that present with abdominal pain

Major diseases that cause acute abdomen of immediate surgical interest are described further.



• Biliary: Cholecystitis, cholangitis, cholelithiasis
• Colic: Colitis, diverticulitis, ileitis, retrocecal appendicitis, perforated duodenal ulcer
• Hepatic: Abscess, hepatitis, masses, hepatic congestion
• Pulmonary: Pneumonia, pulmonary embolism
• Renal: Nephrolithiasis, pyelonephritis
• Biliary: Cholecystitis, cholangitis, cholelithiasis
• Cardiac: Acute myocardial infarction, angina, pericarditis
• Gastric: Esophagitis, gastritis, peptic ulcer
• Pancreatic: Pancreatitis or tumors
• Vascular: Aortic dissection, mesenteric ischemia
• Cardiac: Acute myocardial infarction, angina, pericarditis
• Gastric: Esophagitis, gastritis, peptic ulcer
• Pancreatic: Pancreatitis or tumors
• Pulmonary: Pneumonia, pulmonary embolism
• Renal: Nephrolithiasis, pyelonephritis
• Splenic: Rupture/infarction/distension
• Vascular: Aortic dissection, mesenteric ischemia
• Colic: Colitis, diverticulitis, ileitis, appendicitis, constipation
• Hepatic: Abscess, hepatitis, masses, hepatic congestion
• Renal: Nephrolithiasis, pyelonephritis, ureteral calculi
• Fitz–Hugh–Curtis syndrome
• Colic: Colitis, diverticulitis, constipation
• Splenic: Abscess, rupture/infarction/distension
• Renal: Nephrolithiasis, pyelonephritis, ureteral calculi
• Colic: Appendicitis, colitis, diverticulitis, inflammatory bowel disease, irritable bowel syndrome, regional enteritis, epiploic appendicitis,
• Meckel's diverticulum, Crohn's disease, inguinal hernia
• Gynecological: Pelvic inflammatory disease, ectopic pregnancy, endometriosis, mittelschmerz, ovarian torsion
• Muscular: Psoas abscess
• Renal/Urinary: Nephrolithiasis, pyelonephritis.
• Testicular torsion, ureteral calculi
• Vascular: Aortic aneurysm (leaking, ruptured)
• Colic: Appendicitis, colitis, diverticulitis, inflammatory bowel disease, irritable bowel syndrome, regional enteritis, epiploic appendicitis, inguinal hernia
• Gynecological: Pelvic inflammatory disease, ectopic pregnancy, endometriosis, mittelschmerz, ovarian torsion
• Muscular: Psoas abscess
• Renal/Urinary: Nephrolithiasis, pyelonephritis. testicular torsion, ureteral calculi
• Vascular: Aortic aneurysm (leaking, ruptured)
Diffuse abdominal pain
• Vascular: Aortic aneurysm, aortic dissection
• Intestinal: Appendicitis (early), bowel obstruction, peritonitis (all causes), perforated bowel, mesenteric ischemia.
• Volvulus, gastroenteritis, peritonitis. Inflammatory bowel disease, strangulated, incarcerated hernia
• Miscellaneous: Herpes zoster (any single localization, not diffuse), muscular, diabetic gastroparesis, familial Mediterranean fever, sickle cell crisis, narcotic withdrawal, heavy metal poisoning, metabolic disorders (diabetic ketoacidosis, porphyria), hereditary angioedema, malaria
• Colic: Appendicitis
• Gastric: Esophagitis, gastritis, peptic ulcer, small bowel obstruction
• Vascular: Aortic dissection, mesenteric ischemia
• Cardiac: Acute myocardial infarction, angina, pericarditis
• Colic: Appendicitis, colitis, diverticulitis, inflammatory bowel disease, irritable bowel syndrome
• Gynecological: Pelvic inflammatory disease, ectopic pregnancy, endometriosis, mittelschmerz
• Renal/urinary: Cystitis, nephrolithiasis, pyelonephritis

FIG. 1: Correlation between the anatomical site of abdominal pain and the differential diagnosis.

Acute Appendicitis

The inflammatory process is due to appendicular lumen obstruction, which can cause an increase in pressure within the lumen with consequent local circulatory dysfunction with ischemia of the wall (catarrhal or phlegmonous form) and necrosis. If perforation of the necrotic bowel wall occurs, appendicitis becomes complicated by perforative peritonitis, localized, or diffuse (gangrenous or perforated form), generally caused by aerobic (*Escherichia coli*, *Streptococcus*, and *Staphylococcus*) and anaerobic (*Bacteroides*) bacteria superinfection.

In case of acute inflammation, there will be spontaneous, dull pain, which arises in the epi-mesogastric or periumbilical area. Later, when serosa involvement and peritoneal irritation develop, the pain is localized in the right lower abdominal quadrant. In addition, the pain is exacerbated by the cough and is not modified by body position changes. Vomiting is sometimes present, and a low-grade fever (37–38°C) can be detected. Steadily, the patient loses appetite, so that the evaluation of this data is very important for diagnostic exclusion of appendicitis. At the physical examination, pain is evoked by palpating the right lower quadrant (RLQ) or, more commonly, Blumberg's sign can be present, but Markle's sign is more sensitive to define a peritoneal irritation. Markle's sign, or jar tenderness, consists in the evocation of pain in RLQ by dropping from standing on the toes to the heels with a jarring landing. In case of suspicion, a white blood cell count (WBC) and C-reactive protein (CRP) detection should be tested since the concomitance of neutrophilic leukocytosis and elevated CRP significantly increases the possible diagnosis of appendicitis.

In the presence of a striking clinical picture, no further tests are necessary, but surgical advice must be activated as soon as possible. In less obvious cases, it is necessary to study the diagnosis more in depth. With an expert operator, ultrasonography (US) has good specificity, but if this examination is not diagnostic or not reliable, a computed tomography (CT) scan of the abdomen and pelvis must be performed. Then, based on the evidence of direct examination, the radiologist will decide whether to complete CT using an intravenous or an oral contrast agent.

Intestinal Ischemia

Intestinal ischemia can present itself with three distinct syndromes, of which the first two generally have a favorable prognosis. The first syndrome is "*chronic mesenteric ischemia,*" determined by gradual reduction of blood supply to the affected intestinal tract, generally due to mesenteric vessels

atherosclerosis. This condition is present with postprandial intermittent abdominal pain (angina abdominis). The patient is ill when he/she eats and consequently tends to reduce food intake and may appear debilitated to medical examination, also considering that elderly subjects are the most affected by the disease.

"*Ischemic colitis*" is caused by inadequate vascularization of some colon fragments, not necessarily on atherosclerotic basis, and generally starts as per rectal bleeding rather than abdominal pain.

"Acute mesenteric ischemia" is due to acute thrombo-embolic occlusion of the celiac tripod, superior or inferior mesenteric artery, which leads to rapid necrosis of a no longer vascularized intestinal region, with subsequent development of a systemic toxic syndrome if not operated immediately.

The syndrome occurs more often in the presence of risk factors for ischemia. Most frequently, the symptom of onset is a severe periumbilical pain with an abdominal physical examination not proportional to the pain described by the patient. When the intestinal infarction has already been established, signs of peritoneal involvement are present. Rectal bleeding is rare.

Blood tests show signs of dehydration, metabolic acidosis, and multiorgan involvement when the situation is advanced, while in earlier stages it is possible to detect leukocytosis or increase in D-dimer, but with little specificity. It is important to consider the risk factors and the onset symptoms, as the mortality once the intestinal infarction has been established is approximately 90%.

Acute Diverticulitis

About 30% of people over 50 years and 60% of those over 80 years of age have a diverticular disease that mainly affects the sigmoid colon. Diverticulitis is caused by the inflammation and perforation of the diverticulum, which can be circumscribed and buffered by the mesentery or can be opened with abscess formation or frank peritonitis. The patient presents with cramping abdominal pain, more frequently located in the left lower quadrant (LLQ), but in the case of dolichocolon or diverticulosis of the ascending colon, the right lower quadrant (RLQ) can also be affected. Nausea, vomiting, and anorexia are frequently associated. The diagnostic workup, in case of clinical suspicion of diverticular disease, involves a CT scan with an intravenous or oral contrast medium (**Fig. 2**), while the colonoscopy is contraindicated when diverticular perforation is suspected. Uncomplicated diverticulitis can be managed at home with antibiotic therapy and liquid diet, while perforation with abscess or peritonitis requires immediate surgical evaluation.

Bowel Obstruction

Intestinal occlusion occurs when a mechanical block prevents the progression of intestinal contents. This causes bowel distension upstream from the obstruction due to the ingested air, the gases produced by the bacteria, and the endoluminal secretions. If the occlusion is not recognized and treated rapidly, ischemia and subsequent necrosis of the intestinal tract will develop. **Box 1** lists the main causes of intestinal obstruction. The abdominal pain is widespread and intermittent and the passage of feces and gases is absent; however, in the initial stage, diarrhea may be present, caused by the irritation of the mucosa. In advanced stages, vomiting will occur, which may be fecaloid due to bacterial activity.

At the physical examination, the abdomen is distended and painful and the bowel sounds could be increased with a metallic sound, reduced or absent. If peritonitis occurs, the abdomen will be rigid with rebound tenderness present. Laboratory tests show hemoconcentration, with possible electrolytic imbalances and renal insufficiency. The abdominal plain X-ray makes evident the presence of hydro-air levels, intestinal distention, and absence of air in the rectum (**Figs. 3** and **4**). The diagnostics can be completed with a CT scan if the clinical condition allows it, which can identify the cause of the occlusion with an approximate sensitivity of 100%. In the event of intestinal obstruction, the surgical evaluation must be timely; however, it is essential to correct fluids and electrolyte imbalances and to decompress the bowel with a nasogastric tube.

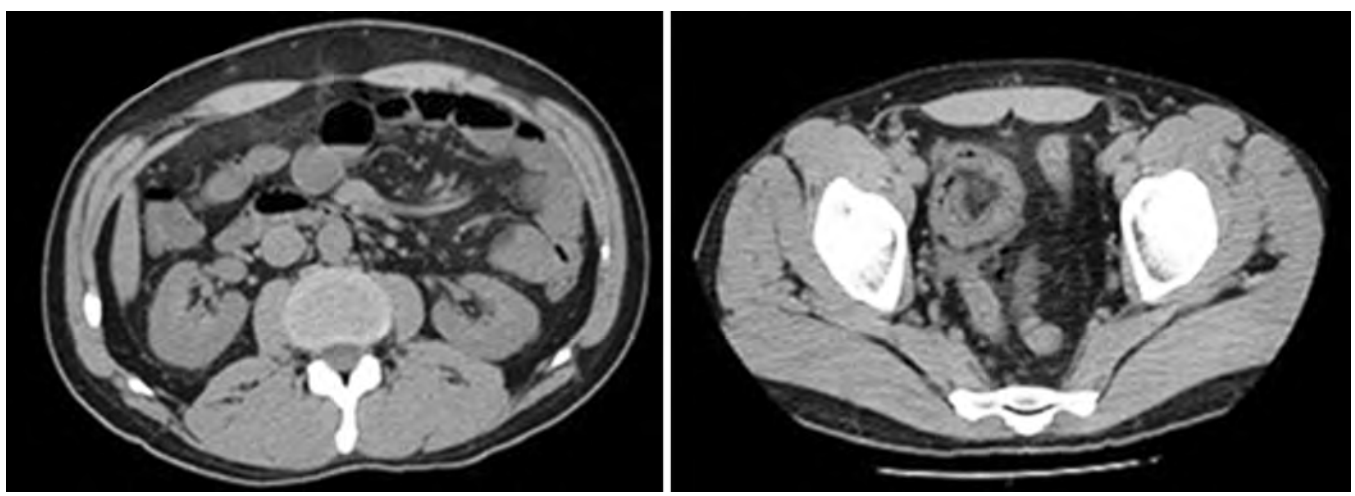


FIG. 2: Contrast enhancement CT scan that highlights the presence of loose ileal loops and with hydro-air levels, thickening of the wall of the sigma with air bubbles in its context, the surrounding liquid flap. The findings are compatible with perforated diverticulitis.

EVALUATION

Evaluation of mild and severe pain follows the same process, although with severe abdominal pain or important systemic impairment, therapy must precede the other steps and include early surgical consultation. Life-threatening conditions should always be ruled out before focusing on less serious diagnoses. In seriously ill patients with severe abdominal pain, early surgical exploration may be appropriate. In less critical patients, observation and diagnostic workup is generally the right choice. **Box 2** summarizes the steps for the evaluation of abdominal pain.

History

A thorough history usually suggests the diagnosis. It is necessary to promptly investigate the symptomatology in particular with regard to onset, quality, duration, intensity, irradiation, relationship with meals, and trigger or relieving factor. Of particular importance are characteristics and pain location, associated symptoms, and duration. Concomitant symptoms such as fever, melena, mucus or blood in the stools, hematuria, vomiting, hematemesis, heartburn, nausea, diarrhea, constipation, jaundice, and weight loss help direct subsequent evaluation. Past medical history and medications are essential, taking care that anticoagulants can increase the chances of bleeding and hematoma formation and alcohol predispose to pancreatitis. The use of nonsteroidal anti-inflammatory drugs is also associated with epigastric pain. Recent antibiotic use should be asked if the patient experiences diarrhea. Collect information on the known allergies, on the date and time of the last meal, on any travel and activity employment, and on the use of drugs of abuse.

It is necessary to consider that while in most of the cases an acute abdominal inflammatory process, so as an acute bleeding, causes tachycardia, if the process affects the diaphragm wall and therefore leads to the terminations of the vagus nerve, the patient may have a normal or bradycardic heart rate.

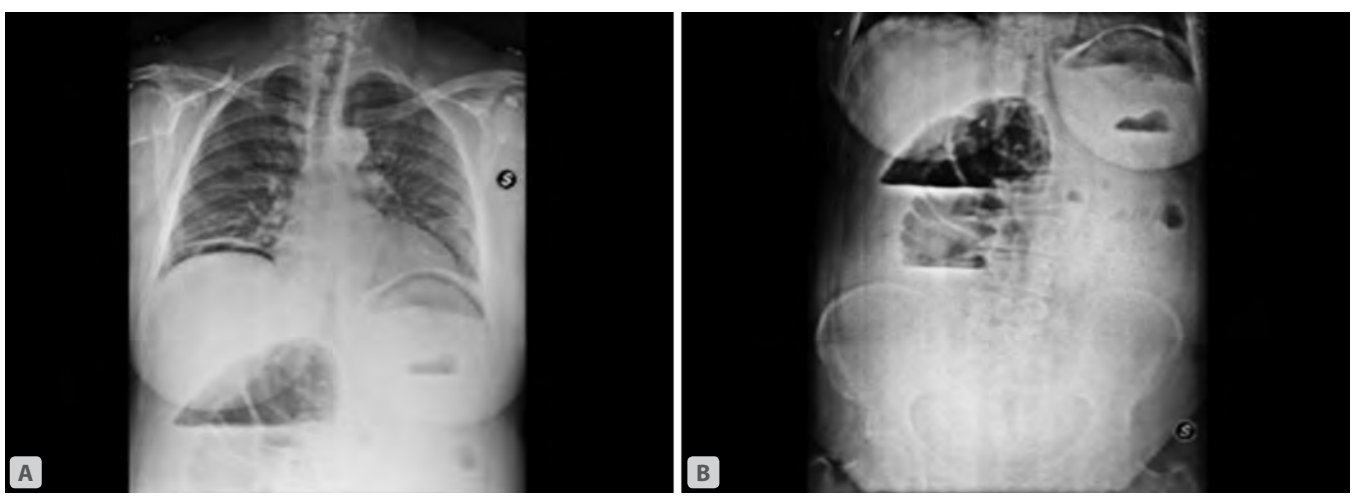
BOX 1: Main causes of intestinal occlusion.

- Postlaparotomy adhesions
- Incarcerated or strangulated hernia
- Tumors
- Crohn's disease
- Volvulus
- Intussusception
- Calculations
- Ischemia

Note: The most common cause of obstruction is constipation with fecalith.

Physical Examination

Vitals signs must be evaluated in all patients as well as the level of consciousness. The general appearance is important: A sick patient is anxious, pale, diaphoretic, or in obvious pain. The abdomen must be evaluated starting with the inspection to evaluate skin color, palpation to check distention of obvious masses, and auscultation of bowel sounds. Decreased bowel sounds suggest functional ileus or mesenteric infarction while hyperactive bowel sounds are present in small bowel obstruction. Palpation starts gently, away from the area of referred pain, detecting areas of particular tenderness, as well as the presence of guarding, rigidity, and rebound (all suggesting peritoneal irritation) and any masses. Voluntary guarding can be diminished by asking patients to flex their knees. Distracting the patient with conversation may divert attention from the examination. The inguinal area and all surgical scars should be palpated for hernias. It is important to look for typical signs such as Murphy sign or stopping the breathing because of the intense pain evoked by palpation of the gallbladder; rebound, or Blumberg sign, indicative of peritoneal irritation, which consists in evoking release pain after deep palpation; and the characteristics of the bowel signs. There are controversial opinions on the indication in literature to perform rectal exploration routinely in a patient with abdominal pain. In fact, the sensitivity and the specificity of this maneuver are rather low, but the presence of blood in the ampoule can suggest diagnosis such as diverticulitis,



FIGS. 3A AND B: (A) Plain X-ray of the chest; (B) X-ray of the abdomen with evidence of perforation, with typical free gas between the hemidiaphragm and the bowel wall, and hydro-air levels.

FIG. 4: Plain X-ray of the abdomen with evidence of the classic signs of intestinal obstruction: Distension of ileal loops, presence of hydro-air levels, absence of air in the rectum.

BOX 2: Evaluation of abdominal pain.

- *History:*
  - Extreme ages
  - Impossibility to feed
  - Vomiting in jet
  - Hematemesis
  - Syncope
  - Pregnancy
  - Recent surgical or endoscopic treatment
  - Fever
  - Severe pain of rapid onset
  - Caustic ingestion of foreign bodies
- *Physical examination:*
  - Abnormal vital signs
  - Bleeding per rectum and melena
  - Incarcerated or strangulated hernia
  - Mental deterioration
- *Laboratory testing:*
  - Renal insufficiency
  - Metabolic acidosis, BGA lactates
  - Hyper-hypoglycemia
  - Anemia, leukocytosis
  - High levels of lipases and amylases
  - High levels of bilirubin, alkaline phosphatase, and transaminases
- *Imaging:*
  - Free air in the abdomen
  - Thickening of the walls of the gallbladder and pericholecystic fluid
  - Dilatation of the biliary tract
  - Hydro-air levels
  - Intra-abdominal abscess
  - Air in the portal venous system

(BGA: blood gas analyzer)

BOX 3: Extra-abdominal diseases that can present with abdominal pain.

- *Cardiac:*
  - Acute myocardial infarction
  - Aortic aneurysm
  - Aortic dissection
- *Dermatological:*
  - Herpes zoster
- *Endocrinological and metabolic:*
  - Diabetic ketoacidosis
- *Other acidosis:*
  - Addison crisis
  - Porphyria
- *Gynecological and obstetric:*
  - Ectopic pregnancy
  - PID
  - Ovarian cyst rupture
  - Ovarian torsion
- *Hematologic:*
  - Familial Mediterranean fever
  - Sickle cell crisis
- *Musculoskeletal causes*

(PID: pelvic inflammatory disease)

tumor, or intestinal ischemia, while rectal tenderness poses in differential diagnosis anal fissures, perirectal abscess, and prostatitis. It is important to consider all the extra-abdominal conditions that can present with abdominal pain (**Box 3**).

Interpretation of Finding

Abdominal distention, vomiting, dullness at percussion, and high-pitched peristalsis strongly suggest bowel obstruction. Severe pain in a patient with a silent abdomen who is lying as still as possible suggests peritonitis whereas a patient who cannot sit or stand still suggests renal colic. Back pain and migrant pain with shock suggest ruptured abdominal aortic aneurysm, particularly if there is a tender, pulsatile mass. Previous abdominal surgery makes obstruction caused by adhesions more likely. Advanced age, generalized atherosclerosis, and hypertension increase the possibility of myocardial infarction, aortic abdominal aneurysm, and mesenteric ischemia. Shock and vaginal bleeding in a pregnant woman suggest ruptured ectopic pregnancy.

INVESTIGATIONS

Laboratory Tests

Blood tests in abdominal pain should be focused according to clinical evaluation, keeping in mind that specificity and diagnostic accuracy are low. For example, a positive likelihood ratio (LR+) of acute appendicitis with WBC > 10,000/mm^3 is only 1:59, while that with WBC > 15,000/mm^3 is 4:5.

Among laboratory tests, it is important to include glucose, electrolytes, creatinine, and liver function tests. A dangerous

approach is to rely on "normal" blood test rather than on clinical evidence and avoid observation and re-evaluation. In the case of women of childbearing age, pregnancy must be considered, both as a cause of the pain (ectopic pregnancy) and for the treatment to use. Finally, urinalysis, tested by dipstick or laboratory, is a routine test. It provides data in suspicion of renal colic, urinary tract infections, or porphyria, to test ketonuria and glycosuria and to define urine-specific gravity.

Arterial blood gas analysis is essential for critically ill patients with abdominal pain: Metabolic acidosis and hyperlactatemia, if combined with high levels of creatine phosphokinase and creatinine, must create the suspicion of a systemic involvement, a widespread and advanced pathologic process.

Role of Abdominal X-ray

A standing chest radiograph remains the primary investigation of choice for the detection of free intraperitoneal gas and may detect lower lobar pneumonia. Plain abdominal radiography should be used selectively in the event of suspected intestinal obstruction or perforation (**Figs. 3A** and **B**). In several studies, the use of abdominal X-ray as the first diagnostic step for abdominal pain has shown a very low diagnostic power, being significant only for intestinal obstruction (**Figs. 3** and **4**). In this situation, the sensitivity of abdominal X-ray is 65–90% while specificity is 50–80%. Therefore, even if the CT scan sensitivity and specificity are higher, in the suspicion of intestinal obstruction the abdomen X-ray is a first-level test. Ingestion of foreign body is another indication for abdominal X-ray, which allows to evaluate the shape, the size, and the position in order to establish the subsequent procedures. Several studies have shown a higher sensitivity of US in the suspicion of hollow organ perforation (US 90% vs. abdominal X-ray 70%). The only limit is the operator skill.

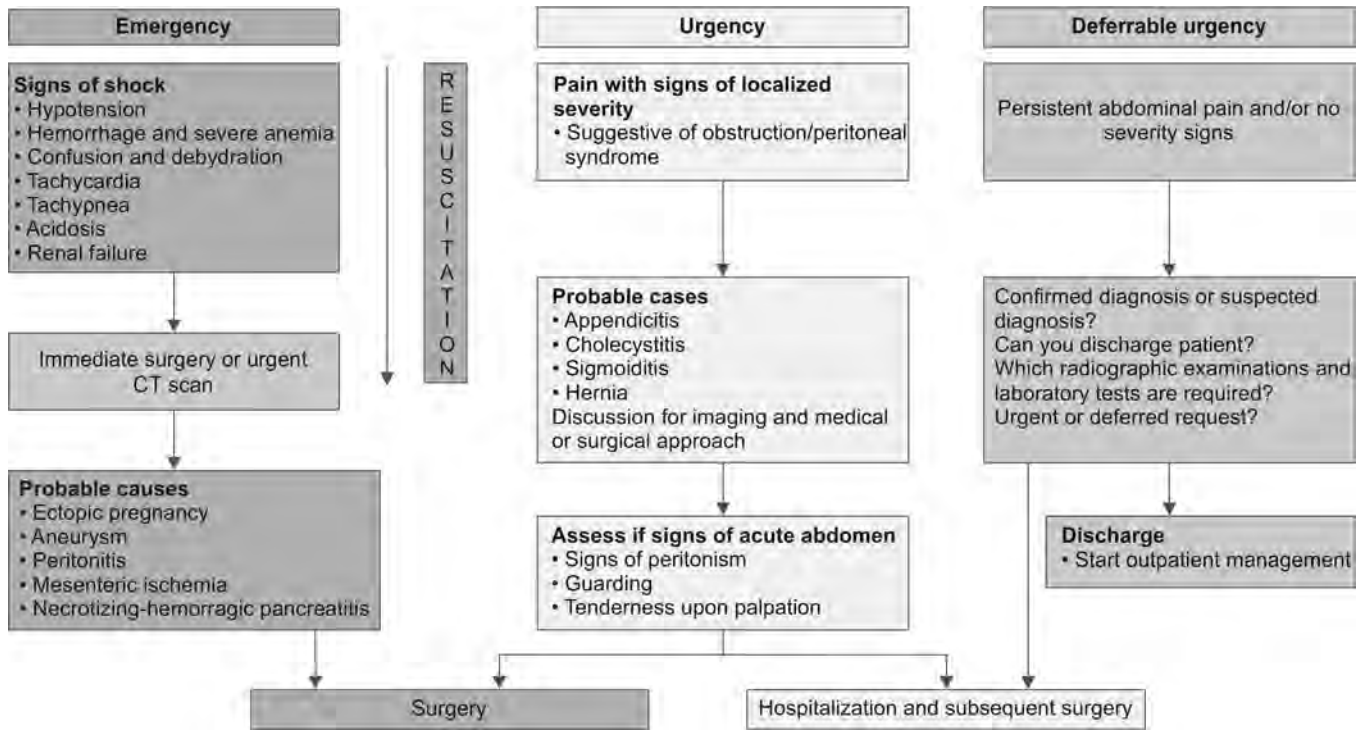
Role of Ultrasonography and Computed Tomography

Abdominal, contrast enhancement CT scan is the exam with the highest specificity and sensitivity, but bedside ultrasound is now considered the first diagnostic approach in the emergency department. In most cases, the ultrasound abdominal examination is sufficient to diagnose diseases of the upper right abdominal quadrant (cholecystitis, cholangitis) and in the diagnosis of renal colic, urinary tract infections, and ectopic pregnancy. It is also fundamental in the diagnosis of the aortic syndrome, also in diagnosing perforation in intestinal obstruction.

If the ultrasound examination is negative or nondiagnostic but the clinical presentation is persistently altered, it is necessary to perform an abdominal CT scan, generally with the contrast medium, except that there are absolute contraindications (history of anaphylactic shock or severe renal impairment). In the literature, it has been shown that by using this method of approach (CT execution to patients with nonconclusive ultrasound), it is possible to reduce the number of CT scans to <50%.

TREATMENT

It is still not uncommon to think that treating abdominal pain with an analgesic can mask the clinical evidence. On the contrary, it has been widely demonstrated that correct analgesia facilitates clinical evaluation because it makes the patient better and more collaborative to examination, thus reducing possible complications, increasing the sensitivity of instrumental investigations, without altering the objective framework. **Flowchart 1** summarizes the management of abdominal pain.



FLOWCHART 1: Summary of management of abdominal pain.

The class of drugs most indicated in the treatment of acute abdominal pain is that are effective, almost without side effects, and have an antidote if necessary. Nonsteroidal anti-inflammatory drugs, used extensively in the past because considered "safer," are actually burdened from important cardiovascular, gastrointestinal, and renal side effects, particularly in elderly patients. In mild-to-moderate abdominal pain, paracetamol can be used as a first-choice drug. Antibiotics are indicated in diseases such as peritonitis and abdominal sepsis, urinary tract infections, and pelvic inflammatory disease (PID). Particular attention must be reserved for spontaneous bacterial peritonitis due to gram-positive aerobes.

Remember two nonpharmacologic treatments: (1) Nasogastric tube to decompress a bowel obstruction or to confirm a gastrointestinal bleeding; and (2) Urinary catheter in presence of bladder obstruction or to monitor urinary output in the critically ill patient.

SUMMARY

Although patients with abdominal pain in most cases do not have severe pathology, the symptom may accompany very serious and potentially deadly clinical conditions, if not recognized promptly. The knowledge of abdominal anatomy and the careful evaluation of clinical signs and symptoms, together with a precise focused medical history, allows to correctly orient the diagnosis in 80% of cases. There are no specific laboratory tests for the various morbid conditions, but the laboratory investigation serves mainly to quantify the degree of systemic involvement of the disease. The most cost-effective diagnostic-instrumental approach in terms of cost/benefit is represented by the execution of abdominal-focused ultrasound in all patients; an abdominal CT scan must be performed only in case of nonconclusive ultrasound. Abdominal pain must be treated even before diagnosis, and the use of opioids is safe and recommended. Also, fluids and electrolytes imbalance must be treated promptly while making the diagnostic workup. When the diagnosis is uncertain but the patient is still symptomatic, it is often advisable and safe to keep patients under observation to evaluate the possible evolution. It is important to keep in mind that normal exams do not exclude an abdominal serious process. A plain X-ray of the abdomen is significant only in the suspicion of intestinal obstruction or perforation.

92 CHAPTER

Nausea, Vomiting, Hiccups, Constipation

Devendra Richhariya

NAUSEA AND VOMITING

Vomiting refers to expulsions of gastric contents due to strong abdominothoracic muscle and gut contractions. It may occur as a protective response to certain ingested toxins or may be an indicator of serious organ system dysfunction. Vomiting is usually associated with nausea (subjective feeling to vomit) and retching (abdominal contraction without oral expulsion). Vomiting should be differentiated from regurgitation and rumination which are effortless expulsion of food.

Etiology

Nausea and vomiting are associated with a variety of gastrointestinal (GI) and non-GI disorders (**Table 1**). In tropical countries, acute onset vomiting most commonly is due to gastroenteritis or systemic infections and is usually associated with diarrhea. Food-borne infections can be due to contaminated water or food material. *Staphylococcus aureus* and *Bacillus cereus* produce toxins which cause emesis. Viral infection by rotavirus, adenovirus, etc., can also cause gastroenteritis. Systemic infections such as meningitis, hepatitis, and upper respiratory infections can also cause nausea and vomiting.

TABLE 1: Etiology of vomiting.

Gastrointestinal causes	*Other organ systems*	*Miscellaneous*
• Gastric • Gastritis GERD peptic ulcer • Gastric outlet obstruction • Gastroparesis malignancy • Bowel obstruction • Ischemic bowel, food poisoning • Hepatobiliary • Hepatitis cholecystitis • Biliary colic pancreatitis	• Endocrine metabolic • Uremia • Diabetic ketoacidosis • Pregnancy • Addison's disease • Hypercalcemia • Cerebral lesions • SOL brain hemorrhage • Cardiac—acute MI • Psychiatric • Bulimia anorexia nervosa	• Drug-induced • NSAIDs • Antimalarials • Chemotherapeutic agents • Oral contraceptive • Alternative medicine • Toxins • Alcohol foodborne poisoning • Radiation • Motion sickness • Cyclic vomiting syndrome

(GERD: gastroesophageal reflux disease; MI: myocardial infarction; NSAIDs: nonsteroidal anti-inflammatory drugs; SOL: space-occupying lesion)

Another most frequent cause is medication. Drugs act on the vomiting center as well as on the GI tract to cause nausea and vomiting. Nonsteroidal anti-inflammatory drugs (NSAIDs) commonly cause gastritis and peptic ulcers, sometimes resulting in stricture and resultant obstruction. They also can cause acute kidney injury. Non-NSAID analgesics, such as tramadol, frequently cause nausea and emesis. Aspirin and cardiac antiarrhythmic and antihypertensive can induce emesis. Other common agents are anticancer treatment, metronidazole, antidiabetic (metformin, exenatide), antidepressants [selective serotonin reuptake inhibitors (SSRIs), *tricyclic antidepressants* (TCAs)], oral contraceptives, diuretics, and nicotine. Consumption of bottle gourd (known as *lauki* or *dudhi* in India) juice is a treatment advocated by alternative medicine practitioners. Bitter juice contains the toxin cucurbitacin and can lead to nausea, vomiting, GI bleeding, and death.

Mechanical gut obstruction due to various causes is associated with abdominal distension, pain, and nausea which may get partial relief on vomiting. The obstruction could be due to strictures, volvulus, or adhesions or due to extrinsic compression by the superior mesenteric artery. Gastroparesis due to diabetes and neurological conditions, such as Parkinsonism and malignancy, can cause nausea and vomiting in 70–80% of patients. Other abdominal conditions such as acute cholecystitis, appendicitis, and pancreatitis may also induce nausea and vomiting.

Cyclic vomiting syndrome is an idiopathic disorder characterized by intermittent episodes of nausea vomiting with intervening normal periods. Each episode lasts for 4–6 days with exacerbation due to emotional stress, food allergy, menses, or pregnancy. Patients with diabetic gastroparesis and marijuana addicts can also have cyclic patterns of vomiting.

Pathophysiology

Vomiting primarily appears to be a protective reflex; it may occur in response to various types of stimuli. Unpleasant, strong thoughts, pain, smell, or sight can produce vomiting. Area postrema, also known as the chemoreceptor trigger zone (**Fig. 1**), is located outside blood–brain barrier and is sensitive to various toxins including foodborne as well as endogenous such as in uremia and ketoacidosis and drugs. The labyrinth in the inner ear is sensitive to movements. Muscarinic M1 and histaminic H1 receptors get stimulated in motion sickness, morning sickness, and ear infection. Cannabinoid CB1 receptors located in dorsal vagal nuclei in the brain stem inhibit the vomiting reflex. Neurokinin NK-1 receptors in area postrema are activated by substance P and are responsible for chemotherapeutic agents-induced vomiting. Serotonergic 5-HT3 receptors on vagal afferents are stimulated by serotonin release by enteroendocrine cells in response to toxins and drugs. Coordination of vomiting is done at the vomiting center in the medulla. Stimulation of brain 5-HT3 receptors release dopamine which acts on D2 receptors in the vomiting center. This starts emesis by induction of nausea, gastric contraction, and inhibition of gut peristaltic slow waves. Thoracic muscles contract with closed glottis which leads to retching. Reverse peristalsis in the small intestine in a combination of thoracoabdominal muscle contraction leads to the expulsion of food contents through the mouth.

Clinical Presentation

Vomiting must be differentiated from regurgitation which is the effortless expulsion of gastric contents. Acute onset vomiting usually is a result of strong painful stimuli in the abdomen, gut obstruction, toxins, metabolic causes (uremia, diabetic ketoacidosis), or foodborne infections. Early morning vomiting is seen in pregnancy, alcohol, and metabolic disorders. Vomiting after meals occurs in gastroparesis, gastric outlet obstruction, and achalasia cardia. Achalasia patients may also report regurgitation of food at night and nasal regurgitation. Bilious vomiting with obstipation and abdominal distension suggest intestinal obstruction. Sudden onset vomiting without nausea or retching (projectile vomiting) may indicate raised intracranial pressure usually due to intracerebral space-occupying lesions. It may be associated with headache and visual symptoms. Symptoms of concern (red flags) are abdominal pain, jaundice, weight loss, hematemesis, presence of lump, severe headache, and postural symptoms.

Evaluation

History: Evaluation of the patient with acute onset vomiting (<1-week duration) requires a detailed history of recent travel, food habits, associated abdominal pain, or diarrhea. Vomiting and diarrhea of acute onset suggest acute gastroenteritis. History of amenorrhea is important in women of

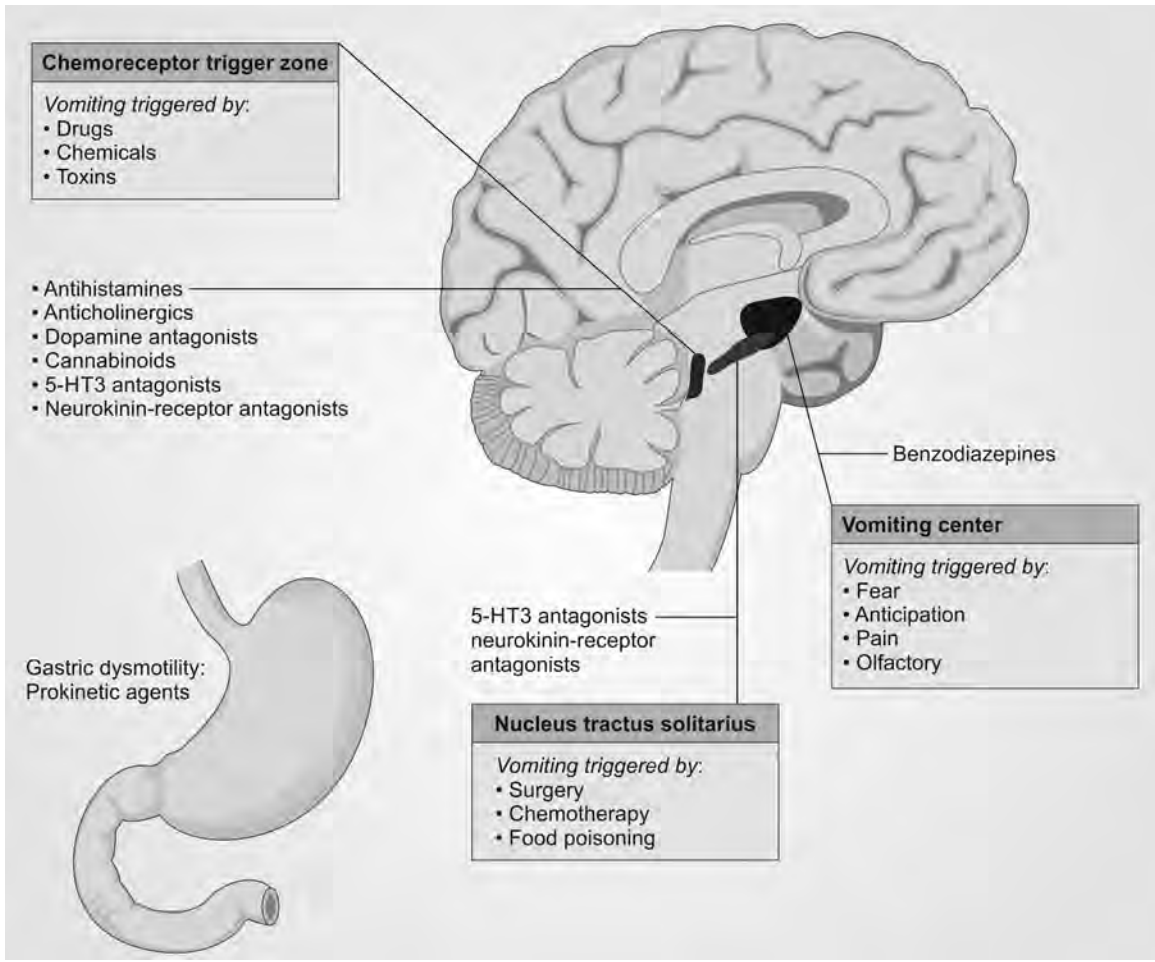

FIG. 1: Areas of the brain and triggers involved in the vomiting reflex, with sites of action of antiemetic and prokinetic agents.

childbearing age. Careful interrogation about any poisoning or drug overdose is required. History of associated abdominal pain, distension, and obstipation may suggest peritonitis due to perforation, pancreatitis, or obstruction. Vomiting relieves abdominal pain due to obstruction but not in other conditions such as pancreatitis and cholecystitis. The presence of anorexia, nausea, and vomiting before the onset of jaundice suggests acute hepatitis. History of postural giddiness, excessive thirst, and oliguria suggest significant volume depletion. History of fever and headache with or without altered sensorium points toward meningeal irritation or raised intracranial pressure. Vomiting due to gastric outlet obstruction or gastroparesis occurs within an hour after meals and may contain food ingested hours before. It may be associated with postprandial fullness. Cough and fever may be indicative of aspiration. Dyspnea and chest pain after vomiting should alert for possible esophageal perforation.

Physical examination: Assessment should be made for hydration and nutritional insufficiency. Tachycardia, orthostatic hypotension, and dehydration suggest significant volume loss. Lymphadenopathy may be due to tuberculosis or disseminated malignancy. Jaundice and epigastric lump with excoriation marks on skin may suggest obstructive jaundice due to malignancy. Distended abdomen with high-pitch bowel sounds suggests intestinal obstruction while absent bowel sound and tender abdomen with guarding suggest peritonitis. Per rectal examination may reveal impacted fecal matter, growth, rectal shelf (pelvic metastatic deposits), or empty rectum (intestinal obstruction). The presence of blood on the examining finger could be due to rectal growth, ulceration, or ischemic bowel. Epigastric lump with visible peristalsis and presence of succussion splash suggest gastric outlet obstruction.

Investigations

Complete blood counts, creatinine, electrolytes arterial blood gas (ABG), serum calcium, serum glutamic pyruvic transaminase (SGPT), random blood sugar, and ketones should be sent for examination and chest and abdominal radiographs should be ordered to look for obstruction, bowel perforation, and esophageal perforation (Boerhaave's syndrome). Further evaluation with cross-sectional imaging (CT/MRI) may be required. ABGs are to be sent for acid–base imbalance.

Treatment

Management of acute vomiting requires assessment for etiology, dehydration, electrolyte imbalance, and possible complications. Patients with mild symptoms can be managed with oral prokinetics and antiemetics. Poisoning and drug overdose are to be treated by nasogastric aspiration and lavage, activated charcoal, and a specific antidote. Antiemetics should be started. Fluid resuscitation should be started according to the degree of dehydration. Endoscopy can be done, if required, after initial resuscitation. Patients with gastric outlet obstruction may require nasogastric aspiration and lavage to empty stomach before endoscopy. Patients with chronic vomiting should be assessed for malnutrition. Replacement of fluid, electrolytes, and vitamins is done wherever indicated. Chronic vomiting should be treated with prokinetics and antiemetic agents. The most commonly used antiemetics (**Table 2**) are substituted benzamides, which act as D2 receptor antagonist. D2 receptor antagonism at area postrema reduces nausea and vomiting while the effect on gastric D2 receptors improves gastric emptying.

Metoclopramide and levosulpiride are available in oral and intravenous (IV) preparation (**Table 3**). Rapid IV metoclopramide injection may produce restlessness. Metoclopramide crosses blood–brain barrier and causes dystonia, extrapyramidal symptoms, tardive dyskinesia, QT prolongation, and hyperprolactinemia. It also acts on peripheral 5-HT4 receptor causing acetylcholine release leading to increased antroduodenal motility. *Domperidone* is much safer as it does not cross the blood–brain barrier although it can cause hyperprolactinemia and galactorrhea. It can be used in levodopa to induce vomiting in Parkinson's diseases. *Itopride* acts as an antagonist of the D2 receptor and acetylcholine esterase inhibitor. Motilin agonist erythromycin enhances gastric emptying.

TABLE 2: Commonly used agents for the treatment of nausea and vomiting.

Class	*Drug*	*Comments*	*Adverse effect*
Antihistamine	• Dimenhydrinate • Diphenhydramine • Meclizine	Useful in motion sickness, migraines, and vertigo	Drowsiness
Benzodiazepine	• Alprazolam • Diazepam • Lorazepam	Add-on therapy in chemotherapy-induced nausea and vomiting	Sedation
Butyrophenone	Haloperidol	Chemotherapy-induced nausea and vomiting	Sedation, restlessness
Corticosteroids	Dexamethasone	Chemotherapy-induced nausea and vomiting	Insomnia
Serotonin antagonist	• Ondansetron • Granisetron • Dolasetron	Prolongs QT_c	Constipation, dizziness
Phenothiazine	• Prochlorperazine • Promethazine	Also useful in the treatment of migraine, vertigo, motion sickness	Extrapyramidal symptoms
Benzamide	• Metoclopramide • Trimethobenzamide	Useful in gastroparesis and reflux in children	Extrapyramidal symptoms

TABLE 3: Dopamine antagonists most commonly used in nausea and vomiting and their properties.

Drug name	*Usual oral dose and frequency*	*Oral bio-availability*	*Pharmaco-kinetics*	*Half-life*	*Drug interactions*	*Side-effects*	*Comments*
Prochlorperazine	5–10 mg, 2–3 times daily	<10%	Extensive first-pass metabolism	7 hours	Other drugs causing hypotension, lithium	Sedation, extrapyramidal reactions, hypotension	Available in several formulations including buccal tablets, oral liquid and injection
Metoclopramide	10 mg, 3 times daily	>90%	Undergoes first-pass metabolism; clearance is by hepatic metabolism; only 20% is excreted in the urine unchanged	4 hours	Antipsychotics	Extrapyramidal reactions, restlessness, stimulation of prolactin release	Also available as an injection; can be used as a prokinetic agent; contraindicated in gastrointestinal patients with an obstruction, perforation or hemorrhage. **Caution:** Can cause severe dystonic reactions (see main text for details)
Domperidone	10–20 mg, 3–4 times daily	13–17%	Undergoes extensive presystemic metabolism	12–16 hours	None significant	Stimulates prolactin release, reduced libido	Less likely to cause extrapyramidal side effects and sedation; also available as suppositories and oral liquid but not as an injection; also has prokinetic properties. **Caution:** Can lead to increased cardiac side effects (see main text for details)

The 5-HT3 antagonists ondansetron and granisetron are useful in postsurgical and chemotherapeutic agents-induced vomiting. They block 5-HT3 receptors in the stomach and vomiting center. Side effects are raised liver enzymes, QT prolongation, and headache. Ondansetron can be used safely in pregnancy. Palonosetron is very effective in chemotherapeutic drugs-induced nausea and vomiting. Ginger and doxylamine–pyridoxine combination is also used in pregnancy.

Phenothiazines such as prochlorperazine block D2 receptors and muscarinic M1 receptors. They are potent antiemetic but with extrapyramidal side effects. Olanzapine does not have extrapyramidal side effects and is a good alternative. *Antihistaminic agents*: Cyclizine and dimenhydrinate block central H1 receptors and are useful for motion sickness. A combination of glucocorticoids, NK1 receptor antagonist (aprepitant), and cannabinoids (tetrahydrocannabinol) is used for chemotherapeutic-induced vomiting. Nausea and vomiting is the expulsion of GI food contents due to abdominothoracic muscle contractions and occurs in a wide variety of conditions. It can be treated by various antiemetics and prokinetics. The presence of significant adverse effects poses difficulty in prolonging treatment with these agents.

HICCUPS

Hiccups as a symptom are very commonly seen in clinical practice and are usually a transient condition affecting almost all people in their lifetime. Intractable hiccups and complications from hiccups are rarely seen. The precise epidemiology of hiccups, including severe intractable hiccups, is uncertain in the general population as well as in the palliative care population. Most people have experienced hiccups at some point in their life, and these hiccups are generally self-limited. Hiccups can, however, become chronic and persistent in rare cases.

What are Hiccups?

Hiccups are sudden, inspiratory activities generated due to contraction of intercostal muscle and diaphragm; contraction is intermittent, involuntary, and spasmodic in nature with the frequency of 5–50/min. On the basis of duration, hiccups can be divided into three groups:

1. A "hiccup bout" is an episode of hiccups lasting up to 48 hours.
2. "Persistent hiccups" are hiccups that continue longer than 48 hours and up to 1 month.
3. "Intractable hiccups" are hiccups that continue longer than 1 month.

Hiccups may be associated with comorbid conditions: Vascular, *chronic kidney disease* (CKD), postoperative, *central nervous system* (CNS) disease, duodenal ulcer, reflux esophagitis, advanced cancer.

Hiccups can cause significant adverse effects which include, dehydration, malnutrition, fatigue, weight loss, insomnia, nervous stress, and poor quality of life.

Pathophysiology

The exact mechanism which provokes the hiccups including severe intractable hiccups remains unclear. In majority of the patients, hiccups involve unilateral contraction of the left

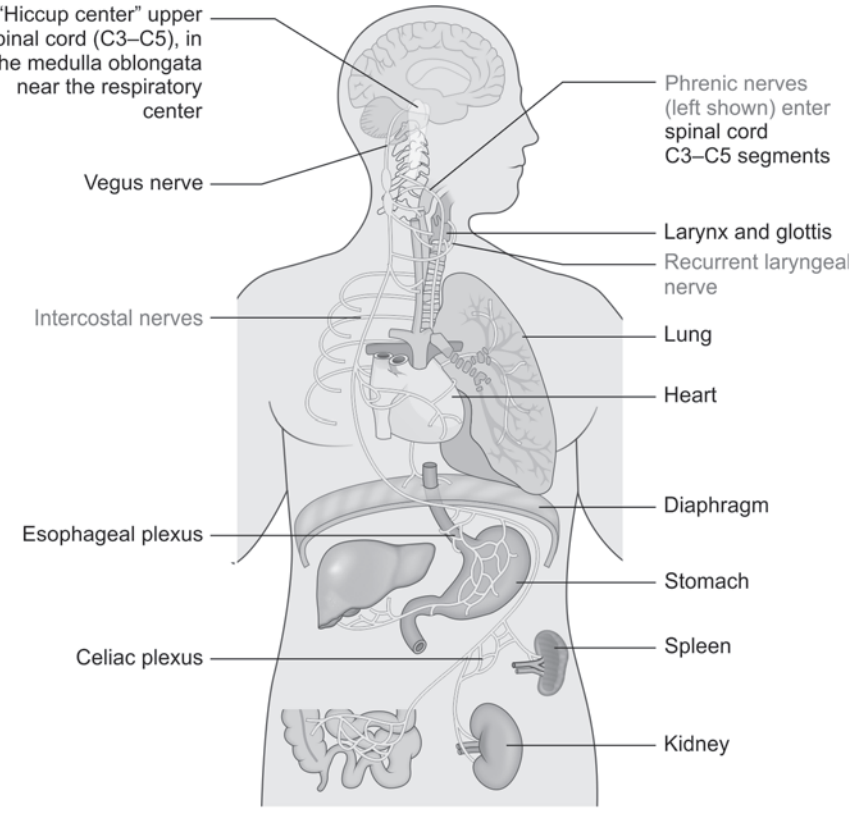

FIG. 2: Hiccups reflux arc. Pathology affecting the brain, diaphragm, thoracic, or abdominal viscera can stimulate vagal or phrenic afferents that activate the diffuse "hiccup center" in the midbrain, brainstem, and proximal cervical cord. This triggers repetitive myoclonic contractions of the diaphragm and other respiratory muscles via the phrenic and the intercostal nerves (motor efferent colored dark gray). Immediately afterward, activation of the recurrent laryngeal nerve closes the glottis, producing the characteristic "hic" in hiccups.

hemidiaphragm. Several neural pathways make up the hiccup reflex arc (**Fig. 2**): Gamma-aminobutyric acid (GABA) appears to be the most important mediator for neural connections in the hiccup reflex arc. Other mediators may include dopaminergic, muscarinic, and serotonergic pathways (i.e., 5-HT1A receptors).

Etiology

Common and benign causes of hiccups are overeating carbonated drinks, stress, emotional changes, and spicy and alcohol ingestion. Intractable hiccups may reflect serious underlying diseases, such as an infection (e.g., meningitis, encephalitis) or a structural lesion (e.g., intracranial neoplasm, hydrocephalus). Potential causes of persistent and intractable hiccups are given in **Box 1**.

Evaluation

Hiccup bouts are common, and most of the individuals do not need thorough evaluation or medical attention. However, intractable hiccups required thorough evaluation to ascertain the underlying causes.

The history should include the severity and duration of hiccups, any associated medical conditions and previous surgery, drug abuse or alcohol intake, and a complete list of medications. The persistence of hiccups during sleep suggests an organic rather than psychogenic etiology.

Physical examination of external auditory canals is done to rule out infection or foreign body which may be a potential irritant of tympanic membranes. A detailed head and neck examination is important to exclude an enlarged thyroid and lymphadenopathy. Neurological examination (including cranial nerve assessment), auscultation of the chest, and per abdominal examination should be done to palpate for any mass lesions.

Investigations

Patients with persistent or intractable hiccups following investigation should be considered:

Complete blood count, renal function test (RFT), liver function test (LFT), serum electrolytes, serum calcium, serum amylase/lipase electrocardiogram (ECG), radiological investigations, X-ray of chest, and contrast-enhanced computed tomography (CECT). A chest radiograph or CT scan is helpful to detect pulmonary and mediastinal abnormalities irritating the vagal or phrenic nerves or the diaphragm in patients presenting with dyspnea. Patients with esophageal symptoms and dysphagia should undergo upper GI endoscopy for evaluation to find out esophagitis stricture or malignancy. In patients with advanced malignancy, the cause of intractable hiccups is often multifactorial, and an exhaustive evaluation is required.

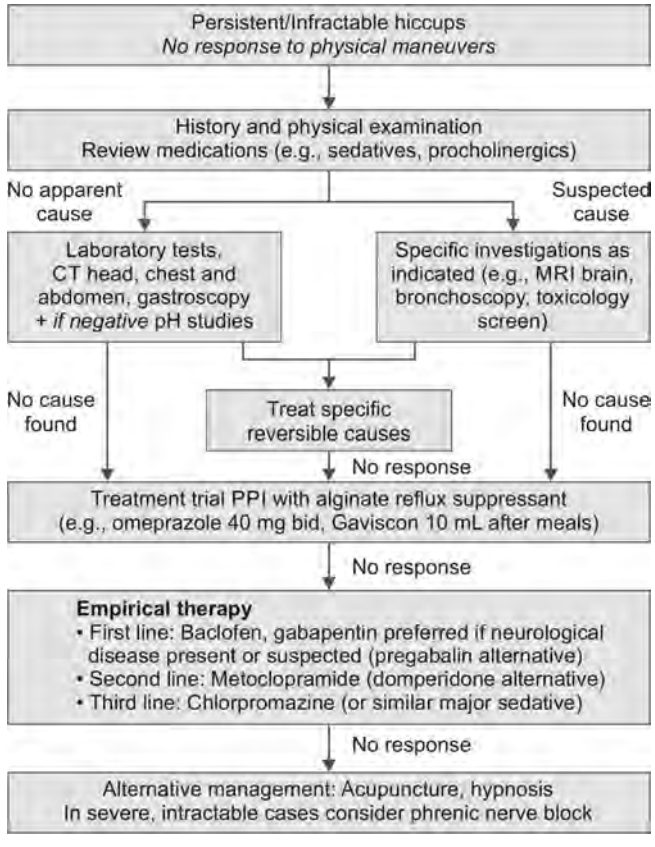
Treatment

Most of the patient hiccups are self-limiting and do not require any treatment. Treatment of an underlying illness is required if it is due to any medical illness. Treatment of intractable hiccups requires pharmacological or nonpharmacological management for persistent or intractable hiccups (**Flowchart 1**).

BOX 1: Causes of persistent and intractable hiccups.

Vascular
Ischemic/hemorrhagic stroke, AV malformations, temporal arteritis
Infections
Encephalitis, meningitis, brain abscess, neurosyphilis, subphrenic abscess
Structural
Head trauma, intracranial neoplasms, brainstem neoplasms, multiple sclerosis, syringomyelia, hydrocephalus
Vagus and phrenic nerve irritation
Goiter, pharyngitis, laryngitis, hair or foreign body irritation of tympanic membrane, neck cyst, or another tumor
GI disorders
Gastric distention, gastritis, peptic ulcer disease, pancreatitis, pancreatic cancer, gastric carcinoma, abdominal abscesses, gallbladder disease, inflammatory bowel disease, hepatitis, aerophagia, esophageal distention, esophagitis, bowel obstruction
CV disorders
Myocardial infarction, pericarditis
Thoracic disorders
Enlarged lymph nodes secondary to infection or neoplasm, pneumonia, empyema, bronchitis, asthma, pleuritis, aortic aneurysm, mediastinitis, mediastinal tumors, chest trauma, pulmonary embolism
Toxic and metabolic
DM, alcohol, hypocalcemia, hyponatremia, herpes zoster, hypocapnia, tuberculosis, malaria, uremia
Postoperative
Drugs
Alpha methyldopa, short-acting barbiturates, diazepam, dexamethasone
Psychogenic
Anorexia nervosa, schizophrenia, stress, malingering, conversion reaction

(AV: arteriovenous; CV: cardiovascular; DM: diabetes mellitus; GI: gastrointestinal)



Persistent/Infractable hiccups
No response to physical maneuvers
History and physical examination
Review medications (e.g., sedatives, procholinergics)
No apparent cause
Suspected cause
Laboratory tests, CT head, chest and abdomen, gastroscopy + if negative pH studies
Specific investigations as indicated (e.g., MRI brain, bronchoscopy, toxicology screen)
No cause found
Treat specific reversible causes
No cause found
No response
Treatment trial PPI with alginate reflux suppressant (e.g., omeprazole 40 mg bid, Gaviscon 10 mL after meals)
No response
Empirical therapy
• First line: Baclofen, gabapentin preferred if neurological disease present or suspected (pregabalin alternative)
• Second line: Metoclopramide (domperidone alternative)
• Third line: Chlorpromazine (or similar major sedative)
No response
Alternative management: Acupuncture, hypnosis
In severe, intractable cases consider phrenic nerve block

(PPI: proton pump inhibitors)

FLOWCHART 1: Treatment algorithm of persistent and intractable hiccups.

- If a specific pathology is found to be potentially causing the hiccups, the choice of treatment should be directed toward treating the illness. As an example, treatment with a proton-pump inhibitor or an H2 blocker should be given if *gastroesophageal reflux disease* (GERD) is a likely cause.
- If the cause is idiopathic, empiric therapy with physical maneuvers is the first-line treatment. These maneuvers are easy to perform and have a low risk of complications.
- Physical therapy (**Table 4**): Common maneuvers suggested are breath-holding, Valsalva maneuver, sipping cold water, gargling with water, swallowing a teaspoon of dry sugar, compression over the eyeballs, pulling knees to chest, and leaning forward to compress the chest.

Pharmacologic therapy: Drug therapy should be reserved for the treatment of hiccups when physical maneuvers have failed. If hiccups subside following treatment, drug treatment can usually be stopped the day after cessation of hiccups. Most drug treatments can be used for 7–10 days. If hiccups persist, it is reasonable to consider another pharmacologic or nonpharmacologic treatment option.

Chlorpromazine: It is centrally acting dopamine, acts by antagonism in the hypothalamus, remained the drug of choice for many years, and is the only medication approved for hiccups by the US Food and Drug Administration. IV administration may be more effective, although the drug must be infused in 500–1,000-mL saline with the patient in the supine position to avoid hypotension; the lower dosing for hiccups is generally well tolerated. It is generally not recommended as the first drug of choice due to serious side effects and is also contraindicated in older people.

TABLE 4: Physical therapy for hiccups.	
Nasopharyngeal stimulation	• Intranasal application of vinegar • Inhalation of "smelling salts" or similar stimulant/irritant (e.g., ammonia, ether) • Oropharyngeal stimulation (e.g., ice water)
Vagal stimulation	• Cold compress to the face • Carotid massage • Induced fright • Induced vomiting
Respiratory maneuver	• Breath-holding (inspiration, expiration) • Valsalva maneuvers • CPAP respiration
Note: These maneuvers are, in general, effective only to shorten an attack of acute hiccups and are not the treatment of persistent or intractable hiccups. None has been subjected to clinical trials.	

(CPAP: continuous positive airway pressure)

Metoclopramide: It also has central dopamine antagonism but slightly weaker than chlorpromazine. The usual oral dose is 10 mg three or four times daily for up to 7–10 days. Metoclopramide is also associated with tardive dyskinesia, especially at high doses and with chronic use.

Other drugs effective in hiccups are: Baclofen, haloperidol, anticonvulsants, nifedipine, methylphenidate, midazolam, lidocaine, antidepressants (e.g., amitriptyline), antiarrhythmic drugs (e.g., quinidine), olanzapine, amantadine, oral viscous lidocaine (2%) solution.

Surgery: A surgical approach including phrenic nerve crushing or blocking with a local anesthetic may be successful in refractory cases.

CONSTIPATION

Less than three bowel movements per week and dry and hard stool are generally considered as constipation. The stool is painful to pass. Very common complaints in outpatient are chronic constipation and few people also experience occasional constipation. Causes of constipation can be divided into primary and secondary causes:

Primary: Primary causes are most common, nonlife-threatening, usually >6 months, and not due to any medication or medical problem. Inadequate intake of dietary fiber, fluid intake, and decreased physical activities are the common cause.

Secondary: Causes are medication such as opiates, endocrine (hypothyroidism) and metabolic disorders, and obstruction such as colorectal cancer.

Fiber in diet: Fiber promotes bowel movements and prevents constipation. It is important to include good quality of fiber in the diet such as fruits, vegetables, and whole grains.

Physical activity: Constipation is common in a less physically active person, especially in the elderly group. The risk of constipation is more in a bedridden patient.

Medications: Opiates, antidepressants, anticonvulsants, iron supplements, calcium channel blockers, aluminum-containing antacids, and diuretics are the drugs which frequently cause constipation.

Irritable bowel syndrome: Patient with irritable bowel syndrome (IBS) is more frequently constipated than other population.

Pregnancy: Hormonal changes in pregnancy make women more susceptible to constipation.

Problem with colon and rectum: Patients with tumor, scar tissue, diverticulosis, and colorectal stricture are prone to constipation.

Disease and conditions: Diseases of the colon, rectum, or anus can cause constipation. Neurological disorders such as Parkinson's disease, multiple sclerosis, stroke, and spinal cord injuries can lead to constipation. Uremia, diabetes, hypocalcemia, hypothyroidism, and other systemic diseases such as lupus, scleroderma, amyloidosis, and carcinoma also cause constipation.

Others: Aging, changes in routine, overuse of laxatives, not going to the toilet when needed, and not drinking enough water are other causes of constipation.

Symptoms

Common symptoms include abdominal pain, bloating, hard and dry consistency stools, difficult to pass. Red flag symptoms (features of concern) are new onset without any cause, weight loss, blood in stool, anemia and family history of malignancy. Complications of constipation clinically present as hemorrhoids, rectal prolapse, anal fissure, urinary incontinence, urinary retention, and fecal impaction.

Diagnosis

Examination

Abdominal examination and rectal examination guide the physician to evaluate constipation further. Rectal examination will provide information about sphincter tone, presence of hemorrhoids, fecal impaction, and any other perianal irregularities. In addition to general physical examination and rectal examination, the following tests and procedures are required to find out the cause.

Investigations

Blood tests, X-ray of abdomen, sigmoidoscopy (examination of rectum lower or sigmoid colon), colonoscopy (examination of rectum and entire colon), anorectal manometry (evaluation of anal rectal muscle function), and defecography (X-ray while defecation) should be conducted.

Management

Stepwise Approach

In most of the cases, constipation resolves without any treatment. Stepwise management of constipation is implemented (**Fig. 3**). Recurrent constipation can be dealt with lifestyle changes such as increase in activities, eating more fiber-rich

diet, and drinking more water; laxative can be used but carefully and only when necessary.

Medications

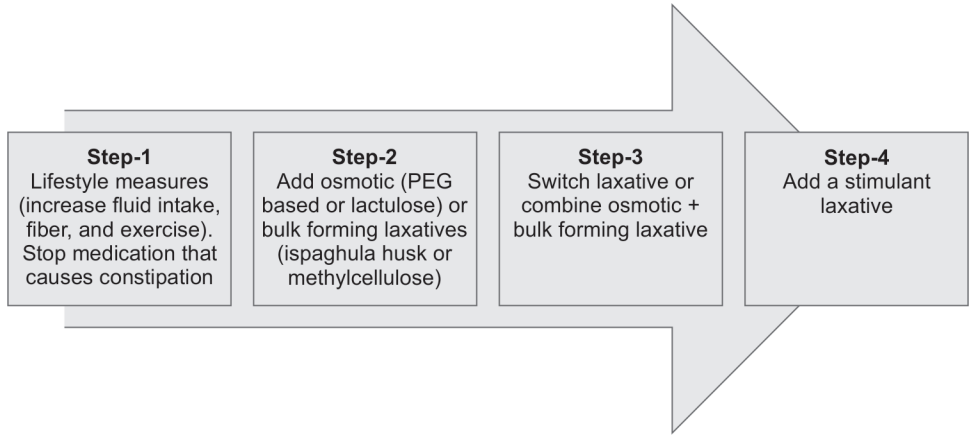
A variety of laxatives are available such as stimulants, lubricants, stool softeners, fiber supplements, osmotic laxatives, saline laxatives, chloride channel activators, and 5-HT4 agonists (**Table 5**). Constipation is a common symptom in general practice. For appropriate management of the constipation, it is important to know the type of constipation, whether it is primary or secondary. General physical examination and rectal examination are important for further evaluation. Lifestyle changes, fiber intake, and medications are helpful in relieving constipation.

Chronic Constipation

Constipation should be evaluated further if lifestyle modification and stepwise medication therapy do not work (chronic constipation) as summarized in **Flowchart 2**.

SUMMARY

Nausea and vomiting are common, usually short-lived and self-limiting symptoms encountered in both inpatient and outpatient settings. Thorough clinical history and physical examination are vital in establishing a cause for symptoms. Simple investigational tests can also lead to a quick but essential diagnosis. It is important to treat not only the symptoms but also the consequences of nausea and vomiting, as



Step-1
Lifestyle measures (increase fluid intake, fiber, and exercise). Stop medication that causes constipation
Step-2
Add osmotic (PEG based or lactulose) or bulk forming laxatives (ispaghula husk or methylcellulose)
Step-3
Switch laxative or combine osmotic + bulk forming laxative
Step-4
Add a stimulant laxative

(PEG: polyethylene glycol)

FIG. 3: Stepwise management of constipation in adult.

TABLE 5: Available medications for constipation.

Fiber	Psyllium	One teaspoon three times a day	Stool bulking agents
Emollient	Docusate sodium	100 mg once/twice a day	
Stimulants	Bisacodyl	10 mg per rectal	Increases intestinal motility by stimulation of myenteric plexus
	Anthraquinones	1–2 tablets orally/twice daily	
	Senna	Two tablets orally twice daily	
Saline laxatives	Milk of magnesium	15–30 mL twice daily	Osmotic laxative
Suppository	Glycerin suppository	One per rectal/day	Locally stimulant
Hyperosmolar agents	Lactulose/sorbitol	15–30 mL twice daily	Pulls fluid into the gut
Enemas	Mineral oil/soap water	100–250 mL per-rectally	Colonic distension
Serotonergic agents	Prucalopride	2 mg daily	Stimulate GI motility
Prosecretory agents	Lubiprostone	24 µg/day	Moves water into the lumen
***Initial options*:** Fiber, magnesium hydroxide, PEG			
***Severe infrequent or acute constipation*:** PEG-3350, saline laxative (magnesium hydroxide), bisacodyl, senna			
***Severe idiopathic constipation*:** Larger doses of osmotic laxatives (saline or PEG), lactulose, neuromuscular drugs combination therapy			
***Outlet obstruction*:** Liquify stool with osmotic laxatives, enemas			
***Pregnancy*:** Fiber and bulk laxatives, PEG, lactulose, bisacodyl			

(GI: gastrointestinal; PEG: polyethylene glycol)

intractable cases or severely affected patients will often present dehydrated and with electrolyte imbalances. Hiccups are familiar to all and remain a medical quiz. Acute hiccups are very common, remain for few minutes, and are self-limiting. Persistent and chronic hiccups are rare, remain for weeks or month, are very distressing, and difficult to treat. Chronic constipation has a large negative impact on the quality of life and causes significant psychological distress. It is a common condition where over-the-counter (OTC) laxatives and visits to physicians are taken. Constipation can be divided into slow-transit constipation, dysfunctional constipation that is treated with biofeedback and medications, and constipation-predominant IBS. Available therapeutic options are lifestyle modifications and medications.

93
CHAPTER

Diarrhea-associated Diseases

Sanjay Kumar

INTRODUCTION

Diarrhea is best defined as increased fluidity of stool though increased frequency and volume are also sometimes a consideration. It is one of the most common gastrointestinal (GI) symptoms. It is the second most common cause of mortality in children and is one of the most common reasons for absenteeism from job in adults globally. Most cases are self-limiting and do not require treatment, but some of them could be serious due to dehydration, acute kidney injury (AKI), electrolyte imbalance, and rarely sepsis. Diarrheal illness accounts for 2.5 million deaths per year worldwide. In the United States alone, an estimated 48 million foodborne diarrheal illnesses occur annually. In the developing world, infectious causes of acute diarrhea are largely related to contaminated food and water supplies.

PATHOPHYSIOLOGY

Increased stool volume/increased fluidity or increased frequency results whenever there is excess unabsorbed fluid/stool traveling through the left colon. So, this would happen either if there is excessive secretion in the small bowel or defective absorption or if there is poor absorption of fluids in the colon. Sometimes, there is no problem with absorption/secretion, but still, there may be diarrhea such as in case of increased motility, seen in functional bowel disease or hyperthyroidism. The most common cause of acute diarrhea in adults is infection. Amongst infections, viral infections are the most common. The causes of diarrhea are listed in **Table 1**.

TABLE 1: Causes of diarrhea.

Causes of acute diarrhea	***Infections (bacteria, viruses, parasites, protozoa), food allergies, food poisoning, medications, initial presentation of chronic diarrhea***
Infection that causes diarrhea	*Bacteria*: • *Aeromonas* species • *Campylobacter* species • *Clostridium difficile* • *Escherichia coli* (enterotoxigenic, enteroinvasive, enterohemorrhagic) • *Salmonella* species • *Shigella* species *Viruses*: • Adenovirus • Norovirus • Rotavirus *Parasites or protozoa*: • *Cryptosporidium* • *Cyclospora* • *Entamoeba* • *Giardia lamblia* • *Microsporidia*

APPROACH TO ACUTE DIARRHEA

Diarrhea is classified as acute or chronic, inflammatory or noninflammatory, osmotic or secretory. But while evaluating a patient at the bedside, it is more useful to ascertain whether it is small bowel diarrhea or large bowel diarrhea because that guides you to further evaluation and proper management. Frequency and volume are the most important points in history. Voluminous stools three to six times a day are suggestive of small bowel origin while more frequent but scanty stools are suggestive of large bowel origin. Next is contents. The presence of blood/mucous suggests a large bowel, i.e., colitis, while profuse watery diarrhea suggests a small bowel, i.e., enteritis. Crampy abdominal pain can be present in both, but the tenesmus points to a large bowel/rectal origin. A detailed history will go a long way in providing a clue to the cause of diarrhea and one can manage accordingly (**Table 2**).

Physical Examination

The goal of the physical examination is to assess the patient's degree of dehydration. Generally, ill appearance, dry mucous membranes, delayed capillary refill time, increased heart rate, and abnormal orthostatic vital signs can be helpful in identifying more severe dehydration. Fever is more suggestive of inflammatory diarrhea. The abdominal examination is important to assess for pain and acute abdominal processes. A rectal examination may be helpful in assessing for blood, rectal tenderness, and stool consistency.

TABLE 2: Clues to diagnosis—based on history and clinical findings.

History	*Potential pathogenic etiology*
Afebrile, abdominal pain with bloody diarrhea	Shiga toxin-producing *Escherichia coli*
Bloody stools with fever	*Salmonella, Shigella, Campylobacter,* Shiga toxin-producing *E. coli, Clostridium difficile, Entamoeba histolytica, Yersinia*
Camping, consumption of untreated water	*Giardia*
Fried rice	*Bacillus cereus*
Raw ground beef or seed sprouts	Shiga toxin-producing *E. coli* (e.g., *E. coli* O157:H7)
Raw milk	*Salmonella, Campylobacter*, Shiga toxin-producing *E. coli*, *Listeria*
Seafood, especially raw or undercooked shellfish	*Vibrio cholera*, *Vibrio parahaemolyticus*
Undercooked beef, pork, or poultry	*Staphylococcus aureus*, *Clostridium perfringens*, *Salmonella, Listeria* (beef, pork, poultry), Shiga toxin-producing *E. coli* (beef and pork), *B. cereus* (beef and pork), *Yersinia* (beef and pork), *Campylobacter* (poultry)
Exposure to daycare centers	Rotavirus, *Cryptosporidium, Giardia, Shigella*
Fecal-oral sexual contact	*Shigella, Salmonella, Campylobacter*, protozoal disease
Hospital admission	*C. difficile*, various drug-induced
Human immunodeficiency virus infection, immunosuppression	*Cryptosporidium, Microsporidia, Isospora, Cytomegalovirus, Mycobacterium avium* intracellular complex, *Listeria*
Medications or other therapies associated with diarrhea	• Antibiotics (especially broad-spectrum), laxatives, antacids (magnesium- or calcium-based), chemotherapy, colchicine, pelvic radiation therapy • Less common: Proton pump inhibitors, mannitol, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, cholesterol-lowering medications, lithium
Pregnancy	*Listeria*
Recent antibiotic use	*C. difficile*
Receptive anal intercourse, with or without rectal pain or proctitis	Herpes simplex virus infection, chlamydia, gonorrhea, syphilis
Rectal pain or proctitis	*Campylobacter, Salmonella, Shigella, E. histolytica, C. difficile, Giardia*
Rice-water stools	*V. cholera*
Several persons with common food exposure have an acute onset of symptoms	• Food poisoning with preformed toxins • Onset of symptoms within 6 hours: *Staphylococcus, B. cereus* (typically causes vomiting) • Onset of symptoms within 8–16 hours: *C. perfringens* type A (typically causes diarrhea)
Travel to a developing country	• Enterotoxigenic *E. coli* is most common • Many other pathogens (e.g., *Shigella, Salmonella, E. histolytica, Giardia, Cryptosporidium, Cyclospora*, enteric viruses) are possible because of poorly cleaned or cooked food, or fecal contamination of food or water

Investigations

Hardly any investigations are required in routine cases. Stool routine and culture may be advised if there is a suspicion of invasive diarrhea based on the presence of fever and blood in stools. Hemogram and renal function tests must be done if the patient is dehydrated. A film for malarial parasite may be handy if there is a high fever with chills as sometimes malaria can present as diarrhea (algid malaria).

Treatment

The mainstay of treatment of acute diarrhea is restoring/maintaining fluid and electrolyte balance.

Rehydration Therapy

The accumulated fluid deficit (calculated roughly as the difference between the patient's normal weight and his or her weight at presentation with diarrheal illness) must first be addressed. Once you know the deficit, you can supplement fluids orally. Various oral rehydration formulae are available. In 2002, the World Health Organization (WHO) endorsed oral rehydration solution (ORS) with reduced osmolarity (250 mOsm/L or less compared with the prior standard of 311 mOsm/L). Reduced osmolarity ORS decreases stool output, episodes of emesis, and the need for intravenous (IV) rehydration without increasing hyponatremia, duplicate by mixing 1/2 teaspoon of salt, 6 teaspoons of sugar, and 1

L of water. If the patient is having vomiting or heightened gastrocolic reflex, oral rehydration is not possible and we have to give IV fluids. While giving IV fluids, the best way to monitor adequacy is urine output but if the patient is too sick or has comorbidities, especially *chronic kidney disease* (CKD)/congestive *heart failure* (CHF)/chronic liver disease (CLD), fluid balance should be ensured by ultrasonographic inferior vena cava (IVC) monitoring or *central venous pressure* (CVP) monitoring by putting in a central venous catheter.

Antibiotic Therapy

Because acute diarrhea is most often self-limited and caused by viruses, routine antibiotic use is not recommended for most adults with nonsevere, watery diarrhea. Antibiotics may be considered in patients who are older than 65 years, immunocompromised, severely ill, or septic.

Zinc Supplementation

Zinc supplementation (20 mg/day for 10 days in children older than 2 months) may play a crucial role in treating and preventing acute diarrhea, particularly in developing countries. Most cases of acute diarrhea are self-limiting and can be managed with ORS. Those who have red flags (features of concern) can be managed with hospitalization IV fluids and antibiotics. Very rare cases will develop complications such as AKI or sepsis and these will require prolonged hospitalization, intensive care, and can be fatal too.

Indications for Hospitalization

Concerning features (red flags), clinical signs of dehydration, blood in stool, high fever, very high frequency, and liquidity leading to incontinence.

TRAVELER'S DIARRHEA

Traveler's diarrhea means loose stools and abdominal cramps during a visit to a place where the climate or sanitary practices are different from yours at home. It is caused by eating contaminated food or drinking contaminated water. It usually begins abruptly during your trip or shortly after you return home. Most cases improve within 1–2 days without treatment and clear up completely within a week. The most common signs and symptoms of traveler's diarrhea are:

- Abrupt onset of the passage of three or more loose stools a day
- An urgent need to defecate
- Abdominal cramps
- Nausea
- Vomiting
- Fever—occasionally

Traveler's diarrhea usually goes away on its own within a few days. But if there is:

- Persistent vomiting
- Bloody stools or severe diarrhea
- A fever of 102°F (39°C) or more or signs of dehydration
- Decreased volume of urine

Then one needs immediate attention and hospitalization. The most common cause of traveler's diarrhea is enterotoxigenic *Escherichia coli* (ETEC). High-risk destinations for traveler's diarrhea include many areas of Central and South America, Mexico, Africa, the Middle East, and most of Asia including India. It is generally low in Northern and Western Europe, Japan, Canada, Australia, New Zealand, and the United States. Certain groups of people have a greater risk of developing this condition.

These include young adults; people with weakened immune systems; people with diabetes, inflammatory bowel disease (IBD), or cirrhosis of the liver; and people who take acid blockers or antacids.

Prevention

Watch what you eat—the rule of thumb is to boil it, cook it, peel it, or forget it. Do not consume food from street vendors, avoid unpasteurized milk and dairy products, and avoid raw or undercooked food.

Drink boiled water when visiting high-risk countries, avoid unsterilized water, and avoid locally made ice cubes and sliced fruit. Keep your mouth closed while showering. Use bottled water to brush your teeth. Experts generally do not recommend taking antibiotics to prevent traveler's diarrhea; some suggest taking bismuth subsalicylate (Pepto-Bismol), which has been shown to decrease the likelihood of diarrhea. However, do not take this medication for >3 weeks.

Treatment

Avoiding dehydration: Dehydration is the most likely complication of traveler's diarrhea, so it is important to try to stay well hydrated. An ORS solution is the best way to replace lost fluids. Bottled oral rehydration products are available in drug stores; you can find packets of powdered ORS, labeled WHO-ORS, at stores, pharmacies, and health agencies. If these products are unavailable, you can prepare your own rehydrating solution.

Drugs

Antimotility agents include loperamide and diphenoxylate and bismuth subsalicylate (Pepto-Bismol). Antibiotics should be taken if you have more than four loose stools a day or severe symptoms.

PERSISTENT AND CHRONIC DIARRHEA

Diarrhea occurring for >14 days is considered as persistent diarrhea and diarrhea >30 days is considered as chronic. The emergency department (ED) may be the first point of contact for patients with chronic diarrhea and their initial management should take consideration of subsequent follow-up testing and initiate appropriate tests or therapies. In addition, patients with chronic diarrhea with systemic involvement require rapid diagnosis and aggressive resuscitation in the ED. Chronic diarrheas for consideration in ED patients are presented in **Table 3** with selected topics discussed in additional detail.

CLOSTRIDIUM DIFFICILE-INDUCED DIARRHEA

Clostridioides (formerly *Clostridium*) *difficile* infection (CDI) is one of the most common hospital-acquired (nosocomial) infections *C. difficile* colonizes the human intestinal tract after the normal gut flora has been disrupted

TABLE 3: Causes of persistent and chronic diarrhea.	
Surgical	Bowel ischemia, partial obstruction, fecal impaction, malabsorption due to resection or gastric bypass, malignancy
Endocrine	Chronic secretory diarrhea due to Addison disease, carcinoid tumors, Verner–Morrison syndrome, gastrinoma (Zollinger–Ellison syndrome), mastocytosis, hyperthyroidism
Bacterial	• *Tropheryma whipplei* (need treatment with systemic antimicrobials) • Tropical sprue (caused enteric bacteria; the combination of antibiotics and folic acid supplementation for 3–6 months) • Small intestine bacterial overgrowth (due to postoperative motility disorders or immune deficiency or reduced gastric acid secretion requires prolonged management)
Other	Irritable bowel syndrome, inflammatory bowel disease, food sensitivities, carbohydrate malabsorption, celiac disease, hepatobiliary or pancreatic disorder, diverticulitis, radiation colitis
Medications	Laxative use and abuse, antibiotics, antineoplastics, colchicine, nonsteroidal anti-inflammatory drugs, acarbose, and others

TABLE 4: Antimicrobial agents associated with *Clostridioides* (formerly Clostridium) *difficile* diarrhea and colitis.	
Frequently associated	• Fluoroquinolones • Clindamycin • Penicillin (broad-spectrum) • Cephalosporin
Occasionally associated	• Macrolides • Trimethoprim-sulfamethoxazole
Rarely associated	• Aminoglycosides • Tetracycline • Chloramphenicol • Metronidazole • Vancomycin

(frequently in association with antibiotic therapy) and is the causative organism of antibiotic-associated diarrhea and pseudomembranous colitis. Almost all antibiotics have the potential to cause diarrhea, but it is more often seen with clindamycin and cephalosporins (**Table 4**). Additional risk factors for CDI include age > 65 years, recent hospitalization, and use of proton-pump inhibitors. Watery diarrhea (≥3 loose stools in 24 hours) is the cardinal symptom of CDI. Other manifestations include lower abdominal pain and cramping, low-grade fever, nausea, and anorexia.

Diagnosis is by stool examination for toxins A and B and glutamate dehydrogenase (GDH) antigen. GDH is an essential enzyme produced constitutively by all *C. difficile* isolates; however, its detection cannot distinguish between toxigenic and nontoxigenic strains. Therefore, testing for GDH antigen is useful as an initial screening step in a multistep approach, which also consists of subsequent testing with more specific assays such as toxin A and B enzyme immunosorbent assay (EIA) or nucleic acid amplification test (NAAT) on specimens that are GDH antigen positive. GDH antigen testing has good sensitivity and results are available in <1 hour.

Most *C. difficile* strains produce both toxins A and B, although some strains produce toxin B only. No CDI due to strains producing toxin A alone has been reported. The sensitivity of EIA for toxins A and B is about 75%; the specificity is high (up to 99%). Lower GI endoscopy may show characteristic pseudomembranes but is not warranted in patients with classic clinical manifestations of *C. difficile* infection, a positive laboratory test, and/or clinical response to empiric treatment. In general, endoscopy may be pursued for circumstances in which an alternative diagnosis is suspected that requires direct visualization and/or biopsy of the bowel mucosa. It may also be helpful for patients with ileus or fulminant colitis in the absence of diarrhea since it may allow visualization of pseudomembranes (severe inflammation of the inner lining of the bowel) and collection of samples. However, an abdominal X-ray is a must before proceeding to colonoscopy to rule out toxic megacolon/perforation. The biopsy is not needed for the diagnosis of *C. difficile* but is sometimes done to rule out the alternative diagnosis.

Treatment

An important initial step in the treatment of CDI is the discontinuation of the inciting antibiotic agent(s) as soon as possible. Treatment with concomitant antibiotics (i.e., antibiotics other than those given to treat *C. difficile* infection) is associated with prolongation of diarrhea, increased likelihood of treatment failure, and increased risk of recurrent CDI. If ongoing antibiotics are essential for the treatment of the primary infection, if possible, it may be prudent to select antibiotic agents that are less frequently implicated in antibiotic-associated CDI (**Table 4**). Further treatment depends upon stratifying the patient as per the severity and follow the antibiotic protocol (**Table 5**).

TABLE 5: Antibiotic regimens for treatment of *Clostridioides difficile* infections in the adult.	
Nonsevere disease (white blood cells ≤15,000 cells/mL and creatinine <1.5 mg/dL)	• Vancomycin 125 mg orally four times daily for 10 days or fidaxomicin 200 mg orally twice daily for 10 days or if both drugs are not available • Metronidazole 500 mg orally thrice daily for 10 days
Severe disease (white blood cells ≥15,000 cells/mL and creatinine >1.5 mg/dL)	Vancomycin 125 mg orally four times daily for 10 days or fidaxomicin 200 mg orally twice daily for 10 days
Fulminant disease (hypotension or shock, ileus megacolon)	• Enteric vancomycin plus parenteral metronidazole • Vancomycin 500 mg orally via a nasogastric tube four times daily • Metronidazole 500 mg intravenously thrice daily for 10 days • If ileus presents, rectal vancomycin as retention enema every 6 hours (500 mg in 100-mL normal saline per rectally, retain as long as possible)

Nonsevere CDI: White blood cell count ≤15,000 cells/mL and serum creatinine <1.5 mg/dL

Severe CDI: White blood cell count >15,000 cells/mL and/or serum creatinine ≥1.5 mg/dL

Fulminant colitis (previously referred to as severe, complicated CDI): Hypotension or shock, ileus, or megacolon

For those who do not respond to standard medical management, options are FMT (fecal microbiota transplantation) or surgery. Factors that have been associated with poor prognosis in patients with CDI are:

- Hypotension
- Fever ≥38.5°C
- Ileus or significant abdominal distention
- Peritonitis or significant abdominal tenderness
- Altered mental status
- White blood cell count ≥20,000 cells/mL
- Serum lactate levels >2.2 mmol/L
- Admission to the intensive care unit
- End-organ failure (e.g., requiring mechanical ventilation, renal failure)
- Failure to improve after 3–5 days of maximal medical therapy

In all these situations, the surgeon should also be involved in management. In spite of good recovery, recurrences are common in CDI and require a methodical approach. For the first recurrence, tapered and pulsed vancomycin or fidaxomicin should be considered if the initial episode was treated with standard vancomycin. Alternatively, fidaxomicin or a standard 10-day course of vancomycin can be used for those previously treated with metronidazole. For the second recurrence, tigecycline or vancomycin followed by rifaximin, a standard course of fidaxomicin or FMT can be considered. To conclude, physicians should be aware of CDI; a high index of suspicion and a methodical approach are rewarding in most cases.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease is an immune-mediated chronic intestinal condition where there is inflammation and ulceration of bowel and can have extraintestinal manifestations too. IBD majorly has two diseases: (1) Ulcerative colitis (UC) and (2) Crohn's disease (CD). They generally present with abdominal pain, diarrhea, or bleeding per rectum.

Ulcerative colitis should be suspected in any patient who presents with diarrhea with or without blood which has persisted for >2 weeks or even earlier if it has not subsided after adequate antibiotic use and stool examination shows increased fecal leukocytes. The presence of tenesmus and crampy lower abdominal pain followed by small-volume frequent stools are characteristic features. Stool examination shows pus cells and *red blood cells (*RBCs) and the same can be quantified by doing stool calprotectin or lactoferrin. Lower GI endoscopy with rectal biopsy is usually diagnostic. Though the disease process may involve variable extent of colon, the rectum is almost always involved; hence, in a sick patient, we may avoid doing a full-length colonoscopy and only sigmoidoscopy may be sufficient.

On the contrary, the diagnosis of CD is more complex and challenging. Symptoms will depend on the site of involvement which could be ileocolonic, jejunoileal, colonic, gastroduodenal, or perianal. The colonic disease presents such as UC while jejunal disease presents as malabsorption, gastroduodenal as vomiting, and postprandial pain. Hence, one has to keep a high index of suspicion, especially in patients with chronic symptoms. Fistula is common in CD as inflammation extends transmurally while it is rare in UC as it is a mucosal disease only.

The most important differential diagnoses of IBD are infective diarrheas, intestinal tuberculosis, malabsorption syndrome, eosinophilic enteritis, radiation enterocolitis, colonic malignancies, and irritable bowel syndrome (IBS).

Once a diagnosis of IBD is suspected, the clinically next step is to do an endoscopy to visualize a mucosal lesion. It could be colonoscopy/gastroduodenoscopy/enteroscopy or capsule endoscopy depending upon the suspected part of the bowel involved. Endoscopic biopsies must be taken as they show characteristic features though they may not be diagnostic. Serum markers such as anti-*Saccharomyces cerevisiae* antibodies (ASCA) and antineutrophil cytoplasmic antibodies (ANCA) are often done but rarely help to make a diagnosis. Stool tests are useful as fecal leukocytes confirm the inflammatory nature of colitis. Stool for calprotectin is useful in differentiating from noninflammatory causes of diarrhea, such as IBS, and also helps in the follow-up of a patient to avoid repeated sigmoidoscopies.

Treatment of IBD is complex. One can take a step-up approach starting with salicylates and adding steroids, immunosuppressants, and biologicals in that order or a step-down approach where you start with biological agents such as infliximab or adalimumab or steroids to achieve quick remission and then keep the patient on maintenance regimens. In UC, there is a good role of local preparations in the form of enemas or suppositories, especially for a limited-extent disease such as proctitis or proctosigmoiditis (**Table 6**).

Similarly, in CD, a stepwise approach is important and the need for surgical intervention is more than that in UC as CD is a structuring and fistulizing disease (**Flowcharts 1** and **2**).

The most important aspect of IBD is patient education and follow-up as this is a lifelong disease, and exacerbations and remissions are common. These patients also need surveillance for malignancy after a certain duration; hence, treating physicians and patients should be aware of it.

CELIAC DISEASE

Celiac disease may present as chronic diarrhea with weight loss, vitamin deficiency (iron, folic acid, B12, and fat-soluble vitamins) and steatorrhea, and the most common inflammatory disorder of the small intestine in the Western world. The inflammation results from an immune reaction against gluten that is present in wheat, barley, and rye and can be detected initially by tissue transglutaminase or endomysial antibodies and will ultimately require gastroenterologist referral for biopsy (the gold standard for diagnosis). Management focuses on a lifelong gluten-free diet.

TABLE 6: Therapy for ulcerative colitis.

	Mild	*Moderate*	*Severe*	*Fulminant*

FLOWCHART 2: Algorithm for managing fistulizing perianal Crohn's disease.

SUMMARY

Initial management of a diarrheal illness starts with a thorough history and examination, evaluation of dehydration, or risk for treatment failure. Valuable education and counseling should be provided for patients and caregivers regarding symptomatic care and the expected course of their illness. Antibiotics should be avoided in patients presenting with bloody diarrhea and no fever as they are associated with the hemolytic uremic syndrome. Public health authorities should be informed if the diarrheal illness is suspected from cholera, enterohemorrhagic *E. coli*, *listeria*, *Salmonella*, *Shigella*, or Norovirus. The emergency physician should focus on the evaluation of chronic diarrhea, its stabilization with further advanced testing, and coordination for ongoing care.

CHAPTER

Gastrointestinal Bleeding

Anukalp Prakash, Anshu Nagpal

INTRODUCTION

Acute gastrointestinal (GI) bleed is a serious life-threatening emergency which is a common cause of hospital admission, responsible for more than a million hospitalizations annually in the United States. The GI bleed can originate from the upper gastrointestinal (UGI) tract (50%), i.e., from the esophagus, stomach, and duodenum, or from the lower gastrointestinal (LGI) tract [from the colon and anorectum (40%) or small bowel (10%)].

Severe GI bleeding is defined as bleed associated with shock or syncope or decrease in hemoglobin level of at least 2 g/dL or requiring a minimum of two units packed red blood cells (PRBCs) transfusion.

Blood in vomiting is known as hematemesis, which signifies the source in the UGI tract proximal to the ligament of Treitz. Melena is defined as black tarry foul-smelling, sticky stools occurring due to degradation of blood in the intestinal lumen by bacteria; melena can occur due to bleeding originating from the esophagus, stomach, small intestine, or proximal colon. Hematochezia refers to fresh red bleed per rectally and it signifies active UGI bleed, distal large bowel, or anorectal bleed.

EPIDEMIOLOGY

There are approximately 300,000 patients admitted to hospitals across the United States due to GI bleed annually. The annual incidence of UGI bleed is about 40–150 cases per 100,000 with a mortality rate of 4–10% whereas the annual incidence of LGI bleed ranges from 20 to 25 cases per 100,000 population with a mortality rate of 4–10%. Men have more chances of having GI bleed as compared to women and advancing age is a risk factor.

CAUSES

The GI bleed is defined as bleeding in the GI tract from mouth to anus. It is further divided into UGI bleed (bleed that occurs from source in the esophagus to ligament of Treitz in the duodenum) and LGI bleed (bleed that occurs from source distal to the ligament of Treitz). The most common causes of UGI bleed are peptic ulcer, varices (esophageal or gastric), Mallory–Weiss tear, and neoplasms. Other common causes of UGI bleed include esophagitis, erosive gastritis, vascular malformations, and Dieulafoy's lesions. LGI bleed signifies bleed from the colon, rectum, or anus; common causes of LGI bleed are diverticular hemorrhage, neoplasm, colitis, ischemia, inflammatory bowel disease, infections, rectal ulcers, hemorrhoids, and vascular malformations. Diverticulosis is the most common cause accounting for almost 30% cases of LGI bleed followed by colonic polyps/cancer (18%) and colitis (17%). The causes of GI bleed are enumerated in **Table 1**.

TABLE 1: Causes of GI bleed.

Upper GI bleed	• Peptic ulcer disease • Variceal hemorrhage (esophageal or gastric) • Mallory–Weiss tear • Esophagitis • Cameron ulcer • Erosive gastritis/duodenitis • Neoplasms (esophageal/gastritis/duodenal) • Portal hypertensive gastropathy • Vascular malformations • Gastric antral vascular ectasia (GAVE) • Dieulafoy's lesion • Crohn's disease
Lower GI bleed	• Diverticular disease • Malignancy (colon and rectum) • Inflammatory bowel disease • Colitis (infective, radiation, ischemia) • Vascular malformation • Hemorrhoids • Anal fissure • Rectal varices

(GI: gastrointestinal)

INITIAL ASSESSMENT AND PROGNOSTICATION

Rapid evaluation and resuscitation should be done before the diagnostic evaluation in unstable patients with acute severe bleeding. The patient should be evaluated for the immediate risk of rebleeding, complications, and the cause of bleed after he/she is hemodynamically stabilized. Patients who are hemodynamically stable at the time of presentation with minor GI bleed can be evaluated in an outpatient setting. The Rockall score (**Table 2**) and Glasgow–Blatchford score (GBS; **Table 3**) have been developed and validated for stratification of the patients at the time of presentation as UGI bleed. While the Rockall score uses endoscopic findings, the GBS is based upon the patient's clinical presentation such as systolic blood pressure, pulse, presence of melena, syncope, hepatic disease, cardiac failure, and laboratory parameters such as blood urea nitrogen (BUN) and hemoglobin. A meta-analysis found that a GBS of 0 decreases the likelihood of requiring urgent intervention [likelihood ratio 0.02, 95% confidence interval (CI): 0–0.05]. Therefore, the GBS may be best suited for initial risk evaluation of suspected acute UGI bleeding such as in the emergency department setting.

Approximately 80% of GI bleed stop spontaneously and 15% of the patients continue to bleed requiring urgent intervention like endoscopy. Patients who present with continued bleed, history of syncope, hypotension, tachycardia, low urine output, hemoglobin level <8 g, and advanced age can be categorized as high-risk patients who require urgent intervention whereas patients of younger age, without any feature of hypovolemic shock, are low-risk patients. So, early categorization of patients in the emergency department is important for management planning.

The mortality associated with GI bleed is correlated with advanced age and presence of comorbidities. The cause of death is not mostly blood loss but rather an end-organ injury, blood transfusion-related complications, worsening of the underlying comorbidities, and nosocomial infections. According to a study of LGI bleed, advanced age, intestinal ischemia, and associated comorbidities were the strongest predictors of mortality. The severe GI bleed, defined as a presentation with features of shock and fall in the hematocrit level by 6%, is associated with a mortality rate of 20–39%.

HISTORY AND PHYSICAL EXAMINATION

The clinical history, physical examination, and initial laboratory findings are crucial in ascertaining the likely cause of bleeding, therefore helping us in deciding the appropriate definitive investigation and intervention. A history of consumption of any drug, especially nonsteroidal anti-inflammatory drugs

TABLE 3: Glasgow–Blatchford scoring system.

Admission risk marker	*Score value*
Blood urea (mmol/L)	
6.5–8.0	2
8.0–10.0	3
10.0–25	4
>25	6
Hemoglobin (g/dL) for men	
12–12.9	1
10–11.9	3
<10.0	6
Hemoglobin (g/dL) for women	
10.0–11.9	1
<10	6
Systolic blood pressure (mm Hg)	
100–109	1
90–99	2
<90	3
Other markers	
Pulse ≥ 100/min	1
Presentation with melena	1
Presentation with syncope	2
Hepatic disease	2
Cardiac disease	2
Patients with a score of >6 are at >50% risk of requiring some intervention to stop the bleed	

TABLE 2: Rockall score.

Variable	*Score 0*	*Score 1*	*Score 2*	*Score 3*
Age (years)	<60	60–79	>80	
Shock	No shock	Pulse >100/min Systolic BP >100 mm Hg	Systolic BP <100 mm Hg	
Comorbidities	Nil major		CHF/IHD, major comorbidity	Kidney/liver failure, metastatic cancer
Diagnosis	Mallory–Weiss tear	All other diagnoses	GI malignancy	
Evidence of bleeding	None		Blood, adherent clot, spurting vessel	
A Rockall score <3 carries a good prognosis whereas a total of >8 indicates a high risk of mortality				

(CHF: congestive heart failure; GI: gastrointestinal; IHD: ischemic heart disease)

(NSAIDs) or aspirin or anticoagulants, is very important, as these drugs are a very common cause of UGI bleed, particularly in elderly patients.

The degree of blood loss should be determined with functional assessment rather than the patient's reporting as mostly it is inaccurate. Patients presenting with features of hypovolemia, such as lightheadedness, dizziness, syncope, and marked weakness, have had a massive GI bleed. The bright red color of the bleed indicates recent massive or active GI bleed whereas patients having coffee-colored or black-colored blood indicate that bleed has stopped.

On physical examination, the presence of pallor, tachycardia, and hypotension (systolic BP <90 mm Hg) is suggestive of massive GI bleed. We must look for the stigma of chronic liver disease, such as jaundice, alopecia, gynecomastia, spider nevi, and ascites, during the physical examination as the presence of these features favors varices (esophageal or gastric) as the cause of bleed. A history of chronic alcohol abuse also favors variceal bleed.

LABORATORY INVESTIGATIONS

Laboratory reports are helpful in the stratification of the risk and also may be useful in determining the probable cause. Hemoglobin levels <10 g% at the time of admission are correlated with higher mortality. Coagulation profile, liver function tests, and platelet counts are helpful in the determination of cause and assessment of coagulopathy. Electrocardiogram and cardiac enzymes should be evaluated particularly in elderly patients as these patients may develop silent cardiac ischemia due to GI bleed. Initial serum lactate levels can be a predictor of the amount of blood loss or GI ischemia and the final outcome of the patient. In one of the studies by Shah et al., the mortality rate was 6.4 times higher in those patients who had lactate levels >4 mmol/L in the emergency department. There is a mild increase in BUN in patients with GI bleed due to renal hypoperfusion and absorption of digested blood from the GI tract. Derangement of kidney function tests is more common in patients with a massive GI bleed and in the elderly with a history of hypertension, diabetes, and coronary artery disease and is associated with poor outcomes.

TREATMENT

The emergent treatment of the patient presenting with GI bleed is very important. Initial rapid resuscitative measures should be promptly started in the emergency which includes putting two large-bore intravenous (IV) cannulas and fluid resuscitation. Blood samples should be collected for complete blood counts, liver and renal function tests, coagulation profile, and blood grouping/cross-matching. Patients with massive UGI bleed may need endotracheal intubation for airway protection.

Antibiotics

Every patient should be started with antibiotics to prevent sepsis caused by bacterial translocation from the gut, particularly in cirrhotic. The risk of rebleed is more in a patient who develops bacterial infections. Patients with liver cirrhosis presenting with acute UGI bleed have shown to have improve survival with short-term prophylactic antibiotics. A dose of 1-g IV ceftriaxone has been recommended for the prevention of serious bacterial infections in patients with GI bleed.

Packed Red Blood Cell Transfusion

Patients presenting with massive GI bleed should be given PRBC in the emergency department only as rapid blood loss can result in vital organ hypoperfusion leading to multiorgan dysfunction. In euvolemic patients with UGI hemorrhage, the PRBC transfusion should be planned to target a hemoglobin level of 7 g%. An overzealous PRBC transfusion should be avoided as it may increase the risk of rebleed and transfusion-related complications.

In patient with LGI bleed, the decision of PRBC transfusion should be individualized as no specific target hemoglobin level has been identified. Clinicians should assess the hemodynamic status and transfusion-related untoward reactions before planning for PRBC transfusion.

Nasogastric Tube Placement

There is a controversial role of nasogastric tube placement in all GI bleeds, which can be useful in UGI bleed. Bloody nasogastric aspirate confirms the source in the UGI tract. Nasogastric tube placement should be done in patients with suspected UGI bleed and gastric lavage should be done as it facilitates in clear view during the endoscopic procedure. The role of nasogastric tube placement in LGI bleed is not indicated. The sensitivity of nasogastric aspirate for UGI bleed ranges from 42 to 84% in a recent systemic review. However, the nonbloody nasogastric aspirate does not rule out the UGI source of the bleed.

Anticoagulation Reversal

For patients with acute GI bleed who are on anticoagulants, efforts should be made by emergency physicians to reverse the effect of anticoagulants. Patients on warfarin or dicoumarin (vitamin K antagonists) should be given IV vitamin K. Patients with elevated prothrombin time and international normalized ratio (INR) with acute GI bleed should be transfused with prothrombin complex concentrate (PCC) or fresh frozen plasma (FFP). For patients on newer direct oral anticoagulants such as dabigatran or rivaroxaban, the ideal strategy remains unclear due to the unavailability of the antagonist of these agents. Fluid resuscitation can increase the renal clearance of these drugs.

Proton-pump Inhibitor

An intravenous proton-pump inhibitor (PPI) is recommended in all patients presenting with acute UGI bleed. The emergency physician should consider IV PPI in all patients with UGI hemorrhage before the endoscopic therapy. In patients with ulcer-related UGI bleed, 80 mg IV pantoprazole/omeprazole in the emergency department followed by continuous infusion of 8 mg/h for at least 72 hours (preferably up to 5 days) reduces the risk of rebleed and need for surgery.

Somatostatin and its Analogs

Somatostatin and its long-acting analog, octreotide, cause selective splanchnic vasoconstriction, thus causing a reduction in portal pressure. These drugs reduce the chances of ongoing UGI bleed in both variceal and nonvariceal bleed. Somatostatin and its analog reduce the blood flow to the portal system by causing vasoconstriction, thus decreasing the variceal bleed.

The dose of somatostatin is 250 μg IV bolus followed by 250 μg/h continuous infusion for 3–5 days whereas the dose of octreotide is 50 μg IV bolus followed by 50 μg/h continuous infusion for 3–5 days.

Vasopressin Analog (Terlipressin)

Terlipressin causes vasoconstriction and therefore reduces portal blood flow and also increases the resistance to variceal blood. This drug is widely used and recommended for variceal bleed. Terlipressin also has the advantage of preserving renal function so it is particularly useful in patients with variceal bleed with renal dysfunction. The dose of terlipressin in variceal bleed is 1 mg IV every 6 hours for 5 days. Cardiac and bowel ischemia are potential side effects which can limit the use of this agent.

ENDOSCOPY THERAPY

Upper Gastrointestinal Endoscopy

In patients with UGI bleed, the endoscopy is both diagnostic and therapeutic as it helps in confirming the cause of the bleed and also enables us to take measures to stop the bleed. High-risk patients, such as those with hypotension, tachycardia, and fresh red nasogastric aspirate, have been shown to have mortality benefit with early endoscopy, i.e., within 12 hours of the presentation. In low-risk patients, the endoscopy can be done in a planned manner after stabilization. For varices-related bleed, endoscopic band ligation of varices, glue injection (for gastric varices), and endoscopic sclerotherapy can be performed to stop the bleed. For nonvariceal bleed (such as ulcer related, Mallory–Weiss tear, Cameron ulcer, esophagitis), injection therapy/hemoclip/argon plasma coagulation/hemospray, or combination therapy can be used to achieve hemostasis. It is recommended to use combination therapy over a single intervention to stop the bleed. Hematochezia may be an indicator of massive UGI bleed so it is reasonable to do upper endoscopy before colonoscopy. Every patient who presents with UGI bleed should undergo endoscopy unless the patient is very hemodynamically labile or we are able to get an informed consent for the procedure.

Colonoscopy

Urgent colonoscopy after rapid colonic purge has been shown to be safe and localizes the cause of bleed and also helps to perform therapeutic intervention to achieve hemostasis. As most of the bleeds stop spontaneously, the colonoscopy can be performed on a semielective basis after initial stabilization. Injection therapy can be done, in case of bleed ulcer, to stop the bleed. Glue injection is a recommended method in bleeding rectal varices. Polypectomy can be done if bleeding polyp has been identified. Diverticular hemorrhages are mostly self-limiting with conservative treatment.

Conventional Angiography

Angiography is particularly useful if endoscopy and colonoscopy fail to localize the site of the bleed. It can detect the site of bleed if the bleed rate is 0.5–1 mL/min and allows us to perform transcatheter embolization of the bleeding vessel, particularly in LGI bleed. The potential risks of angiography include acute kidney injury, contrast reaction, and bowel ischemia. Therefore, angiography is particularly useful in patients with massive ongoing GI bleed where endoscopy is not possible or colonoscopy failed to localize the site of bleed.

Nuclear Scan

Technetium (Tc) 99m-labeled RBC scan is noninvasive and sensitive but a less specific modality to detect GI bleeds as low as 0.1 mL/min. This scan itself is not therapeutic but an extremely useful guide to decide further course of action such as endotherapy, surgery, or angiography.

Obscure Gastrointestinal Bleed

Obscure GI bleed is defined as bleeding from the GI tract where no source is identified even after performing upper endoscopy and colonoscopy. Obscure GI bleed can be occult and overt. Occult GI bleed means where blood is not visible but suggested by persistent hemoglobin drop and positive fecal occult blood testing. Overt obscure GI bleed means bleed is visible in the form of melena or hematochezia, but the source is not identified. Obscure GI bleed constitutes almost 5% of all GI bleeds. The common causes of obscure GI bleed include angioectasia of the small bowel, NSAID-induced enteropathy, and inflammatory bowel disease, especially Crohn's disease. Other uncommon causes include tumors (leiomyoma, carcinoids, lymphoma, and adenocarcinoma), Meckel's diverticulum, Dieulafoy's lesion, or small bowel varices. It is recommended to repeat the upper endoscopy and colonoscopy before small bowel evaluation. The methods of small bowel evaluation include double-balloon enteroscopy, *computed tomography* (CT) enterography/angiography, video capsule endoscopy, and nuclear scan which have different success rates in identifying the source of the bleed.

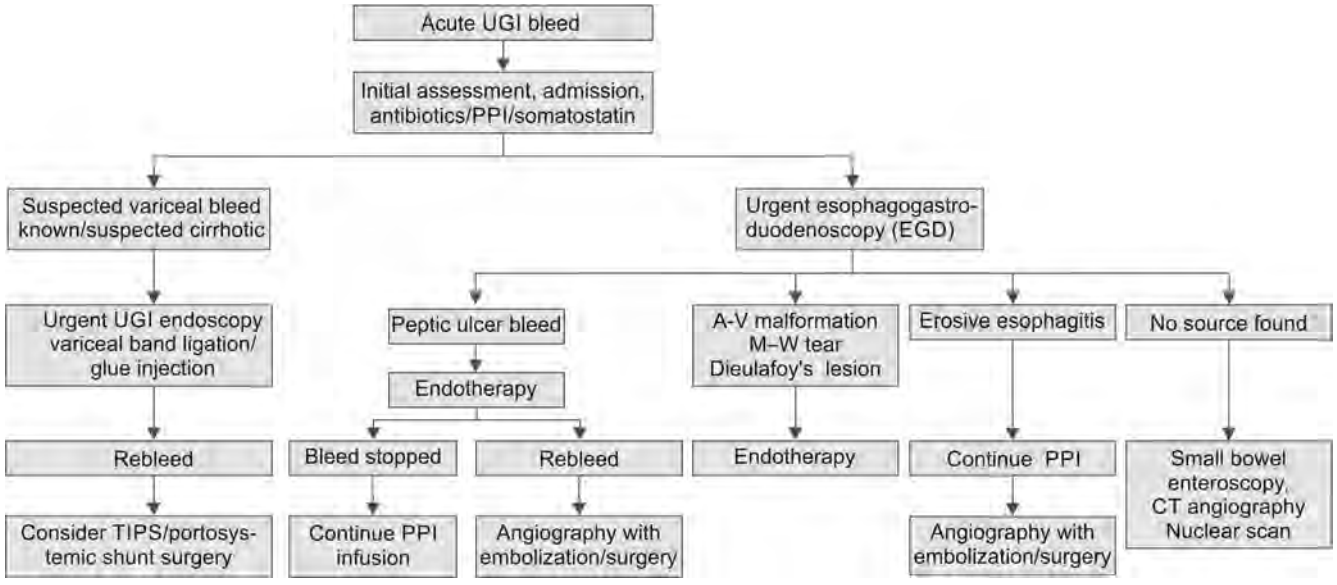
Surgery for Gastrointestinal Bleed

Indications for surgical intervention include intractable GI bleed where endoscopic and other resuscitative measures failed to stop the bleed. In portal hypertension-related UGI bleed, portosystemic shunt surgery can be lifesaving if medical, endoscopic and radiological interventions and transjugular intrahepatic portosystemic shunt (TIPS) have failed to control the bleed. Surgical interventions are more commonly needed in the case of LGI bleeds as compared to UGI bleeds. Causes of GI bleed requiring surgery include diverticular hemorrhage, neoplasia, mesenteric ischemia, anorectal disease (hemorrhoids), and angiodysplasia. Surgical interventions are seldom required to control the GI bleed due to advancements in endoscopy and intervention radiology.

SUMMARY

The acute GI hemorrhage is a serious emergency accounting for approximately 300,000 admissions in the United States and mortality ranging from 4 to 10%. UGI bleed is relatively common as compared to LGI bleed. The most common causes of UGI bleed include peptic ulcer, varices, esophagitis, and Mallory–Weiss tear whereas diverticulosis, neoplasm, anorectal diseases, and colitis account for the majority of cases

of LGI bleed. With the advancements of radiology, nuclear medicine, and endoscopic procedures, most GI bleeds can be localized and managed conservatively. In approximately 5% of the patients with GI bleed, the source is not identified on routine UGI and LGI endoscopies; these are called obscure GI bleed. Patients with obscure GI bleed require meticulous evaluation with CT enterography/angiography, double-balloon enteroscopy, and nuclear scan to localize the source of the bleed. The approaches to the treatment of UGI and LGI bleed are summarized in **Flowcharts 1** and **2**, respectively.



(A-W: arteriovenous; CT: computed tomography; M–W: Mallory–Weiss; PPI: proton-pump inhibitor; TIPS: transjugular intrahepatic portosystemic shunt; UGI: upper gastrointestinal)

95
CHAPTER

Esophageal Emergencies

Purushottam Vashistha

INTRODUCTION

The esophagus is a hollow tube-like structure which acts as a conduit for the passage of food from mouth to stomach. This is about 18–26 cm in length and usually collapsed but stretches to 3 cm laterally and 2 cm anteroposterior during swallowing. The esophageal wall consists of four layers and is devoid of serosa, the outermost layer. There are four physiological constriction areas where a large food bolus or foreign body can be held up and gives rise to clinical dysphagia. There are few situations which can force a patient to seek medical help in emergency hours. These situations are as follows:

- Atypical chest pain
- Acute dysphagia
- Esophageal foreign bodies
- Caustic injury
- Esophageal perforation

ATYPICAL CHEST PAIN

Chest pain is the usual presentation to the emergency room at odd hours. Atypical chest pain means when a person presents with complaints of chest pain and does not fit into the pain of cardiac origin. A classic angina needs the following three criteria: (1) Substernal pain or discomfort which aggravates by exertion or emotional stress and is relieved by rest or nitroglycerine (NTG), (2) Atypical chest pain means the person is having only two criteria and here we need to examine and look for chest pain of esophageal origin, (3) It may be difficult to differentiate a cardiac pain from an esophageal one because the heart and esophagus are in the same vicinity and also share innervation. Also, esophageal pain is the second most common cause of chest pain. In one of the studies, it was found that 30% of coronary angiography have a normal study; of these, esophageal pain contributes to about 18–56%.

Evaluation and Management of Atypical Chest Pain

Esophageal pain is usually substernal discomfort which can be burning or squeezing sensation which radiates to the back, neck, and jaw or arms. Sometimes, patients can have perspiration and mimic classic angina too. It can be aggravated by food or stress and may awaken the patient from sleep. It can last for minutes to hours and may come intermittently. It usually disappears on its own or to a proton-pump inhibitor (PPI) or other antacids, but sometimes it may be severe and need the help of NTG or narcotics. Most of these patients also have some history of other dyspeptic symptoms.

Is history reliable enough to differentiate classic angina from esophageal chest pain and the answer is no. Exercise also aggravates reflux which can cause chest pain. Moreover, >50% of patients suffering from cardiac pain also have esophageal symptoms. Furthermore, sublingual NTG relieves both kinds of pain. Another factor is that both diseases may coexist in a patient and interact with each other.

Any patient who comes to the emergency room with chest pain must be evaluated for the cardiac cause. Appropriate tests to rule out cardiac disease in the emergency room are noninvasive cardiac tests and cardiac markers such as troponin T, troponin I, and creatine phosphokinase-myocardial band (CPK-MB) along with ECG and 2D echo. One entity that is difficult to diagnose in the emergency room is microvascular angina (insufficiency of coronary blood flow with normal-appearing coronary arteries).

Once we rule out cardiac disease, the institution of PPI and relief of pain usually indicate pain of esophageal origin. Esophageal pain usually originates due to gastroesophageal reflux disease (GERD), motility disorders, and enhanced visceral sensitivity of esophageal mucosa. Antidepressants or anxiolytics are needed in some patients who have increased sensitivity to esophageal mucosa.

Later on, these patients can be evaluated as outpatient by upper endoscopy, 24-hour pH metry, impedance pH metry, and manometry to establish the diagnosis of GERD, refractory GERD, alkali reflux, or motility disorders of esophagus such as hypercontractile (jackhammer) esophagus, nutcracker esophagus, distal esophageal spasm, and hypertensive lower esophageal sphincter (LES).

ACUTE DYSPHAGIA OR ODYNOPHAGIA

Dysphagia means difficulty in swallowing food. Patients usually complain of sticking sensation or holding food in

chest or throat or say that food is not going down and may complain of even swallowing their saliva along with pain while swallowing. Dysphagia is a common symptom that is present in 12% of patients admitted to an acute care hospital and in >50% of those in a chronic care facility. Dysphagia is usually of two kinds: (1) Oropharyngeal; and (2) Esophageal.

Oropharyngeal dysphagia means inability to propel a food bolus successfully from the hypopharynx to the upper esophagus across the upper esophageal sphincter. This happens usually immediately or within 1 second of swallowing. Patients normally describe choking or aspiration or nasal regurgitation upon eating food. They might have dysarthria, nasal speech, and hoarseness of speech. Most patients with esophageal dysphagia localize their symptoms to the lower esophagus but may sometimes locate to a suprasternal notch despite having a lower esophageal lesion. Esophageal dysphagia is usually relieved by repeated swallowing attempts, raising the arms overhead or Valsalva maneuvers.

The most common reasons for a patient to come to the emergency room with acute dysphagia or odynophagia are foreign body ingestion, caustic ingestion, pill injury, peptic stricture, esophageal candidiasis, esophagitis due to cytomegalovirus (CMV), Epstein–Barr virus (EBV), human immunodeficiency virus (HIV), herpes or Koch's (tubercular) etiology, especially in immunocompromised patients, esophageal rings or web, eosinophilic esophagitis (poorly distensible lumen) or radiation esophagitis (poorly distensible lumen) and extrinsic compression of the esophageal lumen by vascular structures, osteophytes or cervical implant, and mediastinal mass.

To identify esophageal dysphagia, we need to get some information. Which kind of solid food or liquid is causing dysphagia? Whether it is progressive or intermittent? Is there any history of recurrent heartburn? Difficulty in swallowing solid food indicates mechanical obstruction. Benign peptic or malignant strictures, achalasia, and scleroderma have progressive dysphagia unlike Schatzki ring or other motility disorders. How to approach a dysphagia patient usually depends on proper history, site, severity of symptoms, and etiology of disease. We can use an X-ray of neck or chest, barium or contrast study, computed tomography (CT) scan of neck or chest, endoscopic evaluation, and manometry according to their clinical diagnosis.

PILL INJURY

Medication-induced injuries are common but underdiagnosed conditions which can present to the emergency department as severe chest pain which aggravates on inspiration, associated with acute dysphagia, or odynophagia, or heartburn. Some of the medicines which can produce mediastinitis or esophageal perforation or bronchopleural fistula are potassium chloride (KCl), quinine, nonsteroidal anti-inflammatory drug (NSAID), and bisphosphonates.

Pill injury is usually caused by direct injury to the esophageal mucosa by the production of acidic or alkali solution or may produce a hypertonic environment and direct toxicity to the esophageal mucosa. Most of the time, patients have underlying motility or anatomic disorders along with a history of medications taken just before sleep with a small amount of water. The severity of injury depends on the duration of exposure of medication to the esophageal mucosa and the type of pill.

The most common medications which give rise to pill injury are: Tetracycline, doxycycline, clindamycin, antiretroviral drugs, bisphosphonates, NSAID, iron tablets, quinidine, KCl, and even a PPI like lansoprazole, along with certain chemotherapeutic agents.

Endoscopy is the best test to diagnose pill injury. We can find variable findings from discrete ulcers to diffuse esophagitis or pseudomembrane mimicking candidiasis by Kayexalate or bisphosphonates or tumor-like mass.

ESOPHAGEAL FOREIGN BODY

Gastrointestinal (GI) foreign bodies are composed of food boluses or ingested foreign objects. Children from the age of 6 months to 3 years are most commonly affected by it and make almost 80% of true foreign body ingestions. Coins, marbles, pins, crayons, and disc batteries are some objects commonly ingested by children. In adults, the commonly ingested objects are dentures, coins, nails, pins, food boluses, and iatrogenic bodies. Food bolus impaction (fishbone) is the most common foreign body which needs urgent attention. Most of these patients have some underlying predisposing factors such as esophageal rings, web, strictures, eosinophilic esophagitis, prior operation on esophagus such as fundoplication or esophagectomy, or bariatric surgery. Most of these patients are in their fourth to fifth decade of life.

Normally, 80% of GI foreign body passes through the GI tract without any issue but 20% need endoscopic intervention and about 1% need surgical operation. Most of the GI foreign body is trapped in the hypopharynx but once it passes into the esophagus it can lodge at four areas of physiological constrictions: (1) Upper esophageal sphincters, (2) aortic arch, (3) mainstem bronchus, and (4) LES. One important thing to notice here is that the longer the foreign body stays in the esophagus, the chances of having complications are more; these complications are perforation, abscess, mediastinitis, pneumothorax, fistula, or cardiac tamponade.

Evaluation and Management

We need proper history, wherever we can get, from the patients although 20–30% of patients are asymptomatic. The presence of acute dysphagia, dysphonia, odynophagia, drooling of saliva, retrosternal pain, and chest pain suggests that a foreign body is present in the esophagus or hypopharynx. The localization of foreign body is not appropriate according to symptoms and it correlates only with 30–40% if the esophagus is the site of impaction. Various tests that can be done to detect a foreign body are X-ray of neck and chest and anteroposterior and lateral views, especially if a foreign body is known and radiopaque. For nonradiopaque objects, an X-ray does not help and a CT scan or magnetic resonance imaging (MRI) can help in such cases. Moreover, a CT scan can detect complications such as perforation, abscess, or pneumomediastinum. Contrast studies, such as barium and other contrast studies, are avoided due to the risk of aspiration and later on due to interference in endoscopic interventions.

Endoscopy is the most important tool to diagnose the object irrespective of its radio-opaqueness. It helps in diagnosis along with inspection of the esophagus for any predisposing factors or damage of the esophagus by objects and simultaneously offering treatment to such cases.

Endoscopic extraction success rates range from 90 to 100% with most series reporting success rates of >95%. Treatment offered should be dependent on the location, size, type, and duration of the object in the esophagus. Medical treatment in terms of muscle relaxants [most commonly intravenous (IV) glucagon 0.5–2-mg bolus] is used to relax the LES by 60% and succeed in almost 15–55% of cases. Carbonated beverages, nifedipine, and NTG are not recommended due to the risk of aspiration and hypotension. Generally, all esophageal foreign bodies need urgent attention and intervention. As a rule, no object should be lodged in the esophagus for >24 hours.

Flexible upper endoscopy is the preferred treatment of choice for esophageal foreign bodies. All foreign bodies should be removed within 6–12 hours except button battery or any sharp or long or large blunt objects in the esophagus which need immediate attention due to fear of pressure necrosis followed by perforation and fistula formation. There are different equipment for removal of foreign bodies in the esophagus, such as overtube, retrieval net, grasping forceps, Dormia basket, snare, vacuumed cap, or latex protector hood. Sedation in the endoscopic procedure is usually chosen by seeing the type and number of objects. Conscious sedation is usually adequate, but intubation is also needed in the case of children.

CAUSTIC INJURY TO ESOPHAGUS

Caustic ingestion causes progressive and devastating injury to the esophagus where the patient can survive an acute injury, but the reparative process might result in esophageal stenosis and increased chances of esophageal cancer. Most of the caustic injuries happen as accidental ingestion in children who are <6 years old and in adults as suicidal attempts in a person having a known or unknown mental health issue. The seriousness of injury is more in adults due to ingestion of a large amount of caustic agents.

Caustic agents are of two types: (1) Acidic or (2) alkali. Both kinds of agents are being used as household cleaning agents and for other uses. The main difference between acidic and alkali agents is that alkaline agents cause liquefaction necrosis which produces transmural necrosis contrary to coagulative necrosis by acidic agents. Moreover, they affect the esophagus more than the stomach due to neutralization by gastric acid in the stomach.

Evaluation and Management of Caustic Injury

The patient usually presents with different symptoms which might be dysphagia, odynophagia, oropharyngeal pain, chest pain, epigastric pain, drooling of saliva, hoarseness of voice, and dyspnea. One thing to remember is that the symptoms and signs of patients often do not correlate with the amount of ingestion. Plain X-ray of chest does not give much information but can guide about the presence of pneumomediastinum and pneumothorax. Usually, a CT scan of chest is done to rule out any perforation but can be avoided if there is no strong suspicion. Upper endoscopy is the modality of choice to diagnose, grade, guide the treatment, and prognosticate the injury. It should be done within 48–72 hours of ingestion. Almost 50% of a patient's symptoms do not correlate with endoscopic findings. Endoscopic injury is classified as given in **Table 1**.

TABLE 1: Endoscopic grading of injuries.

Grade	*Injuries*
Grade I	Edema and erythema
Grade IIA	Hemorrhages, erosions, blisters, ulcers with exudates
Grade IIB	Circumferential ulcerations
Grade III	Multiple deep ulcers with brown, black, or gray discoloration
Grade IV	Perforation

Treatment

Resuscitation: Airway, breathing, circulation. No gastric lavage should be done to such patients; no nasogastric tube or induced emesis should be tried in such circumstances. Neutralization is recommended by so many manufacturers and it should not be done with any other agents in the absence of controlled studies. Steroid and antibiotics should not be used until perforation is present where antibiotics should be given to prevent mediastinitis. Grade I or IIA patients are usually stable patients and can be managed in wards after endoscopic evaluation. Patients are given oral feed and can be discharged also within 24–48 hours. Grade IIB and more severe injury should be admitted in an intensive care unit to monitor for any early complications such as perforation and resultant mediastinitis. Documented perforation or having a strong suspicion of perforation in a patient is a contraindication for upper endoscopy. Emergency surgery is the best modality for documented perforation depending on the availability of highly skilled services in the hospital despite evidence of having high mortality prediction in emergency surgery. The patients who have deep necrosis and extensive damage are usually managed conservatively, although opinion differs in approaching such patients about the timing of surgery. Usually, 30% of patients develop fibrosis and strictures within 2–12 weeks of injury. The more severe the injury, the more the chances of developing strictures in such patients. Esophageal strictures are managed with repeated endoscopic dilatation. Endoscopic dilatations are done with the rule of 3 which means incremental gradual dilatation from the start point to avoid a perforation (0.5% perforation rate). Some institutions believe in early stent placement or early dilatation to avoid having strictures in the future, but results are inconsistent. Surgical interventions have very good results in dealing with refractory esophageal strictures. Colonic interposition is required in some patients with extensive injury. Intralesional injection of steroid is also effective in some patients with refractory strictures.

ESOPHAGEAL INJURY AND PERFORATIONS

Traumatic injury to the esophagus is common during motor accidents and other accidents. Besides motor accidents, gunshots, knife injury and fall are other common reasons. Cervical esophagus is involved more than the thoracic or distal esophagus. Cervical esophageal perforation can be diagnosed by the presence of extramural air on a plain X-ray of the neck and can be confirmed with a CT scan of neck and chest and

contrast (gastrografin) studies. Cervical esophageal injuries are associated with injuries of nearby organs too and hence there are different opinions for the management of such injuries. Some studies favor managing them conservatively and some favor aggressive management due to fear of developing sepsis and tissue dehiscence and later on the need of two-step closure if timed surgery is not done.

Upper endoscopy is the choice of investigation to identify the lesion and plan further course of action if a distal esophageal injury is being suspected since these cases are difficult to manage because these injuries may extend to the mediastinum and change the spectrum of management. These injuries are not suitable for primary simple closure due to aberrant esophageal blood supply and the development of ischemia and leakage later on. Therefore, esophagectomy and anastomosis are the choices of surgery. It is difficult to decide to operate or not in most of the cases, but surgery is the better choice and should be done within 12 hours of injury.

MALLORY–WEISS SYNDROME

In this condition, there are lacerations which usually extend from the gastroesophageal junction to the proximal stomach up to 2 cm from the gastroesophageal junction, although 20% can occur in the esophageal mucosa. This occurs due to forceful vomiting or any bodily action which increases the intra-abdominal pressure and resultant shearing force on this region as it herniates through the diaphragm. Most of the patients also have hiatus hernia. Patients usually have a history of forceful coughing, retching, binge alcohol and aspirin use, or recently done procedures such as endoscopy or transesophageal echocardiography. Mostly, these patients have a history of forceful vomiting (70%) followed by hematemesis. Bleeding is usually self-limiting but can be massive in 10% of cases. Endoscopy not only establishes the diagnosis but also finds some associated lesions in 30% of cases and simultaneously gives options of endotherapy such as injection of diluted adrenalin or clip application or band ligation. For endoscopic therapy failure patients, angioembolization is the choice of therapy. Surgical treatment is very rarely needed for such patients.

BOERHAAVE'S SYNDROME

It is the most extreme form of esophageal tear that occurs due to an increase in intragastric pressure. There is a tear along with perforation at the margin of contact between the clasp and oblique fibers of the esophageal muscle layer. This syndrome differs from the Mallory–Weiss syndrome in that this can present with severe pain in the chest or upper abdomen along with severe sepsis or shock and can mimic pulmonary embolism, acute myocardial infarction, pancreatitis, and aortic aneurysm rupture. The history of such patients is forceful vomiting. All predisposing factors and conditions similar to the Mallory–Weiss tear are important factors and aggravate the severity of tear in this syndrome. On clinical examination, patients usually have subcutaneous emphysema and pneumomediastinum and pleural effusion on imaging. Treatment is mainly primary surgery, but conservative treatment with esophageal stent (self-expanding) and simultaneous chest drain is also an option in some patients where surgery is not feasible.

SUMMARY

Esophageal disease is frequent presentation in the ED and often presents with mild form with a variety of symptoms that can mimic cardiovascular and respiratory disorders. Thus, diagnosis of esophageal disorders is frequently delayed. Laboratory testing and imaging are often helpful only in critically ill patients, and emergency physicians should focus on the history to differentiate esophageal disorders from cardiorespiratory disease and to guide management. Whereas unstable patients require aggressive measures and a multidisciplinary approach, ED treatment of stable patients is often limited to alleviation of symptoms. All patients should be referred for definitive evaluation and treatment.

96 CHAPTER

Dyspepsia and Peptic Ulcer Disease

Ravindra Kale

INTRODUCTION

Dyspepsia is a feeling of upper abdominal pain or vague discomfort which encompasses postprandial fullness, early satiety, burning, nausea, and bloating in the upper abdomen, i.e., symptoms that presumably arise from stomach and duodenum. Heartburn is usually associated with these symptoms, but it is considered to be a symptom of gastroesophageal reflux disease (GERD) and not of dyspepsia.

ETIOLOGY

Dyspepsia most commonly results from peptic ulcer disease, gastritis, and reflux disease, but there are myriads of other causes which may lead to dyspeptic symptoms. Cardiac and pancreatobiliary conditions are particularly important to be differentiated for emergency management.

Peptic ulcer is responsible for 5–10% cases of dyspepsia. These ulcers occur due to acid and pepsin-related mucosal damage in gastroduodenal mucosa. The usual risk factors are *Helicobacter pylori* infection and frequent use of analgesics [nonsteroidal anti-inflammatory drug (NSAID)], particularly in elderly. Alcohol use and smoking are other risk factors. Most of the ulcers are asymptomatic and may directly present with complications. Complications can occur, especially in the elderly, with concomitant aspirin use in cardiac patients or NSAID use in patients with arthritis as they may bleed or perforate. Chronic ulcers may cause stricture and gastric outlet obstruction. Rarely gastroduodenal ulcers occur due to tuberculosis, ischemia, Crohn's disease, and cytomegalovirus (CMV) infection.

Reflux esophagitis is another important cause of dyspepsia in 20% of patients and an equal number of patients with reflux symptoms may not have endoscopic signs of reflux disease (nonerosive reflux disease). Gastric malignancy also causes dyspeptic symptoms. Risk increased with long-standing *H. pylori* infection. Gastroparesis usually due to diabetes is associated with postprandial fullness, nausea, and vomiting.

Medications are another important cause of dyspepsia. NSAID, theophylline, oral iron, potassium chloride, and antimalarials (chloroquine and quinine) frequently cause dyspepsia through direct mucosal injury, reflux, or idiosyncratic mechanisms.

Chronic pancreatitis and pancreatic malignancy may mimic symptoms of dyspepsia but usually have more severe pain, characteristic radiation, and weight loss. Presence of gall stones alone does not cause dyspepsia and other causes should be evaluated. Patients with hyperthyroidism, acute coronary syndrome, renal failure, and chronic obstructive pulmonary disease (COPD) can also have dyspepsia-like symptoms.

Functional dyspepsia is absence of any obvious cause for dyspepsia. The Rome criteria for functional gastrointestinal (GI) disorders (Rome IV) define functional dyspepsia as one or more of the following symptoms in the last 3 months: Bothersome symptoms of (1) postprandial fullness, (2) epigastric pain, (3) early satiety, and (4) epigastric burning, with onset at least 6 months prior to diagnosis. These symptoms should be present in the absence of a significant structural disease (including normal endoscopy) that can explain symptoms. Functional dyspepsia can be further classified as postprandial distress syndrome (PDS) which includes fullness and early satiety and epigastric pain syndrome (EPS) which includes epigastric pain and burning.

PATHOPHYSIOLOGY

There are several proposed mechanisms for dyspepsia. Abnormally enhanced perception of visceral stimuli (visceral hypersensitivity), impaired gastric relaxation to meals, and delayed gastric emptying can be responsible. *H. pylori* infection can be a cause of functional dyspepsia and eradication may improve symptoms. First-degree relatives of patients have increased frequency of dyspepsia suggestive of genetic predisposition.

CLINICAL PRESENTATION

The usual presentation is of chronic upper abdominal discomfort with epigastric pain or burning and fullness after meals, nausea, and vomiting. Food may worsen pain in peptic ulcer disease. Patients with duodenal ulcers usually have pain 2–3 hours after meals or nocturnal pain. Pain due to perforation is acute onset and soon becomes generalized. Most of the patients are well nourished and may be obese.

Some patients are on prolonged NSAID therapy. Presence of anemia and/or weight loss indicates serious disorders such as gastroesophageal or pancreatic malignancy or complicated peptic ulcer with bleeding or stricture. A patient with gastric outlet obstruction presents with vomiting of stale food and a moving lump in the upper abdomen. Patients with acute-onset epigastric pain and dyspnea, especially on exertion and improvement after rest, should be evaluated for cardiac disease. *Red flags*: Old age, significant weight loss, long-term aspirin and NSAID use, GI bleeding, anemia, persistent vomiting, and dysphagia.

EVALUATION

History

All patients should be evaluated with a detailed history of dietary habits and medications including complementary and alternative medicines. History of dyspnea on exertion and fatigue may suggest cardiac disease or anemia due to blood loss. History of melena and hematemesis points toward peptic ulcer disease. Dysphagia may be due to peptic stricture or malignancy. History of psychiatric disorders and past physical or sexual abuse may be relevant in those with refractory symptoms. History of diabetes and other endocrine disorders in the patient/family should be enquired for. Diabetic patients can have gastroparesis and drug- (metformin, acarbose) induced dyspepsia. Improper use of abdominal exercise techniques such as "*kapalbhati*" (a yogic breathing exercise) may be responsible for the aggravation of dyspepsia in some (personal experience).

Physical Examination

A detailed physical examination is to be done. Presence of anemia, lymphadenopathy, abdominal lump, or ascites requires further evaluation. Succussion splash in epigastrium in a fasting patient suggests gastric outlet obstruction or gastroparesis. Per rectal examination may show presence of blood in stools and rectal shelf deposits.

Investigations

A young, otherwise normal patient on examination need not undergo any further evaluation. Age >50 years old, family history of malignancy, history of NSAID use, and presence of alarm features such as GI bleed, anemia, dysphagia, and weight loss warrant further workup.

Initial workup consists of complete blood counts, creatinine, thyroid-stimulating hormone (TSH), blood sugar, electrolytes, calcium, liver function tests, and ultrasound of the abdomen. Upper GI endoscopy is very useful and needs to be done to look for mucosal lesions. Gastric biopsy from antral region and rapid urease test for *H. pylori* can be done. At the same time, bleeding lesions can be endoscopically treated and stricture dilatation can be done. Barium examination and serology for *H. pylori* can be done wherever access to endoscopy is not available. Endoscopy is superior to barium studies in detecting mucosal lesions. Also, biopsy from gastric ulcer (to rule out malignancy), antral biopsy (for a rapid urease test for *H. pylori*), and therapy of bleeding lesions can be performed during endoscopy. Duodenal ulcers rarely need biopsy as they are nonmalignant.

Stool test for ova, parasites, and occult blood is to be done. Contrast-enhanced computed tomography (CECT) of abdomen and manometry (esophageal and antroduodenal) are required in specific circumstances.

Differential Diagnosis

Conditions such as gastritis, pancreatitis, GERD, cholecystitis, stomach cancer, biliary colic, myocardial infarction (inferior), and referred pain should be differentiated from peptic ulcer disease.

TREATMENT

The clinical decision to initial treatment depends on age and presence of risk factors. Young patients without any alarm features can be directly given empirical therapy with acid antisecretory medication: Histamine 2-receptor antagonists (H2RAs) and proton-pump inhibitors (PPIs). PPIs are the mainstay of treatment for ulcers. They act on H^+K^+ATPase on parietal cells and thus reduce acid secretion. It takes 5 days to get maximal effect while H2RA has more rapid onset of action. Both are efficient in relieving symptoms in 33–50% of patients with dyspepsia, particularly in those with predominant reflux-like symptoms. The usual doses are ranitidine 150 mg BD, omeprazole 10–20 mg/day, rabeprazole 20–40 mg/day, and lansoprazole 15–30 mg/day. Lafutidine is a second-generation H2RA with additional gastroprotective ability independent of antisecretory action. It activates capsaicin-sensitive afferent neurons and stimulates calcitonin gene-related peptide (CGRP) which inhibits acid secretion and stimulates mucosal blood flow. The therapeutic benefits of H2RA and PPI in familial dysautonomia (FD) seem independent of antisecretory action.

Dietary modification and lifestyle changes should be advised in every patient. These include eating small meals and avoiding high-fat diet. The patient should be told to avoid tea, coffee, NSAID, alcohol, and tobacco use.

Helicobacter pylori eradication can improve dyspepsia in few patients. Test and treat infection can be a strategy in those not responding to PPI. Those responding will have long-term sustained remission. Usually, a triple-drug regimen with one PPI and two antimicrobials—amoxicillin (1 g BD) and clarithromycin (500 mg BD) or metronidazole (500 mg BD)—for 14 days is given. Quadruple therapy with PPI, tetracycline, metronidazole, and bismuth is now recommended due to widespread antibiotic resistance.

Prokinetic agents stimulate GI motility and hence may be helpful in functional dyspepsia. Metoclopramide, levosulpiride, and domperidone are dopamine receptor antagonists. Domperidone does not cross the blood–brain barrier and is devoid of serious side effects. Levosulpiride additionally acts as a 5-HT_4 receptor agonist and is superior to the other two in improving gastric emptying and alleviating dyspepsia. However, these drugs have a lot of adverse effects including extrapyramidal symptoms and galactorrhea. Mosapride is a 5-HT_4 agonist and 5-HT_3 receptor antagonist and itopride is a dopamine D_2 antagonist and acetylcholinesterase inhibitor. Acotiamide is a new prokinetic and fundus-relaxing drug with muscarinic antagonist and cholinesterase inhibitor action and improves gastric emptying. In doses of 100 mg thrice daily, it improves postprandial fullness, bloating, and early satiety. It

is now approved for managing functional dyspepsia. It is not effective in EPS. Drugs such as erythromycin which have a pure prokinetic effect without an antiemetic effect are not found useful.

Antidepressants, especially tricyclic antidepressants, have some beneficial effects in functional dyspepsia (EPS) even in the absence of depression and can be added to PPI in nonresponders. Anxiolytic agent buspirone, a 5-HT_{1A} agonist, was superior to placebo in improving dyspeptic symptoms. It enhances gastric accommodation by fundic relaxation.

Psychological interventions such as cognitive therapy, hypnotherapy, and relaxation techniques may be useful in refractory patients. Meditation and yoga can also help. Referral to a psychiatrist can be considered in those with associated severe psychiatric symptoms.

Rikkunshito, a Japanese herbal medicine, has shown better response than placebo for treatment of FD. Another herbal preparation Iberogast (STW5), extract from the *Iberis amara* plant, has fundus-relaxing properties and has shown efficacy in FD in double-blind placebo-controlled studies.

Surgical treatment is indicated if the patient is unresponsive to medical treatment, noncompliant, or at a high risk of complications. Surgical options include vagotomy or partial gastrectomy.

Management of Complications of Peptic Ulcers

Bleeding, gastric outlet obstruction, perforation penetration, and stomach cancer are the complications of peptic ulcer disease.

Bleeding ulcer—patient usually presents with melena and coffee ground vomitus. Rarely, a patient may present with sudden onset hypotension or vasovagal reaction without overt signs of bleed. Patients with hemodynamic instability should be admitted to the intensive care unit (ICU). After securing airway and venous access, a large-bore nasogastric tube should be placed for gastric lavage. PPI bolus 80 mg followed by infusion at the rate of 8 mg/h should be started. Blood samples should be sent for hemogram, prothrombin time (PT), activated partial thromboplastin time (APTT), and blood grouping and matching. Volume should be replaced by crystalloids while awaiting packed cells. Endoscopy can be done after hemodynamic stabilization. Adrenaline injection at the base of actively bleeding ulcers and visible vessels followed by either coagulation with thermal probe or hemoclip application stops bleeding in majority. Surgical intervention is needed if there are two failed endoscopic attempts. Angiography with embolization is useful in refractory bleed. Peptic stricture may be managed either surgically or by endoscopic dilatation. Perforation requires laparotomy.

PROGNOSIS

Once the underlying cause is successfully treated, the prognosis of PUD is excellent. Recurrence of the ulcer may be prevented by maintaining good hygiene and avoiding alcohol, smoking, and NSAIDs.

SUMMARY

Dyspepsia is a very common condition defined as epigastric pain or discomfort. Rarely, it may be a manifestation of a serious condition like malignancy. Identification of red flag signs can help in planning further management. Those with no red flags can be treated with empirical PPI initially and investigate further if no response. Management of refractory dyspepsia requires a multidisciplinary approach.

Acute Pancreatitis and Cholecystitis

97
CHAPTER

Sanjay Kumar

ACUTE PANCREATITIS

Introduction

Acute pancreatitis is one of the most common diagnoses in patients presenting with abdominal pain in gastrointestinal (GI) clinics. In fact, it is now the most common GI diagnosis requiring hospitalization. The annual incidence ranges from 13 to 45/100,000 population and has increased by 30–62% in the last two decades. It has significant burden on healthcare costs and resource utilization.

Definition

In clinical practice, acute pancreatitis is defined as abdominal pain, centered in the epigastrium, which often radiates to the back along with raised serum amylase and lipase to >3 times the upper limit and evidence of pancreatic inflammation on imaging. Any two of the above three is sufficient to make a diagnosis. The level of amylase and lipase is diagnostic but does not correlate with severity. In the emergency room or outpatient department, it is very important to make an early diagnosis as damage is done very rapidly and early interventions (hydration) can change the outcome.

Etiology

Gallstone disease and alcohol are the most common causes of acute pancreatitis across the world (**Table 1**). Differential diagnosis includes perforation, myocardial infarction, acute cholecystitis, choledocholithiasis, intestinal obstruction, bowel ischemia, etc.

Pathophysiology

The pathophysiology of pancreatitis is not well known under normal physiology of trypsinogen produced in the pancreas and secreted in the duodenum while in acute pancreatitis trypsin is activated within the acinar cell and maybe because of obstruction, activated trypsin is not eliminated from the pancreas thus resulting in a high level of activated trypsin. This activated trypsin initiates injury, inflammation, and autodigestion of the pancreas by activating digestive enzyme compliments and kinins. Majority of the cases are limited to the local inflammation of the pancreas while the minority of cases progress to necrotizing pancreatitis and further involve the surrounding tissues and distant organ leading to multiorgan failure and death.

Clinical Features

Diagnosis should be considered in any patient who comes with severe abdominal pain in the upper abdomen/back/chest; is apparently in distress; has vomiting, tachycardia, and epigastric tenderness; and his/her pain is not easily controlled with analgesics. He/she may be an alcoholic or there may be a past history of pancreatitis/biliary colic.

Diagnosis

Investigations in the emergency department that would help to differentiate all these are electrocardiogram (ECG), complete blood count (CBC), liver function test (LFT), amylase, creatinine, abdominal X-ray (both erect and supine), and ultrasonography (USG). No laboratory test is the gold standard for acute pancreatitis. Amylase or lipase values should be at least three times the upper limit of the normal values according to the current recommendations. *Amylase* should not be considered as a good choice for diagnosis because it can be raised in nonpancreatic diseases such as renal failure, acute appendicitis, cholecystitis, intestinal obstruction, and ischemia of salivary glands (amylase starts rising few hours after the symptoms, peaks in 48 hours, and takes 3–5 hours to normalize). *Lipase* is more specific for pancreatic injury, remains elevated for a longer period of time, and is less associated with nonpancreatic disease. *Urine trypsinogen-2 dipstick test* is a noninvasive rapid test with high sensitivity and specificity, but it is less in use because of limited availability.

TABLE 1: Causes of acute pancreatitis.	
Common causes	• Gallstones • Alcohol • Hypertriglyceridemia • Endoscopic retrograde cholangiopancreatography (ERCP) • Drugs [azathioprine, 6-mercaptopurine, sulfonamides, estrogen, tetracycline, valproic acid, anti-HIV medications, 5-aminosalicylic acid (5-ASA)] • Trauma (especially blunt abdominal trauma) • Postoperative (abdominal and nonabdominal operations)
Uncommon causes	• Vascular causes and vasculitis (ischemic-hypoperfusion states after cardiac surgery) • Connective tissue disorders and thrombotic thrombocytopenic purpura (TTP) • Cancer of the pancreas • Hypercalcemia (hyperparathyroidism) • Periampullary diverticulum • Pancreas divisum • Hereditary pancreatitis • Viral and parasitic (mumps, coxsackievirus, cytomegalovirus, echovirus, *Ascaris*) • Autoimmune
Recurrent of acute pancreatitis without an obvious cause	• Microlithiasis, biliary sludge • Drugs • Alcohol abuse (hidden) • Hypertriglyceridemia, hypercalcemia • Pancreas divisum with minor papilla stenosis • Pancreatic cancer • Intraductal papillary mucinous neoplasm (IPMN) • Cystic fibrosis • Idiopathic

Note: About 20% still remain idiopathic after all investigations.

In case of a diagnostic dilemma, it is best to do contrast-enhanced computed tomography (CECT) of the abdomen within a few hours in the emergency department itself. But if the diagnosis of acute pancreatitis is clear based on blood tests and imaging, then it is wise to delay the CT scan for 3–4 days as necrosis is not picked up early and you will have to repeat a CT scan anyway on day 4 or day 5. Once a diagnosis of acute pancreatitis is established, one should quickly work on two lines first: First, to assess severity so that you can triage the patient and decide whether to send him to the intensive care unit (ICU) or ward. Second, one should try to establish the cause as quickly as possible because some of the etiologies such as stone in the common bile duct (CBD) and hypertriglyceridemia would need early intervention. The most important aspect of managing an acute pancreatitis patient is assessment of severity. It is always a challenge to talk to the relatives about the severity of an attack and the likely outcome, i.e., the prognosis. Various scales are available to assess the severity such as Ranson's, Imrie's, and acute physiology and chronic health evaluation II (APACHE II), but easiest at the bedside is to use BISAP (bedside index of severity of acute pancreatitis) scoring (**Table 2**). The entire exercise of assessment is to know which patients have organ failure because the outcome depends on the number of organs involved (**Table 3**).

TABLE 2: BISAP score.		
BUN	BUN > 25 mg/dL (8.9 mmol/L)	1 point
Impaired mental status	Abnormal mental status with a Glasgow Coma Score <15	1 point
SIRS	Evidence of SIRS (systemic inflammatory response syndrome)	1 point
Age	Age > 60 years old	1 point
Pleural effusion	Imaging study reveals pleural effusion	1 point
Score: 0–2 points: Lower mortality (<2%), 3–5 points: Higher mortality (>15%)		

(BISAP: bedside index of severity of acute pancreatitis; BUN: blood urea nitrogen; SIRS: systemic inflammatory response syndrome)

Management of Acute Pancreatitis

There are certain general measures, the most important of which is aggressive hydration (**Table 4**). Intravenous fluids of lactated Ringer's or normal saline are initially given as bolus 15–20 mL/kg (1,000–1,500 mL), followed by 3 mL/kg/h (200–250 mL/h), to maintain urine output >0.5 mL/kg/h. Serial bedside evaluations are required every 6–8

TABLE 3: Markers of severe acute pancreatitis.	
Risk factors for severity	• Age > 60 years • Obesity, BMI > 30 kg/m^2 • Comorbid disease (Charlson Comorbidity Index)
Markers of severity at admission or within 24 hours	• SIRS—defined by presence of two or more criteria: • Core temperature <36°C or >38°C • Heart rate > 90 bpm • Respirations > 20/min or pCO_2 < 32 mm Hg • White blood cell count > 12,000/μL, <4,000/μL or 10% bands • APACHE II • Hemoconcentration (hematocrit > 44%), admission BUN (>22 mg/dL) • BISAP score ≥3
Markers of severity during hospitalization	• Persistent organ failure • Pancreatic necrosis

(APACHE II: acute physiology and chronic health evaluation II; BISAP: bedside index of severity of acute pancreatitis; BMI: body mass index; BUN: blood urea nitrogen; pCO_2: partial pressure of carbon dioxide; SIRS: systemic inflammatory response syndrome)

TABLE 4: Treatment of acute pancreatitis.	
Airway breathing circulation	Supplemental oxygen, vital signs, and pulse oximetry monitoring (every 2 hourly)
Pain control	Parenteral analgesics and narcotics
Crystalloid therapy	• Ringer's lactate: 250–500 mL/h, 5–10 mL/kg/h (2.5–4 L) • Monitor hematocrit, creatinine, heart rate, MAP of 65–85 mm Hg, and urine output of 0.5–1 mL/kg/h
Electrolyte therapy	Correction of low ionized calcium, low magnesium, and control hyperglycemia
Antiemetics and antibiotics	• Control of nausea and vomiting, NPO status with early resumption of oral feeding, placing of nasogastric tube and suctioning not indicated • Antibiotics not indicated prophylactically or in mild pancreatitis Antibiotics only indicated in strongly suspected infection
Gastroenterologist consultation	In diagnosed biliary obstruction and cholangitis, ERCP is indicated in the first 24 hours

(ERCP: endoscopic retrograde cholangiopancreatography; MAP: mean arterial pressure; NPO: nil per oral)

hours to assess vital signs, oxygen saturation, and changes on physical examination. Lactated Ringer's solution has been shown to decrease systemic inflammation and may be a better crystalloid than normal saline. A target resuscitation strategy with measurement of hematocrit and BUN every 8–12 hours is recommended to ensure the adequacy of fluid resuscitation and monitor response to therapy; less-aggressive resuscitation strategy may be needed in milder forms of pancreatitis. A rising BUN during hospitalization is not only associated with inadequate hydration but is also higher in hospital mortality. A decrease in hematocrit and BUN during the first 12–24 hours is strong evidence that sufficient fluids are being administered. Serial measurement and bedside assessment for fluid overload are continued, and fluid rates are maintained accordingly. Adjustments in fluid resuscitation may be required in patients with cardiac, pulmonary, or renal disease. A central venous catheter with central venous pressure (CVP) monitoring is handy, but assessment of inferior vena cava (IVC) by bedside USG is equally informative and maybe better in expert hands.

Other measures are to keep the patient NPO, give him/her proper analgesics for relief of pain, and close monitoring for oxygen saturation, urine output, blood pressure (BP), and tachycardia. All patients with severe pancreatitis should be managed in the ICU. Pleural effusions and intra-abdominal fluid collections may need USG-guided pigtail drainage. If there is severe respiratory compromise, he/she may require noninvasive ventilation (NIV) or mechanical ventilation. Early enteral feeding is encouraged; hence, if the patient is not able to take orally or is vomiting, then nasojejunal intubation and feeding should be done. If the patient remains oliguric after restoration of intravascular volume, diuretics may be tried but if there is no response, hemodialysis may be required. There are few situations where urgent interventions are required in 48–72 hours such as endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy in case of gallstone pancreatitis with cholangitis (deranged LFT with dilated CBD on USG) or severe hypertriglyceridemia leading to acute pancreatitis wherein you have to start urgent lipid-lowering drugs. All other cases are managed conservatively.

The 1st week is the time for organ failure and the third week is for local complications such as infection/fluid collections and pseudocyst/walled-off necrosis (WON) (**Table 5**). One has to understand that this is a one-time insult and whatever is occurring in the next 4–6 weeks is actually the sequel of that particular attack. It is generally not recommended to start all patients on antibiotics; they are preferably reserved for a documented infection usually in the second or third week, severe necrotizing pancreatitis being an exception. Antibiotics with gram-negative coverage are ideal and imipenem is shown to be having the best penetration. Various anti-inflammatory agents have been tried in several trials, but none has shown good results.

Local complications such as fluid collections, pseudocysts, WON, or IPN should be managed at a dedicated center with a multidisciplinary approach (a team of gastroenterologist, surgeon, and radiologist). All symptomatic collections require drainage and the best way to drain would depend on location, contents, presence of infection, and presence of vessels in wall or vicinity. A good assessment by endosonography and magnetic resonance imaging (MRI) is a must to plan out treatment. In general, collections in head and body with well-defined walls are best drained by endoscopy provided there are no major vessels in the way and those in tail are better drained radiologically. But in any case, sound surgical backup is must. Those with multiple collections are preferably taken up for surgery. Finally, those with biliary pancreatitis will need

TABLE 5: Pancreatic and extrapancreatic complications of acute pancreatitis.

Pancreatic	*Nonpancreatic*
• Necrosis • Sterile • Infected • WON • Pancreatic fluid collections • Pancreatic pseudocyst • Disruption of main pancreatic duct or secondary branches • Pancreatic ascites • Involvement of contiguous organs by necrotizing pancreatitis • Thrombosis of blood vessels (splenic vein, portal vein) • Pancreatic enteric fistula • Bowel infarction • Obstructive jaundice	• Cardiovascular—hypotension, hypovolemia, myocardial dysfunction, myocardial infarction, pericardial effusion • Pulmonary—hypoxia atelectasis, pleural effusion, pulmonary infiltrates, acute respiratory failure • Gastrointestinal—erosive gastritis, GI perforation, GI bleed, bowel obstruction, splenic infarction • Renal—oliguria, azotemia, acute kidney injury, renal vessels, thrombosis • Metabolic—hyperglycemia, hypoglycemia, hypertriglyceridemia

(GI: gastrointestinal; WON: walled-off necrosis)

laparoscopic cholecystectomy as soon as feasible, i.e., when inflammation has subsided.

The overall prognosis depends on the severity of pancreatitis. Those with mild pancreatitis recover in about 1 week, those with moderately severe pancreatitis take several weeks, and those with severe pancreatitis take several months to recover completely. Severe pancreatitis has a mortality of about 30%, the cause being organ failure in the first 2 weeks and infection or bleeding after 2 weeks.

ACUTE CHOLECYSTITIS

Acute cholecystitis means inflammation of gallbladder (GB) which most commonly occurs due to gall stones. It occurs when a stone gets lodged in the neck of GB or cystic duct leading to mechanical distension, ischemia of wall, and bacterial infection. Usual organisms are gram-negative bacteria such as *Escherichia coli* or *Klebsiella*. In emphysematous cholecystitis, it is usually *Clostridium perfringens*. Less often, it could be acalculous cholecystitis, which is seen in patients undergoing nonbiliary major surgeries, severe trauma, burns, sepsis, etc. (**Table 6**). But even in acalculous cholecystitis, >50% of cases are due to small stone/sludge blocking the cystic duct not picked up on imaging.

Diagnosis of Acute Cholecystitis

Presentation of acute cholecystitis is like an extended biliary colic where pain starts in epigastrium, is usually severe, may radiate to right shoulder or back, and may be associated with vomiting often associated with low-grade fever and ileus. The patient may give a history of similar pain in the past which used to subside in 30–40 minutes and his interpretation is usually a "gas block" in the past. On examination, about 50% of patients will have right upper quadrant (RUQ) tenderness and a sudden holding of breath during deep inspiration (Murphy's sign). USG is usually diagnostic showing stone, thickening of GB wall, and pericholecystic collection of fluid (**Table 7**). But a CT scan may be done to rule out complications such as perforation/empyema/emphysematous cholecystitis (**Box 1**). Magnetic resonance cholangiopancreatography (MRCP) or endosonography should be done if there is a suspicion of CBD stone based on LFT.

TABLE 6: Acute acalculous cholecystitis (AAC).

Critically ill patients	• Major surgery • Severe trauma • Sepsis • Total parenteral nutrition • Diabetes • Atherosclerotic disease • HIV infection
Nonhospitalized patients	Elderly male with atherosclerosis

Note: HIDA scan and sampling of luminal contents may help to establish the diagnosis.

(HIDA: hepatobiliary iminodiacetic acid; HIV: human immunodeficiency virus)

TABLE 7: Criteria for diagnosis of acute cholecystitis.

Local examination	*Right upper quadrant mass pain or tenderness, Murphy's signs*
Systemic features	Fever, raised C-reactive protein, elevated WBC count
Imaging	• USG—sonographic Murphy's sign, GB thickening, distension, pericholecystic fluid • CT scan—GB wall thickening, distension, hyperdense, GB wall pericholecystic fluid, and fat stranding
Diagnosis	• One local + one systemic = Suspected • One local + one systemic + imaging finding = Definitive diagnosis

(GB: gallbladder; WBC: white blood cell)

Treatment

Treatment of acute cholecystitis is urgent laparoscopic cholecystectomy unless the patient is unfit for surgery in which case you can plan for an early cholecystectomy within 4–6 weeks. In sick patients, USG-guided PTGBD (percutaneous transhepatic gallbladder drainage) is a good procedure to tide over the crisis. Laparoscopic cholecystectomy in the presence of acute cholecystitis carries a complication rate of 1–3% (c/f interval cholecystectomy: 0.5–1%), but one must understand that perforation/empyema GB with sepsis has a mortality of 15–30%. So, in an acute case, if you decide to go for conservative treatment, the patient can progress to one of these complications. Hence, urgent laparoscopic cholecystectomy is preferred. Complications after laparoscopic cholecystectomy are CBD injury, bile leak, local hematoma, atherosclerosis, biliary stricture, etc., all of which require treatment in

BOX 1: Complications of acute cholecystitis.

- Suppurative cholecystitis (empyema)
- Gangrenous cholecystitis
- Emphysematous cholecystitis
- Hemorrhagic cholecystitis
- Gallbladder perforation
- Fistula formation, cholecystoduodenal, cholecysto-intestinal, cholecystobiliary
- Mirizzi syndrome

Mirizzi syndrome: Gallstone impacts the gallbladder wall and compresses it causing pressure necrosis which further gets adhered to the common bile duct wall leading to jaundice.

Type 1: Compression of CBD without lumen narrowing

Type 2: Compression causing CBD lumen narrowing

Type 3: Compression causing CBD wall necrosis

Type 4: Cholecystocholedochal fistula

(CBD: common bile duct)

specialized centers. There are no long-term complications of removing GB except mild diarrhea in about 10% of patients due to bile acid malabsorption.

SUMMARY

Acute pancreatitis and cholecystitis remain a common reason for hospitalization. The most common etiologies include gallstones, followed by alcohol. It has a significant impact on healthcare resource utilization, morbidity, and mortality. The disease can vary from mild to severe with systemic complications. The cornerstones to management include aggressive early fluid resuscitation, appropriate nutritional supplementation, and management of complications. Patients with mild acute gallstone-related pancreatitis should undergo cholecystectomy prior to discharge to prevent recurrent episodes. Severe acute pancreatitis and pancreatitis with local and systemic complications should be managed in a multidisciplinary approach with the involvement of intensivists, gastroenterologists, hepatobiliary surgeons, and interventional radiologists.

98
CHAPTER

Acute Hepatitis

Amit Mittal, Akanksha Rastogi

INTRODUCTION

In simple terms, acute hepatitis means an acute inflammation of the liver. Various causes can lead to acute hepatitis, e.g., infectious (viral, bacterial, fungal, and parasites) and noninfectious (alcohol, drugs, metabolic diseases, etc.). Acute viral hepatitis is actually a systemic infection which predominantly involves the liver. The terms fulminant hepatic failure (FHF) and acute liver failure (ALF) are used interchangeably and mean jaundice followed by encephalopathy and coagulopathy (hyperacute: <7 days, acute: 8–28 days, or subacute: 29 days to 26 weeks) in the absence of a preexisting liver disease; however, the majority of cases are of much shorter duration.

ETIOLOGY

Viral infections are most common in acute hepatitis. *Common* viruses include hepatitis A, B, E, C, and D (superinfection/coinfection with B) and *uncommon* viruses include cytomegalovirus (CMV), Epstein–Barr virus (EBV), herpes simplex virus (HSV), dengue fever, and transfusion transmitted virus (TTV).

Toxins and drugs: Drug-induced liver injuries (DILI) include paracetamol, carbon tetrachloride, isoniazid, phenytoin, amoxicillin-clavulanate, mushroom (amanita phalloides), ackee fruit, cycasin, aflatoxin (*Aspergillus flavus*), and sea anemone sting (**Table 1**).

Acute liver failure: Causes of ALF include the above-mentioned viruses and toxins, ischemic hepatopathy (cardiogenic shock, hypotension, heatstroke, and cocaine), vascular (Budd–Chiari syndrome, sinusoidal obstruction syndrome), Wilson's disease, hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome, acute fatty liver of pregnancy, primary graft nonfunction after liver transplantation, and malignant infiltration (breast cancer, small cell lung cancer). HSV hepatitis causes ALF in case of neonates, human immunodeficiency virus (HIV) coinfection, and pregnancy.

In India, 95% causes of ALF are due to viruses (hepatitis E: ~40%, hepatitis B: ~10–15%, hepatitis A: ~1%) and DILI: ~5%; however in America, viruses cause ~10% of ALF.

TABLE 1: Liver toxins and types of injury.

Toxin	*Liver injury*	*Disease*	*Component*
Mushroom	ALF	Liver necrosis	Alpha-amatoxin and phalloidin
Ackee fruit	Steatosis	Jamaican vomiting sickness	Hypoglycin
Cycasin	Acute hepatitis	Liver necrosis	Methylazoxy-methanol
Aspergillus flavus	Acute hepatitis	Liver necrosis and carcinogenic	Aflatoxin B_1
Aspergillus tamari	Acute hepatitis	Liver necrosis	Cyclopiazonic acid

(ALF: acute liver failure)

TABLE 2: Classification of acute liver failure.

Category	*Causes*	*Prognosis*
Hyperacute	Hepatitis A, paracetamol	Fair
Acute	Hepatitis B, drugs	Poor
Subacute	Drugs, indeterminate	Very poor

Acetaminophen (paracetamol) overdose is a suicidal agent and a common cause of ALF (UK: ~57%, USA: ~45%, and France: 22%). It appears that hepatitis C can cause ALF in the presence of hepatitis B coinfection.

PATHOPHYSIOLOGY

Hepatitis A and E infections are mainly noted in areas with poor sanitation and they occur by consuming contaminated water or food and contact with an already infected person. Hepatitis B and C infections spread by exposure to body fluids and blood.

In the chain of events in ALF (**Table 2**), there is significant death of hepatocytes (death exceeds regeneration) due to direct and immune-mediated injury which leads to cytokine storm, release of proinflammatory cytokines [tumor necrosis

factor (TNF)-alpha, interleukin (IL)-beta, IL-6], and systemic inflammatory response syndrome (SIRS). Arterial ammonia levels start rising and lead to raised intracranial pressure (ICP) and cerebral edema in 30% of cases. Gradually, multiple organ damage syndrome (MODS) sets in which include infection; metabolic derangements such as hypoglycemia, hypokalemia, and acid–base changes; hypotension; respiratory depression; gastrointestinal bleeding; renal failure; and ultimately death. Cerebral edema is a very common presentation in the hyperacute category and less common in the acute category. Renal failure and peripheral edema are more common, and cerebral edema is rare in the subacute category.

CLINICAL PRESENTATION

Acute viral hepatitis has an incubation period (2–4 weeks in A, 2–6 weeks in E, and 1–6 months in B and C). Typical features of acute viral infections include variable prodromal symptoms in the form of loss of appetite, nausea, vomiting, tiredness, malaise, photophobia, and coryza followed by jaundice after 1–2 weeks. The acute hepatitis C infection can be symptomatic or subclinical. Serum sickness-like features (fever, rash, joint pain, and angioneurotic edema) may be seen in only 10% of patients with acute hepatitis B. Liver toxins cause abdominal pain, vomiting, diarrhea on day 1–2, and jaundice and renal failure over the next 24–48 hours of consumption. In paracetamol overdose, there is no symptom initially; later, weakness, nausea, and vomiting develop. Initially, ALF can have vague symptoms and signs, i.e., lethargy, nausea, and pain in the abdomen, which eventually becomes more specific, i.e., jaundice, altered sensorium, slurred speech, confusion, seizure, and later coma.

Hepatitis A can have many patterns, i.e., asymptomatic, jaundice <2 months, cholestasis >2.5 months, relapsing pattern (≥2 episodes over 10 weeks), and ALF.

Hepatitis B infection can be occult [detectable hepatitis B virus (HBV) deoxyribonucleic acid (DNA), negative hepatitis B surface antigen (HBsAg)] in few individuals.

Watch for life-threatening causes of jaundice such as acetaminophen overdose and massive hemolysis, e.g., falciparum malaria and FHF (altered behavior or coagulopathy).

Early identification of complications of acute hepatitis B and C should be done [chronic hepatitis, cirrhosis of liver, ascites, portal hypertension, hepatocellular cancer (HCC), and hepatorenal syndrome]. Cushing's triad is a clinical feature of raised ICP suggestive of encephalopathy (respiratory depression, bradycardia, and hypertension).

EVALUATION

History

Age and sex: Type A viral hepatitis in young, type E in pregnant, drugs and alcohol in adults.

Onset: Rapid in hemolysis), *precipitants* (dehydration, fasting), duration of jaundice, *awareness* (who noticed? relative/patient himself/herself), *depth* (maximum recorded level of bilirubin), *progression*, and *fluctuation.*

Acute hepatitis: History of prodromal symptoms (nausea, vomiting, anorexia, myalgia, skin rash, and fever in viral infections), drugs (antibiotics/azathioprine/antitubercular/herbal), toxins (consumption of mushrooms, foodstuffs including grains and nuts contaminated by fungal mycotoxins), injections, blood transfusion, alcohol, and contact with other jaundiced patients.

If acute hepatitis turns into a cholestatic phase: Accumulation of biliary constituents, e.g., itching (site, severity, nocturnal symptoms, and progression), mustard oil-like urine, clay-colored stools, skin darkening, deficiency of bile acids in intestine presenting as fat-soluble vitamin deficiency (night blindness, dry skin, leg cramps, and bleeding).

Past history: Recurrent jaundice (relapsing viral hepatitis A).

*Occupation, place of origin, family history (*hemolysis, congenital hyperbilirubinemias).

Alcohol and smoking can cause HCC. How are the symptoms now? Progression or improvement.

Physical Examination

Look for nutrition, anemia, depth of jaundice, purpura (skin bleed), scratch marks, body hair, liver and spleen size, ascites, flapping tremors, pedal edema, and altered mental behavior. Vesicular skin lesions suggest HSV hepatitis.

General examination: Anemia, bruising, purpura, lymphadenopathy, clubbing, mental state (fetor hepaticus, flapping tremors, intellectual deterioration in hepatocellular jaundice, and hepatic coma).

Abdominal examination: Small liver (hepatitis, cirrhosis), large nodular liver (cancer), tender liver (congestive heart failure, alcoholism), splenomegaly (portal hypertension), ascites (cirrhosis, malignancy).

INVESTIGATIONS

Complete blood count provides complementary information concerning the cause of jaundice. In case of anemia, look for hemolysis or poor oral intake; leukopenia may establish viral etiology; leukocytosis may be a clue to sepsis; and thrombocytopenia (<1.5 lakh/mm^3) may be a clue to cirrhosis or ALF.

Serum biochemical tests: The presence of bilirubin can confirm jaundice and help to know its depth, transaminases [alanine transaminase (ALT) > aspartate aminotransferase (AST) in hepatitis, i.e., >1,000 U/L or >20–25 × normal and AST >2 × ALT, nearly always <300 U/L in alcoholism, but AST > ALT, i.e., >1,000 U/L or >20–25 × normal in cases of drugs or toxins in a patient with an underlying alcoholic liver injury or cirrhosis], and alkaline phosphatase (ALP; elevated in cholestasis). Prothrombin time (PT) is elevated in obstructed biliary tree or ALF [PT/international normalized ratio (INR) > 1.5].

Serologic testing: Viral serologies for hepatitis A, B, C, and E, i.e., anti-hepatitis A virus (HAV) immunoglobulin M (IgM), HBsAg, anti-HBc (anti-hepatitis B core), HBV DNA, anti-HCV (hepatitis C virus), HCV-RNA (ribonucleic acid), anti-HEV (hepatitis E virus) IgM if there is a suspicion of viral hepatitis; HSV DNA, EBV-DNA, and CMV-DNA in nonhepatotropic viruses.

Autoimmune markers: In case of autoimmune hepatitis ANA, ASMA, anti-LKM antibody test should be done. If AST and gamma globulin are elevated the AST:ALP ratio should be >3.

Other laboratory tests: Serum acetaminophen level and urine toxicology screening in suspected overdose cases in ALF.

Serum ceruloplasmin: 24-hour urine copper, genetic testing, and slit-lamp eye examination to look for fulminant Wilson's disease if ALP: Total bilirubin < 4 and AST: ALT > 2.2.

Radiology: Chest film to look for tumor and elevation of diaphragm due to enlarged liver.

Ultrasound: Inexpensive, noninvasive, and portable which allows distinction between intrahepatic and extrahepatic biliary obstruction. Look for vascular disorder, cholelithiasis, intrahepatic space-occupying lesion (SOL), and ascites.

Abdominal computed tomography (CT) scan can detect small SOL, is expensive, and needs normal renal function for contrast.

Liver biopsy: In suspected cases of drug or infiltrative/autoimmune liver disease (after correction of prothrombin time with vitamin K).

Assess severity of liver injury every 8–12 hours early on and daily thereafter in ALF: Complete blood count (CBC), kidney function test (KFT), random blood sugar (RBS), liver function test (LFT), PT/INR, factor V, fibrinogen, arterial blood gas (ABG), ammonia, lactate, blood and urine cultures, peritoneal fluid if ascites, neurological status by bedside neurology examination, Glasgow Coma Score, CT scan of head [if > hepatic encephalopathy (HE) Grade 2, i.e., marked confusion, incoherent speech, sleeping most of the time], ICP monitor if Grade 4 HE, i.e., comatose, unresponsive to pain, decorticate or decerebrate posturing.

TREATMENT

The optimal treatment of jaundice is supportive and treatment of the etiology. Immediate hospitalization is needed if altered mental behavior and coagulopathy, i.e., PT/INR ≥1.5, are present. Prevent and treat the complications of ALF. Paracetamol and mushroom poisoning is treated by N-acetyl cysteine (up to 3 days) 140 mg/kg over 1 hour intravenously followed by 70 mg/kg every 4 hours for at least 12 doses. Supportive treatment is given in acute viral hepatitis. Oral nucleoside analog, i.e., entecavir or tenofovir, is recommended if high jaundice (bilirubin > 20) or high PT/INR or encephalopathy is present. Start steroids in case of autoimmune hepatitis. Keep the patient in the intensive care unit if more careful monitoring is required. Plan to transfer to a liver transplant unit if bilirubin > 17.5, PT/INR > 2, and Grade 2 or more HE develops.

SUMMARY

Multiple clues to the etiology of jaundice can be obtained from the history and examination.

Identify life-threatening causes of jaundice. ALF is a rare but potentially fatal disease. Survival in ALF depends on the cause, urgent management of ALF, and its complications. The treatment approach depends upon the patient, the facilities, and the expertise available. The mortality rate of hepatitis E-related ALF is 15–25% in pregnancy. Also, watch for HELLP and alpha-fetoprotein (AFP) in pregnancy.

Liver transplantation is a rescue therapy in ALF for those who are not recovering or have an advanced disease while milder cases can recover with conservative management. Vaccines can prevent hepatitis A and B. (Vaccine for hepatitis E is not available in India at the time of this publication.) Investigational approaches include extracorporeal treatment, bioartificial support system, and stem cell therapy for ALF.

Many myths exist in India, which practically have no benefit, i.e., role of sugarcane juice, avoidance of yellow-colored food, black magic, and *tantra vidya*.

Chronic Liver Disease and Complications

99
CHAPTER

Ravindra Kale

INTRODUCTION

Most patients remain asymptomatic for years when they are affected by hepatitis B or hepatitis C virus infections, or by nonalcoholic fatty liver disease (NAFLD), or by alcoholic hepatitis. During this asymptomatic period, the disease manifests as mild elevation of transaminase levels, NAFLD is identified as fatty liver, there is incidental finding on abdominal ultrasound studies, and pathologically normal liver parenchyma is replaced by scar and fibrotic tissue. When a significant amount of normal liver parenchyma is replaced by scar and fibrotic tissue, cirrhosis develops. Cirrhosis manifests as generalized weakness, abdominal pain, ascites, spontaneous bacterial peritonitis (SBP), electrolyte imbalance, and altered mental status due to the development of hepatic encephalopathy (HE). Cirrhosis is a progressive disease and is initially asymptomatic (compensated cirrhosis). With gradually declining liver functions, decompensation occurs, leading to different complications. Knowledge of these complications may help in prevention and successful treatment and thus improve the quality of life of these patients.

MALNUTRITION

Malnutrition is a common complication. Chronic liver disease leads to sarcopenia and nutrient deficiency due to various factors. Chronic alcohol use leads to reduced caloric and nutrient intake. Anorexia is a frequent symptom of cirrhosis leading to reduced caloric intake. Moreover, there is dietary restriction due to altered taste sensation, tense ascites, and frequent drug-induced nausea. Patients with recurrent encephalopathy suffer from severe caloric and protein undernutrition. During evaluation, each patient should be enquired about dietary caloric and protein intake. On physical examination, one should look for glossitis, pedal edema, peripheral sensation, and muscle wasting. Patients should have dietary counseling. Each patient should be assessed for and receive thiamine, zinc, and B12 supplementation. Preferably vegetarian diet with frequent meals should be given. Salt restriction is needed in case of ascites and edema. Protein restriction is not needed even in the presence of encephalopathy (1–1.5 g protein/kg body weight should be given). Replacement of protein, usually in the form of branched-chain amino acids, is advisable but some patients could not tolerate it due to its taste.

INFECTIONS

Cirrhotic patients are more prone to infections. Common infections are SBP, urinary tract infections, pneumonia, cellulitis, and *Clostridium difficile* colitis. Use of proton-pump inhibitors, frequent use of urinary catheters, and antibiotics during admission make the patient prone to these infections. SBP is diagnosed by the presence of >250 polymorphonuclear leukocytes (PMNs) in ascitic fluid and is monobacterial (**Table 1**). It is usually caused by gram-negative organisms (*Escherichia coli*). Presence of polymicrobial infection or a very high neutrophilic count in patients with localized abdominal symptoms suggests inflammation/perforation of an organ (secondary bacterial peritonitis). The usual presentation of SBP is with abdominal symptoms such as pain, diarrhea, vomiting, or ileus or it may present with worsening of liver function, encephalopathy, gastrointestinal (GI) bleed, or acute kidney injury. Sometimes, it may be asymptomatic; hence, there is a need to do paracentesis of ascitic fluid in all patients on admission. Untreated patients have high mortality. Treatment usually consists of empirically starting third-generation cephalosporin (cefotaxime or ceftriaxone) after sending ascitic and blood cultures. Culture is positive in 40%

TABLE 1: Diagnosis and treatment of spontaneous bacterial peritonitis.

Diagnosis	• Ascitic fluid cytology: 50 mL of ascitic fluid should be sent for cell count, Gram stain, and culture • Ascitic fluid WBC count > 1,000/mm^3 or polymorphonuclear cell > 250/mL or bacteria on Gram stain
Empiric treatment	• Oral fluroquinolone (in mild cases) • Intravenous fluroquinolones • Cefotaxime or ceftriaxone

of patients only. Treatment should be given for 5 days. Repeat tap after 48 hours to demonstrate that at least 25% reduction in PMN count is helpful in assessing response. Prophylaxis of SBP with quinolones (norfloxacin 400 mg/day) should be started in patients with very low ascitic albumin, jaundice, and Child "C" liver [Child–Turcotte–Pugh (CTP) > 9] function status.

Tuberculosis (TB) is very common in cirrhotic patients, especially in India, and is associated with significant morbidity and mortality. Antitubercular therapy is associated with significant hepatotoxicity. Patients with decompensated cirrhosis require a modified antitubercular regimen for a prolonged period.

GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding could be variceal or nonvariceal. Variceal bleed is common and is associated with mortality in 20% of patients. The common precipitating factors are infections, and nonsteroidal anti-inflammatory drug (NSAID) is used. The initial treatment includes gastric lavage, intravenous (IV) fluids, and packed cell transfusion. Bleeding is frequently associated with further hepatic decompensation, sepsis, and acute kidney injury; prophylactic third-generation cephalosporins should be started on admission. Infusion of octreotide (50 μg stat and 50 μg/h) or terlipressin 1–2 mg 6–8 hourly helps in reducing portal pressure. Upper GI endoscopy after hemodynamic stabilization will help in diagnosing and treating the cause of bleed. Esophageal variceal bleed can be managed by endoscopic variceal ligation (EVL) or endoscopic sclerotherapy (EST). Gastric varices are managed by cyanoacrylate glue injection. Placement of a Sengstaken–Blakemore tube or a metallic (Danis–Ella) stent may be needed in persistent severe bleeding. If bleeding still persists, an emergency transjugular intrahepatic porto-systemic shunt (TIPS) can be considered. Balloon retrograde transvenous obliteration (BRTO) is used for gastric variceal bleed. Follow-up EVL/EST needs to be done every 2–3 weeks to obliterate varices.

Every patient of cirrhosis should undergo surveillance endoscopy to check for presence of varices at baseline. If no varices are found on endoscopy, then repeat endoscopy after 3 years and for those with varices yearly endoscopy is advisable. Those with high-risk varices (small varices with red color signs or large varices with or without red color signs) should receive prophylaxis with nonselective beta-blockers (propranolol, nadolol) or carvedilol or prophylactic EVL. The dose of beta-blocker should be adjusted to a heart rate of 50–60 beats/min. Common side effects are dyspnea, hypotension, and fatigue. Carvedilol worsens fluid accumulation and hyponatremia in patients with high MELD (Model for End-stage Liver Disease) score. Those intolerant to drugs or with refractory ascites should undergo prophylactic EVL.

ASCITES

Development of ascites is the most frequent complication of cirrhosis and reflects declining liver function. The initial event in ascites formation appears to be splanchnic vasodilatation secondary to release of local vasodilators (e.g., nitric oxide) in setting of portal hypertension. Consequent to this, hyperdynamic circulation develops. Decreased arterial pressure leads to activation of the renin–angiotensin–aldosterone system with resultant sodium and water retention in the kidney. An increased hydrostatic pressure gradient across the sinusoids lead to weeping of fluid from the liver surface. Systemic inflammation due to intestinal translocation of bacteria and bacterial products contributes to circulatory dysfunction.

Diagnostic ascitic taping should be done in every case and fluid should be sent for routine examination, culture, cytology, and adenosine deaminase (ADA) levels. Depending on the serum ascitic albumin gradient (serum albumin–ascitic albumin; **Table 2**), ascites can be classified as those related to portal hypertension [high gradient, serum albumin ascites gradient (SAAG) > 1.1] or those not related to portal hypertension (low gradient, <1.1). Low SAAG ascites can occur in TB, malignancy, pancreatitis, and nephrotic syndrome while high SAAG ascites occurs in cirrhosis, myxedema, Budd–Chiari syndrome, and cardiac causes. 5% of patients will have mixed ascites (high SAAG ascites with TB or malignancy).

Treatment of ascites involves treatment of the primary cause of liver disease, such as antivirals for hepatitis B and C and D-penicillamine for Wilson disease. Reversal of fibrosis and improvement in ascites may occur. Mild ascites can be treated by moderate salt restriction (2 g/88 μmol/day) and spironolactone 100 mg daily with or without furosemide 40 mg daily. In some patients, ascites persists (refractory ascites) either after using the maximum doses of diuretics (spironolactone 400 mg and furosemide 160 mg) or when adequate dosing of diuretics is not possible due to side effects. In these patients, large-volume paracentesis (5–10 L) along with albumin infusion (8 mg/L of ascites removed) helps in mobilizing ascites. TIPS should be considered if frequent paracentesis is required. It improves ascitic control and quality of life. However, one fourth of patients may develop post-TIPS HE. Elderly patients, poor liver function (Child–Pugh score > 12, MELD > 18, recurrent encephalopathy), and cardiac dysfunction (EF < 60%) preclude use of TIPS. Liver transplant should be considered in a patient who is otherwise a transplant candidate.

PULMONARY COMPLICATIONS

A patient with cirrhosis has a propensity for pneumonia and should be vaccinated for pneumococcus. Pleural effusion is common and is usually improved with ascites control with diuretics and albumin. Pleural drain should be avoided except

TABLE 2: Serum albumin ascites gradient (SAAG).

SAAG > 1.1 g/dL	• Cirrhosis • Heart failure • Alcoholic hepatitis • Hepatic metastasis • Myxedema
SAAG < 1.1 g/dL	• Peritoneal tuberculosis • Peritoneal carcinomatosis • Pancreatitis • Nephrotic syndrome • Bowel obstruction/perforation

for massive hydrothorax and empyema. *Two pulmonary conditions unique to patients with cirrhosis and portal hypertension are hepatopulmonary syndrome (HPS) and portopulmonary hypertension (POPH), respectively.*

Hepatopulmonary syndrome is characterized by the presence of intrapulmonary vascular dilatation (IPVD) and increased alveolar-arterial oxygen gradient. Patients usually are asymptomatic or have dyspnea. Dyspnea worsens with standing (platypnea) due to predominant vasodilatation in lung bases. Diagnosis requires a high index of suspicion. Arterial blood gas shows a widened alveolar-arterial gradient (>15 mm Hg in those <64 years of age and >20 in those >64 years of age). Pulse oximetry can be used as a screening method. IPVD can be detected by contrast echo and technetium macroaggregated albumin (^{99m}Tc MAA) scan. In contrast echo, agitated saline is given intravenously. Appearance of intravenously injected microbubbles in the left ventricle after three cardiac cycles suggests intrapulmonary shunts. ^{99m}Tc-MAA scan utilizes intravenous injection of 20-μm MAA particles. Normally, these particles get trapped in lung capillaries. But in HPS, some particles cross through abnormal capillaries and reach the brain. Shunt fraction > 6% is termed a positive scan. There is no effective pharmacological treatment of HPS. Multiple drugs and garlic extract have been tried. Liver transplant is effective, but post-transplant mortality is high in severe HPS. POPH is the presence of pulmonary hypertension [mean pulmonary artery pressure (PAP) >25 mm Hg at rest and pulmonary capillary wedge pressure <15 mm Hg in presence of portal hypertension]. POPH can be mild (PAP 25–35 mm Hg), moderate (35–45 mm Hg), or severe (>45 mm Hg). Mortality is high in moderate-to-severe POPH. Treatment is done with vasodilators. Prostacyclin, endothelial receptor agonist (bosentan), and phosphodiesterase 5 inhibitors (sildenafil, tadalafil) are used. The role of liver transplant is controversial.

HEPATORENAL SYNDROME

Acute kidney injury (AKI) in cirrhosis is defined as rise in creatinine >50% over baseline or 0.3 mg more than baseline. It is present in around 20% patients of cirrhosis on admission. The common precipitating factors are infections, dehydration due to diuretics or lactulose overdose, NSAID and other nephrotoxic drugs, and large-volume paracentesis (LVP). Besides this, renal dysfunction may occur due to functional renal failure where no evidence of renal parenchymal abnormality is found and there is no response to initial fluid replacement and diuretic and nephrotoxic drug withdrawal. Functional renal failure is known as hepatorenal syndrome-AKI (HRS-AKI). Previously defined HRS type 1 and 2 terms are abolished now. Pathophysiology of HRS is related to altered hemodynamics in advanced cirrhosis. This consists of splanchnic and systemic vasodilatation and renal vasoconstriction leading to lower renal perfusion. Presence of hypovolemia, infection, and release of cytokines worsens this already compromised renal circulation.

HRS-AKI is diagnosed by the International Ascitic Club AKI criteria (2015) as follows:

- Patient of cirrhosis with ascites and AKI
- No improvement in serum creatinine on volume replacement (decrease to <1.5 mg/dL)
- Absence of shock
- No current or recent nephrotoxic drug use
- Absence of parenchymal kidney disease as indicated by proteinuria (>500 mg/day), microhematuria [>50 red blood cells (RBCs)/high power field (HPF)], and/or abnormal renal findings on ultrasonography (USG)

Treatment of AKI consists of stopping nephrotoxic drugs, NSAIDs, and diuretics; optimizing the dose of lactulose to avoid diarrhea; excluding intrinsic renal disease; treatment of infection; and correction of intravascular volume (1 g albumin/kg body weight—max 100 g/day). If no response to the above measures is seen, then vasoconstrictors should be added. Vasoconstrictors used are terlipressin, norepinephrine, and midodrine. Terlipressin is used in bolus doses of 0.5 mg every 4–6 hourly and increased if there is no response (maximum 2 g 6 hourly for 14 days). Norepinephrine infusion is done to achieve a mean arterial pressure of 10 mm Hg. Treatment is continued till creatinine levels fall below 1.5 mg/dL. Midodrine is an alpha-adrenergic agonist available as 2.5- and 5-mg tablets. Initial doses of midodrine 7.5 mg thrice daily in combination with octreotide 100 μg subcutaneously thrice daily are given. Doses can be increased to achieve a mean arterial pressure of 90 mm Hg.

Those who do not respond should be listed for liver transplant. TIPS can be used as a bridge to transplant in selected patients with a relatively good MELD score.

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is one of the most common cancers. It usually develops in a setting of cirrhosis but may develop in noncirrhotic patients. Early diagnosis of HCC is essential to improve survival. However, the usually available screening methods—USG of abdomen and alpha-fetoprotein (AFP)—lack specificity and sensitivity. Screening of HCC should be done every 6 months. Those with recent decompensation and weight loss should also be evaluated for HCC. A nodule < 1 cm should be followed 3–6 monthly for growth. Larger nodules should be evaluated by triple-phase computed tomography (CT) scan or magnetic resonance imaging (MRI).

A small single tumor in patients with good liver function (Child–Pugh A) and no portal hypertension can be resected surgically with good 5-year survival (75%). Solitary HCC <5 cm or three nodules <3 cm size have good post-transplant survival. Percutaneous ablation by ethanol or radiofrequency ablation (RFA) or transarterial chemoembolization (TACE) are good modalities for reducing tumor burden in transplant candidates awaiting transplant and also in those who have multiple nodules. Systemic chemotherapy with sorafenib, lenvatinib, and other newer agents is used in advanced disease.

HEPATIC ENCEPHALOPATHY

Presence of abnormal neuropsychiatric manifestations in cirrhosis is called HE. About 50–75% of patients with cirrhosis develop HE. The terminology used for HE is given in **Table 3**. It can vary from trivial changes in cognitive abilities on psychometric testing [minimal hepatic encephalopathy (MHE)] to overt encephalopathy (lethargy and coma). Encephalopathy can be episodic, recurrent, or persistent. Grading of HE (**Table 4**) is done according

TABLE 3: Current terminology for the classification of HE.

Type	*Description*	*Subcategory*	*Subdivision*
A	Encephalopathy associated with acute liver failure	–	–
B	Encephalopathy with portosystemic bypass and no intrinsic hepatocellular disease	–	–
C	Encephalopathy associated with cirrhosis or portal hypertension/ portosystemic shunts	Episodic HE	• Precipitated • Spontaneous • Recurrent
		Resistant HE	• Mild • Severe • Treatment dependent
		Minimal	

(HE: hepatic encephalopathy)

TABLE 4: West Haven criteria: Clinical stages of hepatic encephalopathy.

Stage	*Features*
I	General apathy
II	Lethargy, drowsiness, altered sensorium, asterixis
III	Hyperreflexia, extensor plantar reflexes, stupor
IV	Coma

to "*West Haven criteria*". Encephalopathy occurs due to increase in ammonia and various other toxins and systemic inflammation. However, blood ammonia levels do not correlate with the grade of encephalopathy. There are several factors which precipitate HE. Constipation, large protein meal, uremia, infections, sedatives, electrolyte imbalance, and GI bleed are the usual precipitating factors given in **Box 1**. Identification and correction of these factors are helpful in treatment. Assessment of a patient with HE is important for adequate treatment (**Box 2**). Nonabsorbable antibiotics (rifaximin 550 mg BD) and lactulose (or lactitol) in adequate doses to cause two to four soft stools daily are given. Overdose of lactulose can cause diarrhea, electrolyte imbalance, and dehydration and may worsen encephalopathy. In comatose patients, feeding by a nasogastric tube should be started to ensure adequate caloric and protein intake. Dietary protein should not be restricted. Branched-chain amino acid can be considered in patients intolerant to dietary protein.

Subclinical or MHE is characterized by abnormal psychometric tests in a patient with otherwise normal clinical, neurological, and mini-mental scale examination. Various psychometric tests such as paper and pencil tests (number

BOX 1: Precipitating factors for hepatic encephalopathy.

- Constipation
- Electrolyte imbalance: Hyponatremia, hypokalemia, alkalosis
- Gastrointestinal bleeding
- Infection:
  - SBP
  - Pneumonia
  - Urinary tract infections
  - Skin and soft-tissue infections
- Sedative drugs, psychotropic medicines, benzodiazepines, morphine
- Renal failure
- Surgery
- Dehydration:
  - Diuretics
  - Diarrhea
  - Vomiting
  - Excessive paracentesis
  - Fluid restriction
- Alcohol

(SBP: spontaneous bacterial peritonitis)

BOX 2: Assessment of acute episodic encephalopathy in cirrhotic patients.

- Assess for nonhepatic causes of altered mental status, such as delirium, intoxication, alcohol withdrawal, and hypoglycemia. Consider noncontrast CT scan of head to assess for acute intracranial process if new focal neurologic findings are found
- Assess for clinical and neurological examination findings consistent with HE. Grade the severity of HE by West Haven criteria or Glasgow Coma Scale
- Triage for patient safety: Consider hospital admission and monitoring in ICU. Consider intubation if the patient is unable to protect airway
- Assess for precipitating causes of HE and treat accordingly: Thorough clinical exam, labs (e.g., electrolytes, glucose, renal function, cell counts, cultures, urine drug screen, stool for *C. difficile*), and imaging
- Treat HE with lactulose (per oral, nasogastric tube, or rectum) ± rifaximin
- Assess the need for long-term therapy for prevention of recurrent HE
- Assess the need for liver transplant evaluation

(HE: hepatic encephalopathy; ICU: intensive care unit)

connection tests, figure connection tests, digit symbol tests), critical flicker frequency, and computerized tests may be used. Patients with MHE may have problems with driving skills and are more likely to progress to overt HE. Treatment of MHE consists of lactulose and/or rifaximin regularly for long term. Treatment steps of hepatic encephalopathy are summarized in **Box 3**.

BOX 3: Treatment of hepatic encephalopathy.

- Supportive care of unconscious or confused patient
- Identification and treatment of concomitant disease
- Careful search for and correction of precipitating factors
- Reduction of ammonia production and absorption:
  - Lactulose, lactitol, lactose orally or in enema form
  - Restriction of dietary protein
  - Disaccharide inhibitors
  - Probiotics
- Promotion of nitrogen excretion:
  - L-ornithine, aspartate IV, and PO
  - Sodium benzoate IV and PO
- Correction of neurotransmitter abnormalities in the brain:
  - Flumazenil
  - Branched-chain amino acid–enriched formulations
  - Zinc replication (many possible modes of action)
- Portosystemic shunt suppression
- Liver support systems
- Liver transplantation

SUMMARY

Chronic liver disease and cirrhosis are progressive disorders with many associated complications. These can be prevented and treated early. Treatment of the basic cause of liver disease is important in delaying decompensation and sometimes reverses fibrosis. Prophylaxis for infections; avoidance of drugs such as proton-pump inhibitors, NSAIDs, nephrotoxic drugs, and sedative-hypnotics; prophylaxis for variceal bleed; and secondary prophylaxis for HE are important to improve the quality of life in these patients. Liver transplantation should be considered in the end-stage liver disease.

CHAPTER

End-stage Liver Disease

Uday Sanglodkar, Neeraj Mangla

INTRODUCTION

The occurrence of complications in patients with cirrhosis such as jaundice, ascites, encephalopathy, infection, renal dysfunction, or variceal bleeding requiring hospitalization alters the natural history of the disease with an increase in 5-year mortality as high as 40–50%. A significant proportion of these patients with acute decompensation require management in the intensive care unit (ICU) with organ support and have a high rate of in-hospital mortality. End-stage liver disease (ESLD) means that liver function has deteriorated to the point where the damage cannot be reversed other than with liver transplant. We are discussing here the management of these critically ill patients, However, before that, it is important to know few definitions and scoring systems related to the ESLD which will help in risk stratification at the emergency.

DEFINITIONS

Cirrhosis of liver [chronic liver disease (CLD)]: Chronic liver damage from a variety of causes leading to scarring (end stage of fibrosis) and liver failure

Compensated CLD (C-CLD): Patients diagnosed with CLD but asymptomatic in terms of complications such as ascites, encephalopathy, and acute kidney injury (AKI).

Decompensated CLD (D-CLD): Patients diagnosed with CLD, who previously suffered from complications

Acute on chronic liver failure (ACLF): This is the most commonly encountered entity in the emergency department. As per the APASL (Asia Pacific Association of Study of Liver) guideline, it is defined as an acute hepatic insult manifesting as jaundice [serum (S) bilirubin ≥5 mg/dL] and coagulopathy [international normalized ratio (INR) ≥ 1.5] complicated within 4 weeks by clinical ascites and/or hepatic encephalopathy (HE) in a patient with previously known or unknown CLD and associated with a high 28-day mortality.

There are various scores used to define the severity of CLD which also help in prognosticating, such as MELD (model of end-stage liver disease), Child-Turcotte-Pugh (CTP), CLIF-C ACLF (chronic liver failure consortium acute on chronic liver failure), and CLIF-OF (chronic liver failure organ faiure) (**Tables 1** to **3**).

Model for end-stage liver disease (MELD): The original MELD score is a prospectively developed and validated CLD severity scoring system that uses a patient's laboratory values for serum bilirubin, serum creatinine, and the INR for prothrombin time

TABLE 1: Child–Turcotte–Pugh scoring.

Variables	*1 point*	*2 points*	*3 points*
Encephalopathy	None	I–II	III–IV
Ascites	None	Mild	Moderate-to-large
Serum bilirubin (mg/dL)	<2	2–3	>3
Albumin (mg/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time (seconds prolonged or INR)	<4 sec or INR <1.7	4–6 sec or INR 1.7–2.3	>6 sec or INR >2.3
Child class A = 5–6, Child class B = 7–9, Child class C = 10–15			

(INR: international normalized ratio)

TABLE 2: Chronic liver failure—sequential organ failure assessment scoring.

Organ system	*Variable*	*Score = 1*	*Score = 2*	*Score = 3*
Liver	Bilirubin	<6	6 to ≤ 12	>12
Kidney	Creatinine	<2	2 to <3.5	≥3.5 or RRT
Brain	Encephalopathy grade (West Haven)	0	1–2	3–4
Coagulation	INR	<2	2 to <2.5	≥2.5
Circulation	MAP	≥70	<70	Vasopressors
Respiration	PaO_2/FiO_2 or SpO_2/FiO_2	>300 >357	≤300 >200	≤200 ≤214

(INR: international normalized ratio; MAP: mean arterial pressure; RRT: renal replacement therapy)

TABLE 3: ACLF grading as per the CLIF-SOFA scoring system.	
ACLF grade	***Acute liver damage associated with***
Grade 1	Single kidney failure or liver failure, coagulopathy, circulatory failure, respiratory failure, serum creatinine 1.5–1.9 mg/dL, and/or brains failure with creatinine 1.5–1.9 mg/dL
Grade 2	Two-organ failure
Grade 3	Three or more organ failure

(ACLF: acute on chronic liver failure)

TABLE 4: West Haven criteria: Clinical stages of hepatic encephalopathy.	
Stage	***Features***
I	General apathy
II	Lethargy, drowsiness, altered sensorium, asterixis
III	Hyperreflexia, extensor plantar reflexes, stupor
IV	Coma

to predict 3-month survival. The score is useful for listing the patient for liver transplant (MELD ≥14) and prioritize for the same.

CTP: Epidemiologic work shows that the CTP score may predict life expectancy in patients with advanced cirrhosis. A CTP score of 10 or greater is associated with a 50% chance of death within 1 year (**Table 1**). CLIF-C, sequential organ failure assessment (SOFA) score or (CLIF OF) risk score is given in **Table 2**.

CLIF-C ACLF score: $10 \times [0.033 \times CLIF\ OFs + 0.04 \times Age + 0.63 \times Ln(WBC)\ 2]$.

The above-mentioned score has more impact as compared to others. The European Foundation for the study of chronic liver failure (CLIF-C) ACLF score had the best predictive value for 28-day mortality compared with all other scores.

MANAGEMENT OF HEPATIC ENCEPHALOPATHY

Pathophysiology

Mechanisms behind neurological dysfunction, mostly which is caused by HE in hospitalized cirrhotic patients, are varied and are often overlapping with concurrent or precipitating illnesses such as infections and electrolyte abnormalities. Despite the growing understanding of the multifactorial pathophysiology of this disease, ammonia continues to be thought to play a central role. In the brain, ammonia and glutamate are converted into glutamine and the resultant high levels of glutamine then act as an osmolyte, causing astrocyte edema and neuronal dysfunction. Critical care assessment: Severity of HE is given as per West Haven criteria as given in **Table 4**.

Approach and Management for Hepatic Encephalopathy

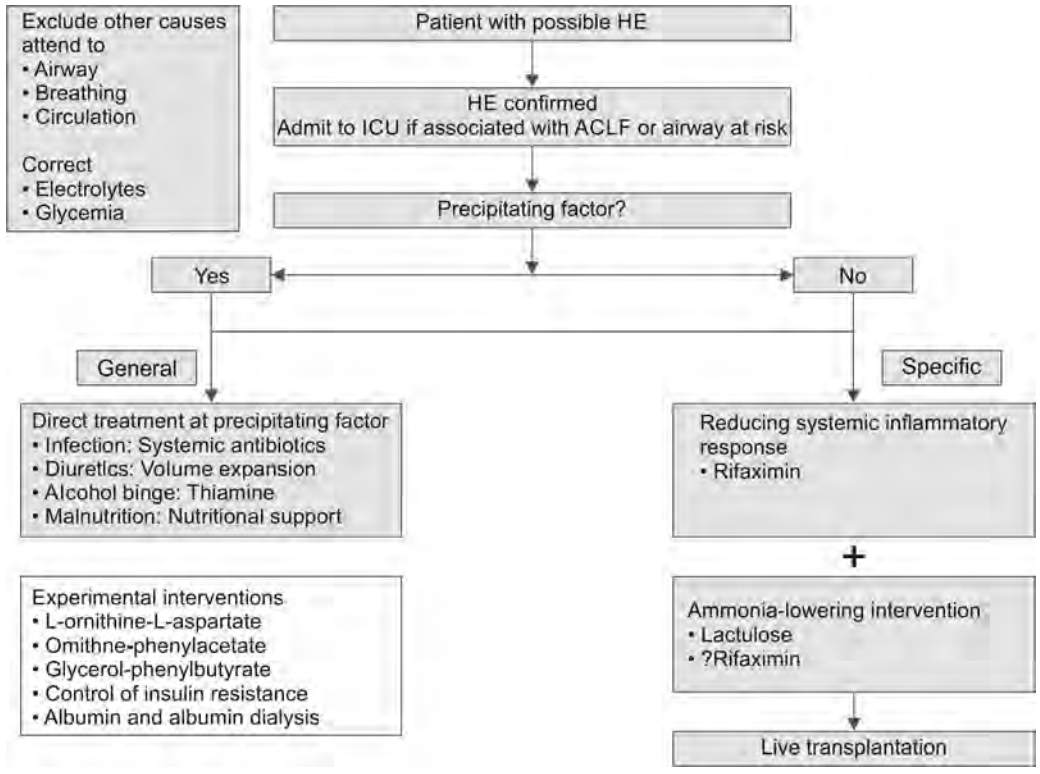
On examination, patients with severe HE may exhibit hyporeflexia or hyper-reflexia, rigidity, myoclonus, ataxia, dilated pupils, and even transient decerebrate posturing. Grading of HE is important in defining the further plan of action. Usually, arterial ammonia level in combination with clinical assessment is recommended in case of doubt of HE. Precipitating factors of HE in ESLD patient are recurrent infections, constipation, electrolyte imbalance, gastrointestinal bleeding and diuretic overdose. ESLD are at high risk for numerous disease state that may cause altered mental status, e.g., sepsis uremia, alcohol withdrawal and intracerebral hemorrhage. As such, an ESLD patient with altered mental status should not be presumed to have HE until other causes have been systematically considered and ruled out.

A patient with grade I or II HE usually does not require airway protection. All patients with grade III or IV HE should be evaluated thoroughly with arterial blood gas (ABG) and ammonia levels. These two parameters usually give an idea about the severity and need of an aggressive treatment such as airway protection. Once the airway is secured, management should be correction of precipitating factors such as dyselectrolytemia, infection, and dehydration. It has been found that early use of lactulose enema and hydration improves encephalopathy. There are various drugs such as rifaximine, L-ornithine L-aspartate (LOLA), and branched-chain amino acids (BCAA) which can be used for early recovery from encephalopathy. Specific points to be remembered in management of HE are as follows (**Flowchart 1**):

- Recognition of the underlying cause of HE and correction of the same should be the primary aim of treatment, e g., correction of dyselectrolytemia.
- Use of lactulose (oral or enema) is highly effective and hence it is recommended. The dose for oral suspension is 30 mL q8h and for enema is 300 mL.
- Serial ammonia monitoring may help in prognosis of HE. Moreover, when the patient is intubated, the response to treatment can be assessed on ammonia levels.
- Other drugs, such as LOLA, BCAA, and zinc, can be used along with the above-mentioned treatment.
- Finally, no response to medical therapy even after correcting the underlying cause is an indication to do electroencephalogram (EEG)/brain imaging and other etiologies should be ruled out.
- Continuous renal replacement therapy (CRRT) is rarely useful in ESLD patients as compared to acute liver failure.

MANAGEMENT OF GASTROINTESTINAL BLEED

The occurrence of GI bleeding in cirrhotic patients is always pointed toward upper GI bleed unless proven otherwise. The incidence of upper gastrointestinal (UG) bleed is 60% amongst all the complications. Patients with CLD usually come to the emergency room (ER) with a history of melena or hematemesis. The history will be short and may refer toward coffee ground vomitus. Most commonly, the source of bleeding is the upper GI tract (i.e., above the second part of duodenum) and is usually related to portal hypertension. The site of occurrence of GI bleed in CLD is 80% variceal and 20% nonvariceal. The most common cause for variceal bleed in cirrhotic patients is increased portal hypertension. The cause for this is severity of liver disease such as MELD



(ACLF: acute on chronic liver failure; HE: hepatic encephalopathy; ICU: intensive care unit)

FLOWCHART 1: Management of hepatic encephalopathy.

>14 or CTP-C. Other causes for bleeding are portal vein thrombosis, development of hepatocellular carcinoma (HCC), infections, etc.

Emergency Critical Care Assessment and Management

In the emergency, one should suspect the GI bleeds if it is not obvious. These patients may have collected altered blood in the stomach which might be too early to manifest as melena or hematemesis. The patient may present with drowsiness, shock, giddiness, or perspiration. There are various clinical criteria to assess for the severity of bleeding and which decide the need of urgent endoscopy and ICU or ward admission and also prognosticate the condition, e.g., clinical Rockall score, Glasgow Blatchford score (GBS), AIMS-65, and T-Score.

Initial assessment and resuscitation–oxygenation. Secure two wide-bore intravenous (IV) lines. If required airway protection IV fluids and blood transfusion packed red blood cells (PRBC), prophylactic antibiotics (ciprofloxacin 400 mg BD or ceftriaxone 1 mg BD), and role of nasogastric (NG) tube placement is controversial. Basic investigations and brief history about known or unknown CLD, past history of similar episodes, latest endoscopy report infection, and medications are required. Drugs used in patients with GI bleed are as follows:

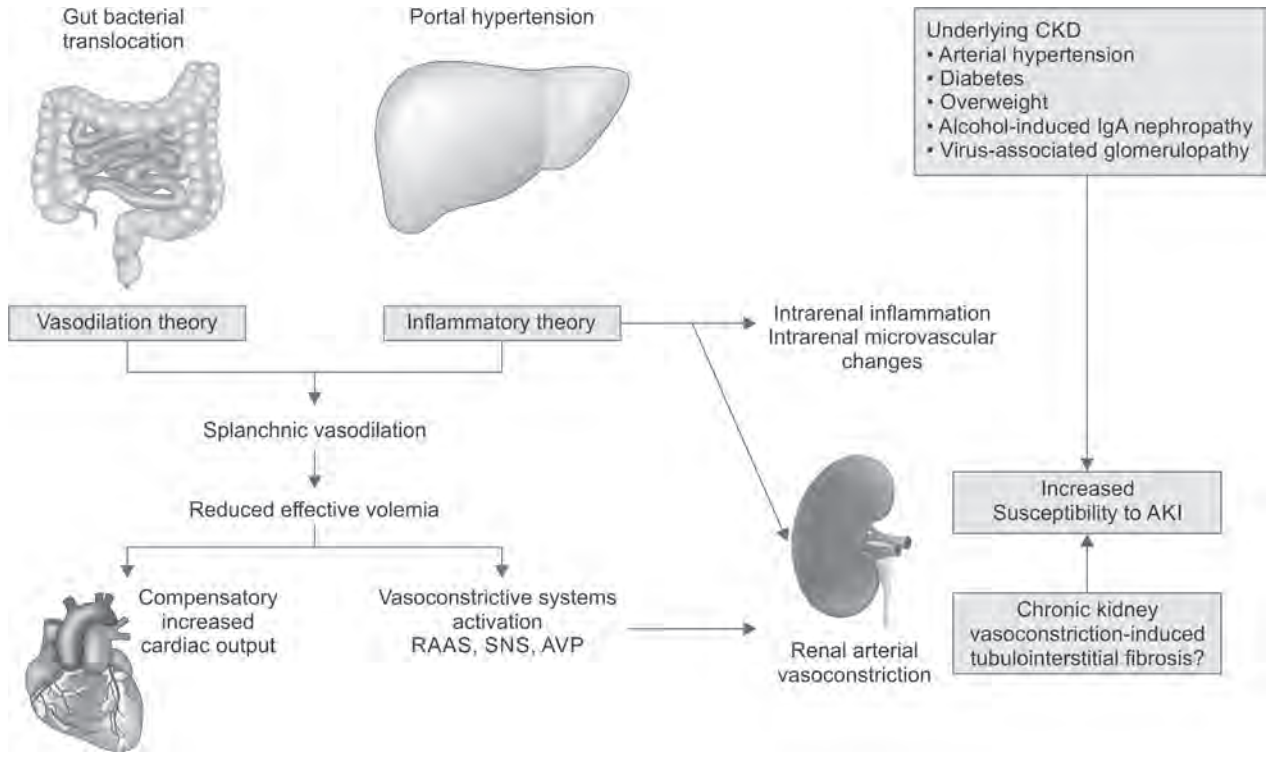
- *Terlipressin* 2 mg q6h [contraindications are coronary artery disease (CAD), peripheral vascular disease (PVD), bradycardia, etc.]

  or
- *Octreotide* 50 μg stat followed by 50 μg/h infusion (as such no obvious contraindications).
- Role of proton-pump inhibitors (PPIs) in variceal bleed is controversial. Still, injectable PPI should be given stat dose till endoscopy is done. 80% of GI bleed are due to varices.
- Endoscopic variceal ligation (EVL)/sclerotherapy/glue 20% nonvariceal—adrenaline injectable/coagulation therapy
- If bleeding is torrential, always insert a Sengstaken–Blakemore (SB) tube as a bridge to further intervention. The primary aim should be reduction of portal pressure.
- Other modalities should be considered when conventional therapy fails such as TIPSS (transjugular intrahepatic portosystemic shunt) or BRTO (balloon-occluded retrograde transvenous obliteration). Vascular surgeries are rarely done nowadays; however, liver transplant is the last resort.

MANAGEMENT OF ACUTE KIDNEY INJURY

Acute kidney injury occurs in 50% of patients who get admitted with cirrhosis, which represents one of the important criteria that defines ACLF and also has the maximum impact factor in the MELD score. The pathophysiology of AKI in CLD is multifactorial (**Flowchart 2**). However, important physiological changes in cardiovascular and the renin–angiotensin–aldosterone system (RAAS) mechanisms are responsible for the same.

The current definition of AKI depends on absolute or relative changes in serum creatinine and urine output. Urine output has been found to be sensitive and an early marker of AKI in ICU patients. There are various criteria or grading systems used for diagnosis of AKI in cirrhotic patients such as acute kidney injury network (AKIN), kidney diseases improving global outcomes (KDIGO), acute dialysis quality initiative (ADQI). Following are various definitions and criteria



(AKI: acute kidney injury; AVP: arginine vasopressin; CKD: chronic kidney disease; SNS: sympathetic nervous system; RAAS: renin–angiotensin–aldosterone system)

FLOWCHART 2: Pathophysiology of acute kidney injury in chronic liver disease.

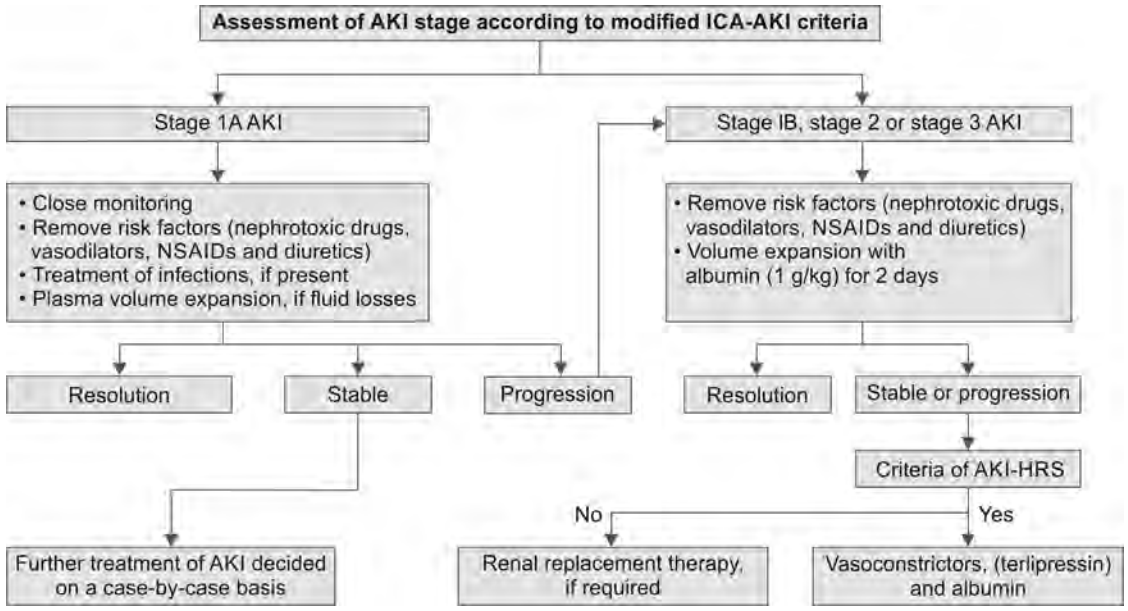
TABLE 5: Definition/Grading/Staging of AKI and HRS.	
RIFLE (2004)	• Increase SCr ≥1.5 times of baseline within 7 days • Or GFR decrease >25% or urine output <0.5 mL/kg/h for 6 h
AKIN (2007)	• Increase SCr ≥0.3 mg/dL within 48 h • Or increase SCr ≥1.5 times of baseline within 48 h • Urine output <0.5 mL/kg/h for 6 h
ADQI (2015) AKI in cirrhosis	• Increase SCr ≥1.5 times of baseline within 48 h • Or SCr percentage increase ≥50% of baseline
ICA-AKI staging	• *Stage 1*: Increase SCr ≥0.3 mg/dL within 48 h • *Stage 2*: Increase SCr 2–3 times of baseline • *Stage 3*: Increase SCr >3 times of baseline
HRS-AKI	• Presence of cirrhosis and ascites • AKI according to ICA-AKI criteria • Absence of shock • No response following 2 days of 1 g/kg albumin volume expansion and diuretics • No signs of structural kidney injury (proteinuria >500 mg/day, microhematuria, and abnormal findings on renal ultrasound)

Note: Baseline SCr: SCr value obtained in the previous 3 months should be used if available; if multiple SCr level is available, value close to admission should be used; if no SCr level is available, admission SCr level should be used.

(ADQI: acute dialysis quality initiative; AKI: acute kidney injury; AKIN: acute kidney injury network; HRS: hepatorenal syndrome; ICA: International Club of Ascites; RIFLE: risk, injury, failure, loss of kidney function, and end-stage kidney disease)

for AKI. Also, there is a specific terminology called hepatorenal syndrome (HRS), the definition of which is also included in the **Table 5**. **Flowchart 3** will help in managing the AKI in CLD hospitalized patients. Specific points to be remembered in CLD patients (recommendations) are as follows:

- Replacement of isotonic crystalloid is recommended in case of volume loss due to diarrhea, overdiuresis, or blood loss in case of GI bleed. Moreover, use of 20–25% albumin in case of infections, HRS, or where etiology of AKI is unclear is strongly recommended.
- To start treatment with vasoconstrictors such as terlipressin, noradrenaline, or combination of octreotide with midodrine. All these drugs to be used with 20%



Assessment of AKI stage according to modified ICA-AKI criteria
Stage 1A AKI
Stage IB, stage 2 or stage 3 AKI
• Close monitoring
• Remove risk factors (nephrotoxic drugs, vasodilators, NSAIDs and diuretics)
• Treatment of infections, if present
• Plasma volume expansion, if fluid losses
• Remove risk factors (nephrotoxic drugs, vasodilators, NSAIDs and diuretics)
• Volume expansion with albumin (1 g/kg) for 2 days
Resolution
Stable
Progression
Resolution
Stable or progression
Criteria of AKI-HRS
No
Yes
Further treatment of AKI decided on a case-by-case basis
Renal replacement therapy, if required
Vasoconstrictors, (terlipressin) and albumin

(AKI: acute kidney injury; HRS: hepato-renal syndrome; ICA: International Club of Ascites; NSAIDs: nonsteroidal anti-inflammatory drugs)

FLOWCHART 3: Steps in management of acute kidney injury in chronic liver disease.

albumin (1 mg/kg on day 1 followed by 20–40 mg/day) in patients with type 1 HRS or persistent AKI.

- Consider as nonresponder to medical treatment when no reduction in serum creatinine happens even after 3 days. Finally, the ultimate treatment option is renal replacement therapy (RRT) like hemodialysis (HD) or CRRT depending on volume status and vitals.

MANAGEMENT OF SEPSIS

Pathophysiology

The risk of infections, especially bacterial infection, is very high in cirrhotic patients because of multiple factors. **Figure 1** depicts the causative factors and pathophysiology of the same. Basically, immune defect facilitates bacterial translocation, induced by increased intestinal permeability and gut bacterial overgrowth. The most common infections in decreasing frequency are spontaneous bacterial peritonitis (SBP), subacute bacterial endocarditis (SBE), respiratory tract infections, urinary tract infections, cellulitis, and others.

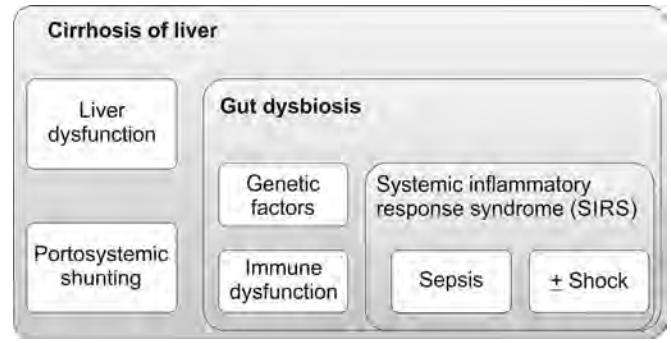


FIG. 1: Pathophysiology of sepsis in chronic liver disease.

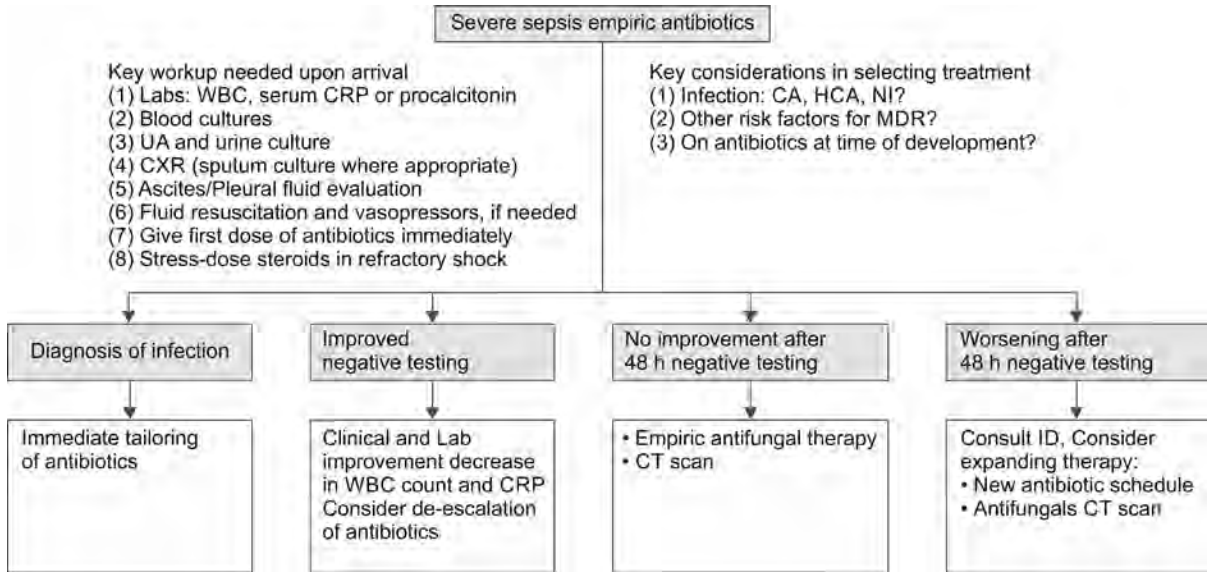
Critical Care Assessment and Approach

Sepsis management in CLD is summarized in **Flowchart 4**. Specific points to be remembered in the management of sepsis and SBP are as follows:

- Diagnosis of SBP should be suspected clinically when the patient complains of abdominal pain and/or fever. Also, the presence of AKI should immediately raise a suspicion towards the presence of SBP in selected cases.
- All patients should undergo diagnostic tapping if clinically indicated. Diagnosis is based on the presence of polymorphonuclear (PMN) counts >500 cells/μL in ascitic fluid analysis or culture positivity.
- After the diagnosis of SBP, it should be classified into community acquired (C-SBP), nosocomial (N-SBP), and health care–associated (H-SBP) because it defines the prognosis and helps in selecting the use of antibiotics.
- All patients should be given antibiotics as per hospital policy and sensitivity, e.g., injectable ceftriaxone (third-generation cephalosporin) 1 mg BD is recommended. Also, injectable albumin 20% 1.5 g/kg on day 1 followed by 1 g/kg on day 3 should be given in patients with low creatinine (>1 mg/dL), [blood urea nitrogen (BUN) 30 mg/dL], or bilirubin (>4 mg/dL).
- Primary prophylaxis should be given in those where ascitic fluid total protein <1.5 g/dL and at least two of the following are met: Creatinine ≥1.2 mg/dL, BUN ≥25 mg/dL, serum sodium ≤ 130 mEq/L, or CTP class ≥ 9 with bilirubin ≥3 mg/dL (norfloxacin 400 mg OD).
- Secondary prophylaxis should be given to all patients [norfloxacin 400 mg OD or alternately sulfamethoxazole-trimethoprim (SMP-TMX), ciprofloxacin, or levofloxacin].



Severe sepsis empiric antibiotics
Key workup needed upon arrival
(1) Labs: WBC, serum CRP or procalcitonin
(2) Blood cultures
(3) UA and urine culture
(4) CXR (sputum culture where appropriate)
(5) Ascites/Pleural fluid evaluation
(6) Fluid resuscitation and vasopressors, if needed
(7) Give first dose of antibiotics immediately
(8) Stress-dose steroids in refractory shock
Key considerations in selecting treatment
(1) Infection: CA, HCA, NI?
(2) Other risk factors for MDR?
(3) On antibiotics at time of development?
Diagnosis of infection
Improved negative testing
No improvement after 48 h negative testing
Worsening after 48 h negative testing
Immediate tailoring of antibiotics
Clinical and Lab improvement decrease in WBC count and CRP Consider de-escalation of antibiotics
• Empiric antifungal therapy
• CT scan
Consult ID, Consider expanding therapy:
• New antibiotic schedule
• Antifungals CT scan

(WBC: white blood cell count; CRP: C-reactive protein; UA: urine analysis; CXR: chest X-ray; MDR: multi-drug resistant; CA: community acquired; HCA: healthcare associated; NI: nosocomial infection; ID: infectious disease)

FLOWCHART 4: Approach to management of sepsis in chronic liver disease.

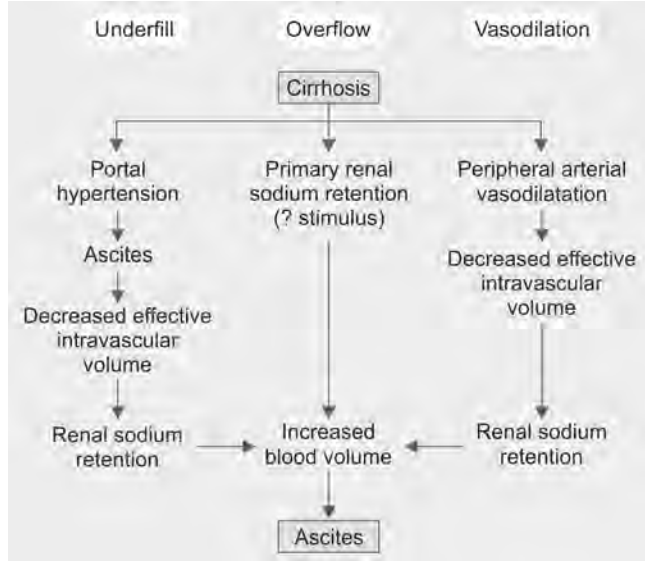
MANAGEMENT OF ASCITES

Ascites is the most common cause of decompensation in cirrhosis and in 5–10% of patients with compensated cirrhosis per year. The mainstay of ascites formation is renal sodium retention due to the activation of sodium-retaining systems, such as the RAAS and the sympathetic nervous system. The resulting positive fluid balance ultimately leads to extracellular fluid volume expansion. Reduced effective volume secondary to splanchnic arterial vasodilation is the main determinant of these alterations. The underfill and overfill theory define the development of ascites (**Flowchart 5**). Grading of ascites is as follows:

Grade 1: Mild ascites—it is only detected by ultrasonography.

Grade 2: Moderate ascites—it is manifested by moderate symmetrical distension of abdomen.

Grade 3: It is characterized by large gross ascites with marked abdominal distension.



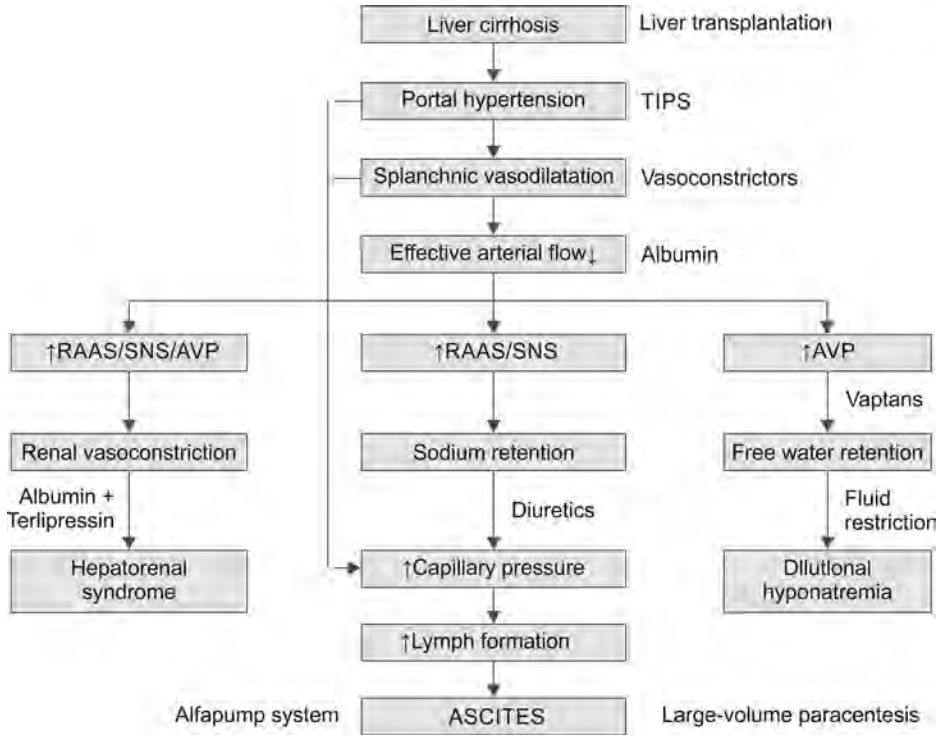
FLOWCHART 5: Underfill and overfill theories of ascites formation in chronic liver disease.

Management of Ascites in End-stage Liver Disease

Once the pathophysiology is understood, it is easier to hit the targets and manage ascites. Various modalities are available in refractory cases such as TIPS, vasopressors, vaptans, and liver transplantation. Management of ascites starts with salt restriction (<5 g/day) that means 1 teaspoon. As per the guidelines, the patient should be started on spironolactone and followed by furosemide if no response. The response is defined as weight reduction of at least 0.5–1 kg in a week. A maximum dose of spironolactone up to 400 mg and furosemide 160 mg is recommended. Finally, those who do not respond to medical therapy need paracentesis. Usually, LVP (large volume paracentesis) is indicated in refractory ascites.

*Management of ascites in Emergency (**Flowchart 6**)*:

- LVP is the first-line therapy in patients with large ascites (grade 3 ascites), which should be completely removed in a single session.
- LVP should be followed with plasma volume expansion to prevent postparacentesis circulatory dysfunction (PPCD).
- In patients undergoing LVP of >5 L of ascites, plasma volume expansion should be performed by infusing albumin (8 g/L of ascites removed), as it is more effective than other plasma expanders, which are not recommended for this setting.
- In patients undergoing LVP <5 L of ascites, the risk of developing PPCD is low. However, it is generally agreed that these patients should still be treated with albumin because of concerns about the use of alternative plasma expanders.
- After LVP, patients should receive the minimum dose of diuretics necessary to prevent reaccumulation of ascites.
- When needed, LVP should also be performed in patients with AKI or SBP.



(AVP: arginine vasopressin; RAAS: renin–angiotensin–aldosterone system; SNS: sympathetic nervous system; TIPS: transjugular intrahepatic portosystemic shunt)

FLOWCHART 6: Pathophysiological rationale for the treatment of patients with ascites and other related complications.

MANAGEMENT OF HEPATIC HYDROTHORAX

It is defined as transudative pleural effusion in patients with decompensated liver disease that is not secondary to cardiopulmonary failure, renal failure, malignancy, or another primary process. It occurs in 5–10% of patients, usually right-sided (85%), left-sided (13%), and bilateral (2%). Similar to SBP, bacterial translocation may cause infection in the pleural fluid which is called SBE. Usually, patients are asymptomatic due to chronicity and customization to ascitic fluid. However, if hepatic hydrothorax is moderate to severe, e.g., fluid quantity >500 mL, it may cause symptoms such as breathlessness and tightness of chest. On examination, the patient might have tachypnea, tachycardia, and hypoxia-reduced air entry on auscultation. Fever and pain should suspect toward the development of SBE. Usually, 50% of patients will have ascites at the same time. Assessment should start with SpO_2 monitoring, ABG, and X-ray of chest in the emergency to decide the severity and admission to ward or critical care unit.

Management of Hepatic Hydrothorax

Usually, management guidelines to be followed for hepatic hydrothorax are similar to that of ascites. In the ER, one should assess the quantity of fluid; if it is moderate to or severe, one should plan for tapping (thoracentesis). Treatment options may include TIPS, pleurodesis, or liver transplantation in refractory cases.

Management of hydrothorax in emergency:

- Patients who are severely symptomatic should undergo therapeutic thoracocentesis.
- Care should be taken to limit fluid removal to 1–2 L on initial thoracentesis, owing to concerns of precipitating negative pressure pulmonary edema or even HRS.
- For each 1 L of fluid drained, albumin 100 mL (20%) should be replaced slowly to prevent re-expansion pulmonary edema or HRS.
- Patients presenting with SBE should be administered ceftriaxone 2 g every 24 hours, with levofloxacin as an alternative agent in penicillin-allergic patients.
- Occasionally, chest tube placement may be necessary in patients with SBE with frank pus or loculations; however, chest tubes should not be placed routinely for the treatment of hepatic hydrothorax.
- Chest tube placement in these patients can result in massive protein and electrolyte losses, and there is no clear endpoint for chest tube removal because of continuous reaccumulation of fluid.
- Chest tube placement in ESLD patients with hepatic hydrothorax has been associated with numerous complications including infection, renal failure, empyema, bleeding, and an increased risk of death.

LIVER TRANSPLANTATION IN CRITICALLY ILL ESLD PATIENTS

Liver transplantation remains the ultimate cure for critically ill ESLD patients. However, risk and benefit should be

weighed before advising the liver transplant. Most of the times, these patients are critically ill and if transplant is considered, the morbidity and mortality intraoperatively and postoperatively are very high. Those patients who have an ACLF (grade 1 or 2) like scenario as mentioned earlier in this chapter might benefit if transplanted early in the course of disease. However, the most common complications of ESLD such as sepsis, AKI, refractory HE, severe sarcopenia, and poor nutrition are responsible for refuting the patients for transplantation.

SUMMARY

The knowledge of the key pathophysiologic mechanisms makes it possible nowadays to counteract the progression of cirrhosis and thus to prevent its complications. ESLD is a syndrome associated with multiorgan/system failure(s) (liver, kidney, brain, coagulation, circulation, and/or respiration) and with extremely poor survival. These patients often require ICU care. Critical care assessment in emergency and management of these patients cautiously might help in bridging the gap for liver transplantation which is a definitive cure for ESLD patients.

101 CHAPTER

Liver Transplant and Related Complications

Amit Ganguly

INTRODUCTION

Liver transplant has evolved from an experimental procedure to a curative procedure for end-stage liver disease (ESLD). From the first paper published by Starzl et al. which had 5 cases to 1,400 cases in India alone in 2014, liver transplant has come a long way. While various complications of portal hypertension such as variceal bleed, ascites, and encephalopathy can be managed medically, endoscopically, or by radiological interventions, liver transplant remains the only curative option, which aims to restore normal physiology.

INDICATIONS

Indications for liver transplant can be easily summarized as follows:

- Where the estimated survival of the patient is <1 year because of liver disease
- Quality of life is unacceptable because of liver disease

However, it is often difficult to assess these in many patients; therefore, more objective criteria were sought. Two such scoring systems which are often used are Child–Turcotte–Pugh and MELD (Model for End-stage Liver Disease) score, respectively. Computed tomography perfusion (CTP) has been in use for assessment of liver function. But it has subjective criteria (e.g., ascites and encephalopathy). The MELD score, on the other hand, is based on the mathematical regression model, which takes serum creatinine, international normalized ratio (INR), and serum bilirubin into consideration. Thus, it is more objective and dynamic. It has been validated as a predictor of 3-month mortality for chronic liver disease (CLD) as per the allocation criteria for deceased donor liver transplantation (DDLT) proposed by the National Organ and Tissue Transplant Organization (NOTTO). The MELD score of <15 is a contraindication for liver transplant. Few common indications are described below.

Chronic Liver Disease

In an Indian setup, the most common indications for transplant in adult are ESLDs related to hepatitis C and B, alcoholic liver disease, and nonalcoholic fatty liver disease (NAFLD).

Viral hepatitis-induced ESLD remains one of the most common indications for transplant. In cases of hepatitis C-related CLD, it is essential to know the viral load and genotype as this helps in predicting the prognosis after transplant. Antiviral drugs and pegylated interferon are often started before transplant to decrease the chances of recurrence of disease in graft. However, these patients have high chances of recurrence.

The outcome of hepatitis B-related CLD has improved with the availability of hepatitis B immunoglobulin (HBIg) and antiviral drugs. Reinfection of graft is rare, though the duration of treatment is still controversial.

Liver transplant for alcoholic liver disease is offered to the patient who is abstinent for a period of 3–6 months. It is believed that a patient who has been abstinent for a particular period is less likely to suffer from recidivism and thus will have a good outcome. Survival rates are similar to any other cirrhotic patients. The role of transplant in patients with alcoholic hepatitis is controversial, with few centers offering transplant.

In India with a large diabetic population, *CLD secondary to NAFLD* is emerging as an important indication for transplant.

Transplant for hepatocellular carcinoma in the presence of cirrhosis definitively provides survival benefits. It is not only curative but also decreases the chances of recurrence as the cirrhotic liver is replaced by healthy liver. Most of the centers are expanding the criteria for transplant, from the Milan criteria to the University of California San Francisco (UCSF) criteria. The UCSF criteria is also accepted by NATTO. These patients may need priority points as their MELD scores may be low.

Cholestatic liver diseases, such as *primary biliary cirrhosis (PBC)* and *primary sclerosing cholangitis (PSC)*, are other indications where quality of life issues such as repeated cholangitis, intractable pruritus, and bone diseases are the indications for transplant. In pediatric population, biliary atresia is a common indication for transplant.

Metabolic diseases which cause irreversible damage and decompensation are an indication for transplant. There is a long list of diseases which can be corrected by liver transplant including *Wilson's disease, hemochromatosis, and alpha-1 antitrypsin deficiency*. Transplant for vascular conditions such as Budd–Chiari syndrome should be considered when portal

decompensation has failed and cirrhosis with decompensation is well established.

Other uncommon indications for transplant include *complicated polycystic liver disease* (with or without kidney disease) and *Caroli's disease.*

Acute Liver Failure

Fulminant liver failure is characterized by encephalopathy, coagulopathy, and jaundice. Common causes of acute liver failure (ALF) in an Indian setting are viral hepatitis (hepatitis A, B, and E), idiosyncratic drug-induced liver injury, and indigenous medications administered for a variety of different etiologies. Antitubercular drug-induced ALF seems to have worse outcomes than hepatitis E, which is a common cause for ALF in India. In the western population, acetaminophen toxicity is a common cause for ALF. Timely identification and referral for transplant are essential in these cases, otherwise the patient may succumb to sepsis and cerebral edema. There are many different scoring systems, e.g., King's college criteria, for urgent transplantation in these patients. The chance of these patients getting an organ in emergency in absence of robust brain-dead declaration and organ donation drive often leaves living donor liver transplant (LDLT) the only likely option.

CONTRAINDICATIONS

Absolute contraindications for liver transplant are as follows:

- Severe cardiopulmonary disease
- Extrahepatic malignancy
- Uncontrolled systemic sepsis originating from a source other than liver
- Active substance abuse

Other relative contraindications are advanced age (>70 years), uncontrolled human immunodeficiency virus (HIV) disease, and diffuse thrombosis of vein.

BRAIN DEAD DONOR AND OPTIMIZATION

An ideal donor is a young, hemodynamically stable patient who is pronounced brain dead. Most of these patients are victims of road traffic accidents. After two separate brain stem death declarations at an interval of 6 hour, the process of organ retrieval is started.

Brain death induces multiple physiological responses in the body, mostly because of dysfunction of the hypothalmo–pituitary axis. As the time of organ procurement from declaration of brain dead increases, there is a possibility of loss of potential donor. While waiting for organ donation, these patients should be carefully managed in the intensive care unit (ICU) in consultation with an intensivist. The cardiorespiratory support is continued so as to maintain sinus rhythm with adequate blood pressure with a mean arterial pressure (MAP) of 60–80 mm Hg. Respiratory targets are to maintain pH of 7.35–7.45, with minimum FiO_2, to have partial pressures of oxygen (PaO_2) >100 mm Hg, oxygen saturations >95%, and partial pressure of carbon dioxide ($PaCO_2$) 35–40 mm Hg. Hypothermia is to be avoided. Hemoglobin is to be maintained at >9 g/dL and if coagulation is deranged, then it should be corrected with fresh frozen plasma (FFP)/platelets. Some other physiological derangements and their management are listed in **Table 1**.

TABLE 1: Correction of physiological derangement.

Hypovolemia	***Corrected with isotonic crystalloid fluid***
Hypotension	Volume correction and use of dopamine and vasopressin
Diabetes insipidus ($Na^+ > 155$)	Desmopressin
T3 deficiency	Thyroid supplementation
Failure of hypothalamic-pituitary-adrenal axis	Low-dose steroids
Hyperglycemia	Insulin

LIVER TRANSPLANT PROCEDURE

The standard liver transplant involves removal of the entire liver from a brain-dead donor and placement of it at the place of native diseased liver which is removed, hence the word orthotopic liver transplant. Most of the centers preserve native inferior vena cava (IVC; piggyback technique), and donor suprahepatic cava is anastomosed with recipient IVC, following which portal vein, hepatic artery, and bile duct are reconstructed end to end. In most the European countries, deceased donor liver transplant accounts for majority of cases.

However, in many Asian countries including India, due to lack of organ donation, living donor transplant accounts for a greater number of cases. This involves removal of the right lobe of liver (VI–VIII) from a healthy donor after workup and implanting it. The minimum size of the graft required is 8% of the recipient to ensure viability of graft and patient. In comparison to DDLT, LDLT requires meticulous right hepatectomy on a healthy, voluntary donor and more demanding reconstruction on the recipient. It also exposes a healthy donor to the morbidity and mortality of major hepatectomy. For a pediatric patient, a left lobe graft (I–IV) can be used, which is less morbid for the donor.

COMPLICATIONS OF LIVER TRANSPLANT

Primary Nonfunction

The exact etiology is not clear; it is most probably multifactorial without any technical complications. The clinical presentation is altered sensorium with diminished bile production, coagulopathy, elevated transaminases, and acidosis. Multiorgan failure occurs and in the absence of pretransplant the outcome is poor. Some of the factors identified are increased cold and warm ischemia time, donor steatosis, intraoperative hypotension, and renal failure in the recipient.

Vascular Complications

Arterial: Hepatic artery thrombosis occurs between 1 and 7% of cases. The common presentation is graft dysfunction. This needs immediate either radiological intervention, revascularization, or retransplant.

Venous: Outflow obstruction due to stenosis of IVC anastomosis is rare with the piggyback technique.

Portal vein thrombosis is also more common in a patient who has a past history of partial or complete thrombus in the

portal vein; however, it can occur in patients with no previous history also.

Biliary: Bile leaks and biliary stricture are the common biliary complications.

- *Ischemic type*: These are due to because of hepatic artery thrombosis, ischemia-reperfusion injury, or ABO incompatibility. These present with diffuse intrahepatic strictures, producing a beaded appearance along with stenosis and dilatation. The clinical presentation is with pruritus and recurrent cholangitis. These may need retransplant.
- *Anastomotic type*: These are often associated with surgical technical issues and bile leak. The first line of management is often endoscopic retrograde cholangiopancreatography (ERCP) with balloon dilatation with endoprosthesis.
- *Associated with partial graft*: Anastomotic strictures are more common with patients undergoing a live donor or split graft. One of the factors proposed for this increased incidence is the size of the duct, which is smaller.

Infections in Liver Transplant

Infections are one of the most common causes of death in liver transplant, which is understandable as these patients are immunosuppressed, malnourished, and have undergone major complex surgical procedures. These can occur immediately postoperatively or subsequently after discharge from the hospital. A brief list of infections and their causing organisms are mentioned in **Table 2**.

IMMUNOSUPPRESSION AND REJECTION

Post liver transplant immunosuppression is in many ways similar to other solid organ transplant except that liver recipients are maintained at lower dosage. Liver transplant does not require human leukocyte antigen (HLA) typing between the host and donor. The long-term aim is to have decreased rejection episodes and also to avoid infection, malignancy, and other side effects of these drugs. The commonly used drugs postoperatively are as follows:

- *Corticosteroid*: It remains the mainstay of treatment. It is used for both induction and treatment of rejection. It is started during the hepatic phase and continued postoperatively.
- *Calcineurin inhibitor (CNI)*: Introduction of cyclosporine in the 1970s improved the long-term survival of liver transplant. Along with tacrolimus (TAC), it has considerably improved the results of transplant. Because of its excellent graft-protecting function, TAC is used by most of the transplant centers and started early to achieve TAC trough level between 5 and 10 ng/dL. Cyclosporine is no longer the first choice among CNIs.
- *Mycophenolate mofetil*: Introduced in the 1990s, this immunosuppressive drug is used in combination with TAC. It is a purine synthase inhibitor with antiproliferative activity against T and B cells.
- *Azathioprine*: It is another purine synthase inhibitor. The use of antimetabolite drugs [mycophenolate mofetil (MMF) and azathioprine (AZA)] has increased due to the need to decrease the dose of CNI, which causes nephrotoxicity. The immunosuppression regimen needs to be tailored for renal impaired patients, hepatitis C virus (HCV) transplanted patients, and patients showing signs of rejection.

Three types of rejections are known following liver transplant:

1. *Hyperacute*: It is rarely seen today. It typically occurs in the setting of ABO incompatibility. It is mediated by preformed antibodies in the recipient.
2. *Acute*: It usually occurs within the first 4 weeks of transplant. It is often detected by raised transaminases. Biopsy is needed to establish the diagnosis, which shows portal inflammation with mononuclear cells, bile duct inflammation and injury, and centrilobular necrosis and lobular inflammation. Treatment consists of bolus dosage of corticosteroid. Steroid-resistant rejection is treated by antithymocyte globulins (ATGs) after review of liver biopsy.
3. *Chronic*: It is multifactorial. It is characterized by progressive loss of bile duct, obliteration of small- and large-sized arterioles, and cellular portal infiltration.

The prevalence of both acute and chronic rejection has been declining steadily with the advent of new immunosuppressive drugs. Acute rejection is seen in 15–30% of cases. This can be treated with increasing immunosuppression. In contrast, chronic rejection (ductopenic) can result in graft loss.

TABLE 2: Common infections related to liver transplant and recommended treatment.

Bacterial	***Gram-negative bacilli Gram-positive cocci (vascular catheter-related)***	***Routine use of broad-spectrum antibiotics Culture-based antibiotics***
	Another bacteremia—pneumonia, biliary, and wound infections	
Viral	• Cytomegalovirus (CMV) • Epstein–Barr virus	Ganciclovir
Fungal	• *Candida* • *Aspergillus/Cryptococcus*	• Fluconazole routinely • Culture-based
Protozoal	*Pneumocystis carinii*	Trimethoprim + sulfamethoxazole

OUTCOME

The results of liver transplant have improved worldwide. The majority of death occur within the early postoperative period. Infections and intra- or postoperative complications are the cause of death or graft loss in 60% of cases in the first year. In long-run cardiovascular diseases, renal failure, infection, and de novo malignancy are other important causes of death. Survival after transplant for fulminant liver failure remains below average.

In most high-volume centers, 1- and 5-year survival rates are close to 90% and 70%, respectively. Some paper has reported 10-year survival close to 60%. In patients with HCV and hepatocellular carcinoma (HCC) recurrence of disease does affect long-term survival, while those patients transplanted for biliary atresia have 10-year survival >75%.

SUMMARY

Despite the rapid strides made in the field of hepatology, liver transplant still remains the final solution to the large number of patients with ESLD. The progress made in the field of immunosuppression, better perioperative care, and refined anesthetic and surgical skills all have greatly contributed to the improved outcome.

102
CHAPTER

Bowel Obstruction

Jesús Daniel López Tapia, Aldo Emigdio Bartolini Salinas

INTRODUCTION

Bowel obstruction is defined as the impairment of passage of intestinal content. It is classified according to a couple of characteristics that are the site of obstruction, the degree of obstruction, and the presence of irrigation impairment (ischemia). The sites of obstruction in general terms are the small bowel and the large bowel, which have an additional subclassification, which can be extrinsic or intrinsic (intraluminal and intramural). The degree of obstruction can be either partial or complete. In a partial obstruction, there is still some passage of intestinal content and gas which could result in constipation; in a complete obstruction, there is no passage of intestinal content and the patient might present with obstipation (incapability of passing gas or stool). We can further classify bowel obstruction on its peristaltic characteristics (dynamic or adynamic). When the obstruction is nonmechanical or adynamic, there is an impairment in the transmission of neuromuscular innervation to the myenteric plexus, which results in paralytic ileus (aperistalsis) and colonic pseudo-obstruction. Dynamic obstruction occurs when there is a mechanical obstruction of the bowel lumen, which impairs peristalsis functionality. These obstructions can be extrinsic or intrinsic (intraluminal or intramural) as determined earlier. It can be challenging to establish a diagnosis due to unspecified symptomatology, radiological, and laboratory results. Learning these classifications can help to identify these differences which have an important outcome in decision-making regarding treatment choices. Mechanical obstruction will be widely discussed in this chapter.

ETIOLOGY

Bowel obstruction can be classified according to their etiology as being intrinsic (intraluminal, intramural) and extrinsic (**Table 1**). The location and onset of obstruction guide us toward a specific etiology; it is important to determine if the obstruction is in the small or large bowel to be able to establish a precise diagnosis. Postoperative adhesions are the most common etiology of small bowel obstruction (SBO) in 60–85% of cases approximately, followed by hernias in 30% cases which result in surgery due to incarceration and obstructive malignancy. The large bowel is most frequently obstructed by a malignant etiology; rectosigmoid tumors are the most common manifestation of these; the benign etiology that obstructs the large bowel more frequently is the presence of sigmoid volvulus, followed by a stricture because of diverticulitis. Other causes of large bowel obstruction (LBO) are presented in **Box 1**.

TABLE 1: Causes of small bowel obstruction.

Intraluminal lesions	• Intussusception • Gallstones • Congenital atresia, duplication, and congenital bands • Neoplasm • Parasites • Bezoars • Foreign body • Strictures due to NSAID enteropathy • Feces • Meconium • Food bolus
Intramural lesions	• Neoplasm • Hematoma • Crohn's disease • Postoperative stricture ring • Radiation enteritis
Extrinsic lesions	• Adhesions (congenital and acquired) • Hernia (congenital and acquired) • Volvulus • Endometriosis • Carcinomatosis • Superior mesenteric artery syndrome • Abscess

(NSAID: nonsteroidal anti-inflammatory drug)

BOX 1: Causes of large bowel obstruction.

- Neoplasm (colorectal cancer)
- Adhesions
- Strictures (diverticular disease, ischemic colitis, Crohn's disease)
- Volvulus (sigmoid volvulus)
- Hernia
- Fecal impaction
- Inflammatory bowel disease
- Bezoars
- Intussusception
- Gallstone ileus
- Endometriosis

PATHOPHYSIOLOGY

Small bowel obstruction occurs when there is a blockage of its lumen, preventing the normal passage of intestinal content through the bowel, impairing its normal functionality. When this happens, the small bowel starts to dilate proximal to the site of obstruction provoking bacterial accumulation and fermentation. Swallowed air, gas, and bacterial fermentation lead to intestinal distention, bowel wall edema, and loss of absorptive function; translocation of bacterial fermentation may lead to sepsis. As this process continues, there is loss of electrolyte-rich fluid by emesis and transudation, this may result in metabolic alkalosis and hypovolemia. Continued bowel distention leads to vascular compromise, loss of perfusion, ischemia, and eventually necrosis and perforation.

Large bowel obstruction occurs in 60% of cases because of a neoplasm. Tumors that tend to cause obstruction with greater frequency are those located at the splenic flexure. Ischemia, necrosis, and perforation in LBO occur due to an inflammatory reaction provoked by tumor invasion. The ileocecal valve plays an important role in the physiopathology of LBO, when the ileocecal valve is competent and a closed-loop obstruction (presence of two obstruction sites) occurs due to the incapability of decompression of the bowel, resulting in ischemia or necrosis.

CLINICAL PRESENTATION

The clinical presentation of SBO and LBO differ slightly from one another, and its symptomatology varies depending on the onset of instauration. These differences will be explained in **Table 2**.

Careful evaluation of symptomatology progress must be done; abdominal pain can evolve from being an intermittent cramping pain to a constant and more severe pain, which might indicate clinical complications such as ischemia and perforation. Nausea and vomiting might be more severe in patients with a proximal SBO and abdominal distention might be minimal. In distal SBO, vomiting might be infrequent and abdominal distention important. Most concerning features (red flag) are shown in **Figure 1**.

TABLE 2: Clinical presentation of small bowel and large bowel obstruction.

Small bowel obstruction (SBO)	*Large bowel obstruction (LBO)*
Acute onset: • Periumbilical pain (colicky, cramping) • Nausea • Vomiting • Abdominal distention • Obstipation	*Acute onset*: • Hypogastric pain • Abdominal distention • Obstipation • Diarrhea • Rectal tenesmus • Rectal obstruction • Nausea and vomiting (may or may not be present)
Chronic onset: Develop same symptomatology of acute onset SBO, but with varying severity	*Chronic onset*: • Weight loss • Weakness • Anorexia • Rectal bleeding • Develop same symptomatology of acute onset LBO, but with varying severity

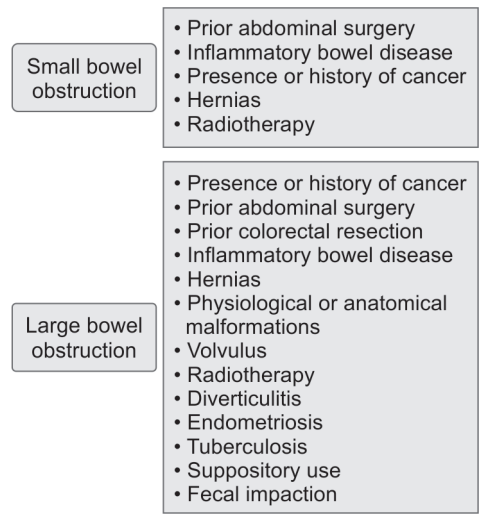

FIG. 1: Most concerning clinical features: "Red flag" bowel obstruction.

EVALUATION: HISTORY AND PHYSICAL EXAMINATION

History

Performing a complete medical history is a crucial step to meet to obtain sufficient information that leads us to an accurate diagnosis. Even though a thorough medical history is necessary, if a patient arrives in the emergency room, there are five main clinical features we should always have in mind. These are the (1) presence of abdominal pain, (2 and 3) constipation/obstipation, (4) abdominal distension, and (5) vomiting. Acknowledging if the patient has had a previous surgical procedure is of equal importance.

Abdominal Pain

When carrying out a physical examination in a patient with abdominal pain, careful attention must be paid to the location and onset of pain. Abdominal pain is the most common complaint. SBO pain usually is in the periumbilical area and is described as a colicky or cramping pain which is generally of severe and acute instauration. In LBO, hypogastric pain is frequently present and generally described as a cramping pain which recurs every 20 minutes approximately. When there is a closed-loop obstruction in LBO, pain can be constantly increasing. In any of these cases, if pain becomes constant and fixed in a specific area the possibility of ischemia or perforation is greater.

Constipation/Obstipation

These clinical manifestations might be present in SBO and LBO, although they are generally indicative of a LBO. Incapability to pass gas or stool might be present in an acute onset of LBO and usually occurs in a distal obstruction. Past surgical history should be acquired as well as changes in intestinal functioning or unprogrammed weigh changes in the last few months.

Abdominal Distension

Once the obstruction develops, peristaltic activity increases in an effort to release the blockage; this process continues until intestinal motility starts to decrease due to relaxation of the bowel wall and dilation. This should be considered, since changes in peristaltic motility might be indicative of ischemia, necrosis, and perforation. In both SBO and LBO, abdominal distension is present, although usually greater in LBO, since vomiting helps alleviate this manifestation in SBO.

Vomiting

Vomiting might appear in both SBO and LBO, even though it is more frequently present in SBO as an early onset manifestation. The characteristics of the vomit are an important clue toward finding out the site of obstruction. Unprocessed food usually indicates a proximal SBO and feculent vomit is generally indicative of a distal obstruction.

Physical Examination

A thorough physical examination should always be performed. In bowel obstruction, even though there are similar physical manifestations between SBO and LBO, paying close attention to these and other systemic features are imperative for an optimal diagnosis and treatment choice. Vital signs should be monitored. The presence of fever might be indicative of an infection or other systemic complications. Heart rate monitoring is important since vomiting in SBO is usually present and this could lead to dehydration, tachycardia, hypotension, and oliguria. Abdominal inspection is a key step, since in its fulfillment we might be able to find some previous surgery marks that could guide us toward the diagnosis. Abdominal auscultation should also be considered; in an acute onset bowel obstruction, as previously mentioned, peristalsis might be increased and accompanied by a hyper-resonant percussion differing from a chronic process in which peristalsis and percussion might be absent or hypoactive. During abdominal palpation, we can be able to identify abdominal masses such as tumors or hernias that could be provoking the symptomatology. A rectal examination should be performed to evaluate rectal obstruction that might be caused by fecal impaction.

Interpretation of Finding

- Persistent and increasing abdominal pain—might be indicative of a closed-loop obstruction or/and ischemia, necrosis, or perforation
- Increased peristalsis—may indicate an early or recent obstruction
- Decreased or absence of peristalsis—may indicate ischemia, necrosis, or perforation
- Persistent and increasing abdominal distension—the presence of LBO must be evaluated
- Active vomiting—could be a sign of early proximal SBO
- Bilious vomiting—main manifestation of intestinal malrotation and duodenal duplication cyst
- Feculent vomiting—might be indicative of a distal obstruction
- Presence of fever—systemic complication, bacteremia, sepsis
- Oliguria, hypotension, and tachycardia—may be found in dehydrated patients due to constant vomiting in SBO
- Rectal obstruction—might be due to fecal impaction.

INVESTIGATIONS

After a general examination has been achieved, special attention should be paid to the abdominal (inspection, auscultation, percussion, and palpation) and digital rectal examination. A full cardiovascular evaluation is recommended; blood pressure, pulse and capillary refill time should be considered. To detect or prevent the presence of systemic inflammatory response syndrome (SIRS), the body temperature and respiratory rate must also be monitored.

Laboratory Studies

Complete blood count with differential, electrolytes, blood urea nitrogen (BUN), creatinine, amylase, arterial blood gas, serum lactate, and blood cultures (if systemic features) should be done.

Imaging Studies

Plain Radiography (X-ray)

Because of its practical use, easy availability, and low cost, it is preferred as the first evaluation diagnostic tool. It can help determine whether an emergent procedure should be performed or not, and it can also help in evaluating the location and type of obstruction (partial or complete).

A plain supine abdominal radiography and an upright chest film should be done. Findings include:

- Small dilated bowel loops that can be indicative of a LBO with an ileocecal valve that is incompetent in about 30% of cases. A dilated colonic diameter above 8 or 10 cm or more dilation of the cecum is considered pathological
- If there is a dilation of the proximal bowel (>2.5 cm) with collapse of the distal bowel, it might be indicative of SBO
- An abdominal radiograph that shows a gasless abdomen might be indicative of a small bowel that is fluid-full. The sign of "*string of pearls*" might be present

- If volvulus is present, pneumoperitoneum, "*northern exposure and coffee bean signs*" might be present in LBO
- In an upright chest film, hydroaerial levels are found in the same levels in adynamic obstruction (paralytic ileus) while in mechanical obstruction these appear at different intestinal levels.

Multidetector Computed Tomography Scan

Multidetector computed tomography (MDCT) scan can find the cause of obstruction in approximately 70–95% of cases and determine the specific location of the obstruction and evaluate any other masses that might be present. Performing a CT scan using contrast might be useful, but not essential, since retained fluid in the bowel can help function as contrast. Contrast imaging might be done by administering oral or rectal contrast; a nasogastric tube can also be used. Intravenous contrast is another possibility although renal pathology patients are not candidates. Some findings obtained can be the presence of submucosal hemorrhage and/or edema, thickening of the abdominal wall, and ascites. A CT scan can also contribute in finding specific signs related to the diagnosis. For example, in volvulus a "whirlpool sign" might be found in SBO, while in LBO there might be a separation of the sigmoid wall which is described as a "split-wall" sign and "X marks the spot" which is found when there are two transition points present; in intussusception, there is a "target sign" and the "cut-off sign," which is found in thrombosis. In a study made in 62 patients with bowel obstruction, it was found that the use of a CT scan for determining the site of obstruction was accurate in 91.9% of cases, while an abdominal ultrasound predicted it accurately in 82% of cases and a plain abdominal radiograph in 90.3%, thus concluding that an abdominal CT scan is the most effective tool for obstruction location.

Ultrasonography and Magnetic Resonance Imaging

These diagnostical imaging approaches are not the best tools for diagnosis of bowel obstruction. These imaging options are used in pregnant women and children.

TREATMENT

General Measures

- Fluid restoration should be done using isotonic fluid
- A Foley catheter must be applied to assure adequate renal function and fluid restoration
- Electrolyte imbalance should be corrected as soon as possible
- Nasogastric tube placement is ideal for decompression.

Small Bowel Obstruction

In SBO, a prompt diagnosis and initial treatment can lead to a nonsurgical management in approximately 73% of cases which consists of fluid restoration and stomach decompression that must be done within 48 hours of diagnosis. If there is evidence of strangulation, ischemia, perforation, or a decline in clinical symptomatology, a surgical management is the treatment of choice. In the case of intussusception in kids, the use of contrast enemas guided by X-rays and hydrostatic pressure is the treatment of choice. When intussusception occurs in adults, surgical resection is the treatment of choice due to its high probability of being caused by a malignant process. The surgical approach for SBO involves a laparotomy or laparoscopic management. Laparotomy is usually preferred because of the possibility of a thorough abdominal examination and is the treatment of choice when there are previous abdominal injuries, dense adhesions, or complicated symptomatology. A laparoscopic approach, even though it has been increasing in popularity, is reserved for well-trained doctors, due to challenging abdominal exploration. Hospital stay, morbidity, and mortality are lower in the laparoscopic approach.

Large Bowel Obstruction

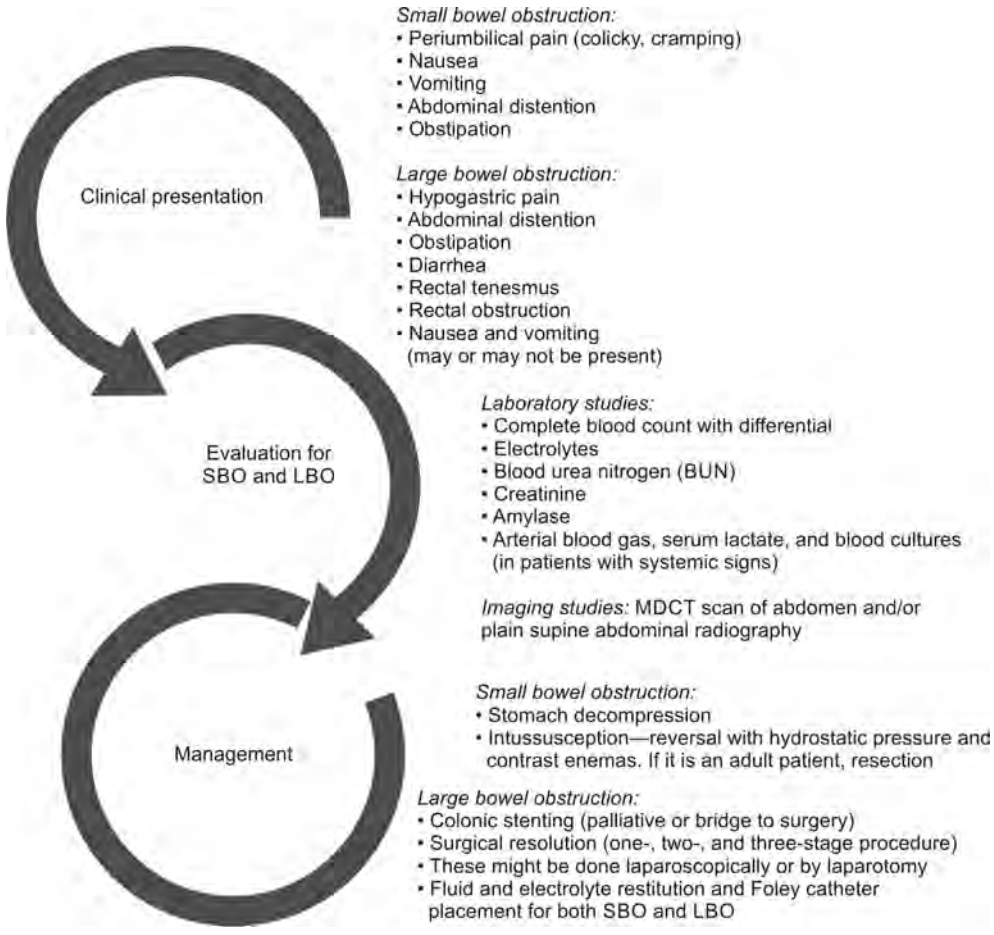
Large bowel obstruction treatment varies depending on the cause of the obstruction, evolution, and clinical condition of the patient. First of all, as in SBO, the patient's fluid and electrolyte imbalance should be managed; this is crucial as a beginning step in treatment. Stomach decompression can also be performed. Around 75% of LBO will require a surgical intervention eventually, but there are a series of treatment alternatives that help "make a bridge" between having to perform and emergency surgery and an elective one. These will be discussed below. In case the patient presents a sigmoid volvulus in the emergency room, a flexible sigmoidoscopy for colonic decompression can be performed initially in order to have a programmed surgery; this procedure is successful in about 90% of the cases, even though the recurrence rates are about 50%. If the patient is in an adequate clinical condition, the first treatment should be elective resection. Colonic stenting might be done for the same two reasons: decompression and having additional time for an elective procedure. When it is used to evade an emergency procedure, colonic stenting which is done laparoscopically can allow resection and anastomosis to be done rather than having an ostomy done. This procedure may also be used as palliation, even though it is not a resolutive treatment; it is successful for deobstruction in the short term. Complications of this procedure might be reobstruction, perforation, and migration of the stent.

Surgical resolutions for LBO might be done at different times (one-stage, two-stage, and three-stage) and with different purposes (curative and palliative). A one-stage procedure should always be preferred; when it is used as a curative solution, the bowel where the obstruction and dilated wall are localized is resected and reanastomosed. This procedure usually has an anastomotic leak of about 2.2–6.9%. When the one-stage procedure is used for palliation, bowel decompression and stenting are the best options. Stenting is usually done endoscopically, and decompression is done by performing a transverse loop colostomy. Cecostomy done with local anesthetics and fluoroscopic guidance might be performed in short life expectancy patients. The two-stage procedure involves the resection of the obstructed and dilated bowel followed by doing a colostomy or reanastomosing the bowel with a diverting loop ostomy, which is then reversed in a second step to re-establish continuity. A three-stage procedure starts with a Hartmann's procedure in which colon decompression is done by proximal diversion. After this is done, the second step consists in removal of the obstructed colon. Anastomosis can be done with an end colostomy or by a proximal diverting ostomy. To finish the three-staged surgeries, reversal of the ostomy and re-establishment of gastrointestinal continuity are done.

SUMMARY

Bowel obstruction is a syndrome characterized by a blockage of the intestinal content, gas, and liquid, through a small or a

large bowel. The block must be complete and permanent. The diagnosis of bowel obstruction usually is made on the basis of the patient's history, symptoms, and physical signs and is then confirmed by plain abdominal X-rays. There are several data that can diversify the intestinal obstruction syndrome. The first is the etiology based on a large number of factors that allow the subdivision into mechanical and functional/paralytic obstruction. The other feature characterizes the syndrome: the seat of the obstruction along the bowel—upper small gut, distal small gut, and large bowel. Finally, the cause of obstruction can involve the vascular supply of an intestinal segment, giving rise to strangulation obstruction that should be differentiated from simple obstruction. Evaluation and management of bowel obstruction are summarized in **Figure 2**.



Clinical presentation
Small bowel obstruction:
• Periumbilical pain (colicky, cramping)
• Nausea
• Vomiting
• Abdominal distention
• Obstipation
Large bowel obstruction:
• Hypogastric pain
• Abdominal distention
• Obstipation
• Diarrhea
• Rectal tenesmus
• Rectal obstruction
• Nausea and vomiting
(may or may not be present)
Evaluation for SBO and LBO
Laboratory studies:
• Complete blood count with differential
• Electrolytes
• Blood urea nitrogen (BUN)
• Creatinine
• Amylase
• Arterial blood gas, serum lactate, and blood cultures (in patients with systemic signs)
Imaging studies: MDCT scan of abdomen and/or plain supine abdominal radiography
Management
Small bowel obstruction:
• Stomach decompression
• Intussusception—reversal with hydrostatic pressure and contrast enemas. If it is an adult patient, resection
Large bowel obstruction:
• Colonic stenting (palliative or bridge to surgery)
• Surgical resolution (one-, two-, and three-stage procedure)
• These might be done laparoscopically or by laparotomy
• Fluid and electrolyte restitution and Foley catheter placement for both SBO and LBO

(LBO: large bowel obstruction; MDCT: multi-detector computed tomography; SBO: small bowel obstruction)

FIG. 2: Summary—evaluation and management of bowel obstruction.

103
CHAPTER

Acute Appendicitis

Mukund Khetan

INTRODUCTION

Acute appendicitis is the most common general surgical emergency, and early surgical intervention improves the final outcome. The diagnosis is at times deceptive, and a high index of suspicion is important to prevent serious complications.

ANATOMY

Embryologically, the appendix and cecum develop as outpouchings of the caudal limb of the midgut loop. At birth, the appendix is located at the tip of the cecum, but the adult appendix typically originates from the posteromedial wall of the cecum. The appendix measures 5–9 cm in length, with its outside diameter ranging from 3 to 8 mm and lumen ranging from 1 to 3 mm. The base of the appendix is consistently found by following the teniae coli of the colon to their confluence at the base of the cecum. The arterial supply of the appendix comes from the appendicular branch of the ileocolic artery. Lymphatic drainage flows to the lymph nodes along the ileocolic artery (**Fig. 1A**). The appendicular tip, however, can vary significantly in location (**Fig. 1B**).

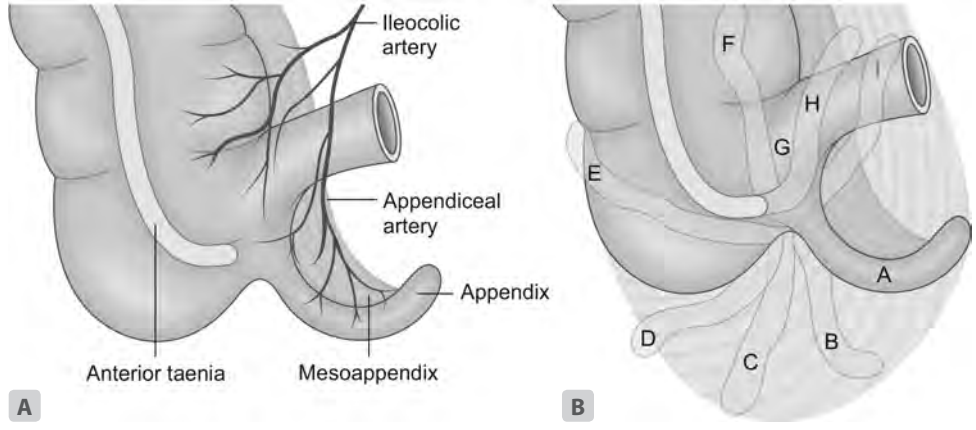
HISTORY

The first description of the appendix dates to the 16th century. The appendix was formally described in 1524 by da Capri and in 1543 by Vesalius. The first description of a case of appendicitis was by Fernel in 1554. Amyand is credited with the first appendectomy in 1736. Lawson Tait in London presented in 1880 the first successful transabdominal appendectomy for a gangrenous appendix. In 1886, Reginald Fitz of the Harvard Medical School first described the natural history of the inflamed appendix, coining the term "appendicitis."

In 1889, Chester McBurney described characteristic migratory pain as well as localization of the pain along an oblique line from the anterior superior iliac spine to the umbilicus. Laparoscopic appendectomy was first reported by the gynecologist Kurt Semm in 1982.

ETIOPATHOGENESIS

Obstruction of the appendiceal lumen is believed to be the major cause of acute appendicitis. This may be secondary to inspissated stool (fecalith or appendicolith), lymphoid



FIGS. 1A AND B: (A) Anatomy of appendix; (B) Variations in locations of appendicular tip (A to I).

hyperplasia, vegetable matter, parasites, or a neoplasm. A fecalith is typically composed of inspissated fecal material, calcium phosphates, bacteria, and epithelial debris.

Obstruction of the appendiceal lumen contributes to bacterial overgrowth, and continued secretion of mucus leads to increased intraluminal pressure and distension. Luminal distension produces typical periumbilical pain. Further impairment of lymphatic and venous drainage leads to mucosal ischemia. This in turn promotes a localized inflammatory process that may progress to gangrene and perforation. Perforation, although there is much variability, occurs after at least 48 hours from the onset of symptoms and is accompanied by an abscess cavity walled off by the surrounding omentum and small intestine.

Although appendiceal obstruction is widely accepted as the primary cause of appendicitis, evidence suggests that this may be only one of many possible etiologies. First, some patients with fecalith have a histologically normal appendix, and the majority of patients with appendicitis show no evidence for a fecalith.

The flora in the normal appendix is very similar to that in the colon, with a wide variety of facultative aerobic and anaerobic bacteria. *Escherichia coli*, *Streptococcus viridans*, *Bacteroides,* and *Pseudomonas* are frequently isolated.

PRESENTATION

Perhaps the most common surgically correctable cause of abdominal pain, the diagnosis of acute appendicitis still remains difficult in many instances and various abdominal conditions need to be differentiated (**Table 1**).

The *classic presentation of acute appendicitis* begins with crampy, intermittent abdominal pain which may be either periumbilical or diffuse and difficult to localize. This is typically followed shortly thereafter with nausea. If nausea and vomiting precede the pain, patients are likely to have another cause for their abdominal pain. Classically, the pain migrates to the right lower quadrant (RLQ) due to inflammation of the peritoneal lining in RLQ due to transmural migration from the appendix. This usually occurs within 12–24 hours from the onset of the symptoms. The character of the pain thus changes from dull and colicky to sharp and constant.

Movement or the Valsalva maneuver often worsens the pain, so the patient typically desires to lie still. Patients may report low-grade fever up to 101°F (38.3°C). Patients who have appendicitis commonly report anorexia; appendicitis is unlikely in those with normal appetite.

TABLE 1: Differential diagnosis.

Children	Gastroenteritis, mesenteric enteritis, Meckel's diverticulitis, intussusception, Henoch–Schonlein purpura, lobar pneumonia
Adult	Regional enteritis, ureteric colic, perforated peptic ulcer, torsion of testis, pancreatitis, rectus sheath hematoma
Adult female	Pelvic inflammatory disease, pyelonephritis, ectopic pregnancy, torsion of ovarian cyst, endometriosis
Elderly	Diverticulitis, intestinal obstruction, colonic carcinoma, torsion appendix epiploic, mesenteric infarction, leaking aortic aneurysm

Typically, *two clinical syndromes of acute appendicitis* can be apprehended: (1) *acute catarrhal (nonobstructive) appendicitis* and (2) *acute obstructive appendicitis*. The latter is characterized by a much more acute course.

The surgeon is constantly reminded that the classic presentation is not present in all patients. Patients may have none or only few symptoms just described. When the pain becomes constant, it may localize to other quadrants of the abdomen due to an alteration in appendiceal anatomy as in late pregnancy or malrotation. In patients with a retrocecal appendix, the pain may never localize until generalized peritonitis from perforated appendicitis occurs. Urinary or bowel frequency may be present due to appendiceal inflammation irritating the adjacent bladder or rectum.

Perforated Appendicitis

It is a not uncommon that if left untreated, appendiceal inflammation will progress inevitably to necrosis and then to perforation. The time course of this progression varies among patients. A longer duration of prehospital delay is the major contributor to perforation. Perforation after presenting to surgical attention appears to be uncommon.

The pain usually localizes to RLQ if perforation has been walled off but may be diffuse if generalized peritonitis occurs. Patients with perforation often have rigors and high fevers to 102°F (38.9°C) or above. Other rare presentations do occur, most likely in the very young and very old, who cannot express their symptoms and often present late in the course of their disease. Abscesses can also form in the retroperitoneum due to perforation of the retrocecal appendix or in the liver from hematogenous spread of infection through the portal venous system. Pylephlebitis (septic portal vein thrombosis) presents with high fevers and jaundice and can be confused with cholangitis.

EVALUATION

History and Physical Examination

The patient should be asked about the classic symptoms of appendicitis, but the surgeon should not be deterred by the absence of many of the symptoms. A previous appendectomy does not exclude the diagnosis of appendicitis, as "stump appendicitis" (appendicitis in the remaining appendiceal stump after appendectomy), although rare, has been described.

On examination, the patient looks slightly ill and may have mildly elevated temperature and pulse. The clinician should systematically examine the entire abdomen, starting in the left upper quadrant. Maximal tenderness is typically in the RLQ, at or near *McBurney's point*, located one third of the way from the anterior superior iliac spine to the umbilicus. This tenderness is often associated with localized muscle rigidity including rebound, shake, or tap tenderness. RLQ tenderness is the most consistent of all signs of acute appendicitis (**Table 2**).

The patient is asked to point to where the pain began and where it moved (*pointing sign*). Pain in the RLQ on palpation of the left lower quadrant results from localized peritoneal inflammation (*Rovsing's sign*). Pain with the flexion of the leg at the right hip can be seen with a retrocecal appendix due to inflammation adjacent to the psoas muscle (*psoas sign*). Pain with rotation of the flexed right thigh internally indicates inflammation adjacent to the obturator muscle (the obturator sign).

In case of perforated appendicitis, if sepsis has developed, blood pressure can be depressed. Perforation walled off by the surrounding structures can create abscess or phlegmon leading to palpable mass. Free intraperitoneal rupture can lead to signs of generalized peritonitis with diffuse rebound tenderness.

INVESTIGATIONS

Laboratory Studies

The white cell count is typically slightly elevated in nonperforated appendicitis but may be quite elevated in the presence of perforation. A completely normal leukocyte count and differential is found in about 10% of patients with acute appendicitis, particularly in early cases.

A urinary tract infection is not uncommon in patients with appendicitis. Its presence does not exclude the diagnosis of acute appendicitis, but it should be identified and treated.

Measurement of serum liver enzymes and amylase can be helpful in diagnosing liver, gallbladder, or pancreatic disease in patients with mid-abdominal pain. In women of child-bearing age, the urine beta-human chorionic gonadotropin (β-HCG) should be checked to alert the clinician to the possibility of ectopic or concurrent pregnancy.

TABLE 2: Clinical presentation of acute appendicitis.

Symptoms	*Signs*	*Signs to elicit*
Periumbilical pain	Pyrexia	Pointing signs
Pain shifting to right iliac fossa	Local tenderness, right iliac fossa	Rovsing's signs
Anorexia	Muscle guarding	Psoas signs
Nausea	Rebound tenderness	Obturator signs

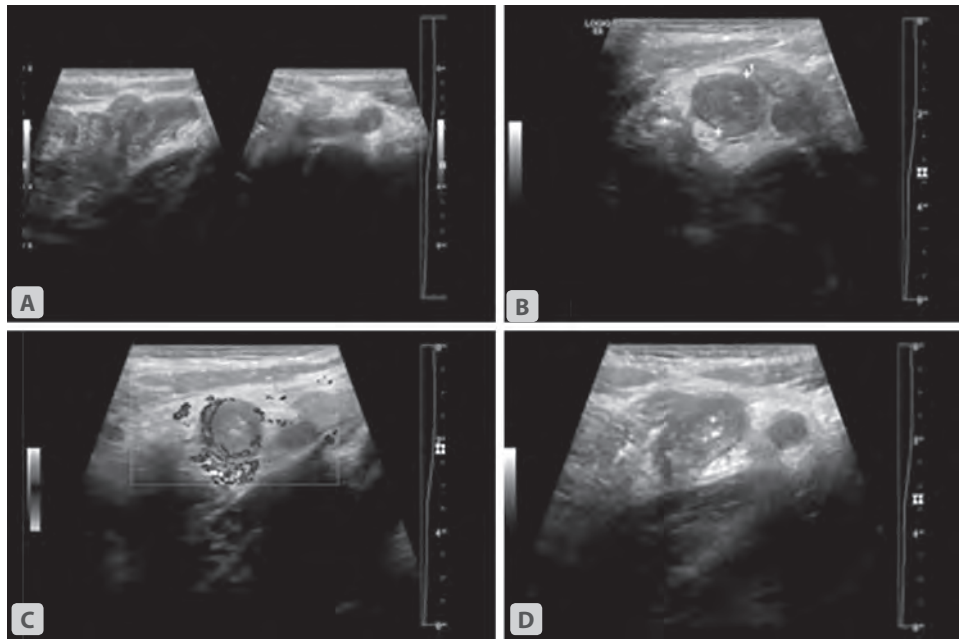
Diagnostic Scores

Diagnostic scoring systems have been developed in an attempt to improve the diagnostic accuracy of acute appendicitis. The most widely used scoring system is the Alvarado score. This scoring system gives point for symptoms (migration of pain, anorexia, and nausea), physical signs (RLQ tenderness, rebound tenderness, and pyrexia), and laboratory values (leukocytosis with a left shift). With the recent improvement in imaging studies, these scores play a smaller role in diagnosis.

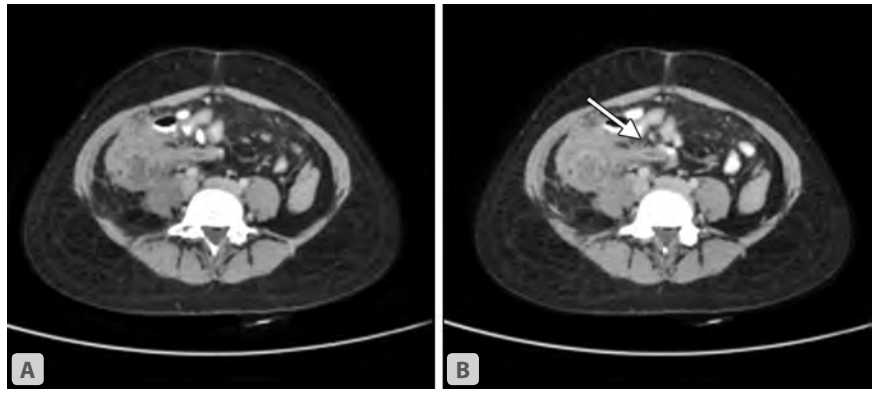
Imaging Studies

The potential imaging modalities for diagnosis of acute appendicitis include plain radiographs, ultrasound (US), and computed tomography (CT). On plain radiographs, fecaliths are nonpathognomonic for appendicitis. Plain radiographs are indicated in elderly patients with severe abdominal pain, in whom a perforated viscus is included in the differential diagnosis. Abdominal *ultrasonography is a popular imaging modality, and findings that suggest appendicitis* include thickening of the appendiceal wall with increased blood flow (leading to the so-called ring-of-fire appearance), loss of wall compressibility, increased echogenicity of the surrounding fat, and loculated pericecal fluid (**Figs. 2A** to **D**). Noncompressible luminal structure seen in cross section as a target lesion. US is highly operator-dependent, and it is frequently unable to visualize the normal appendix.

Computed tomography benefits from a high diagnostic accuracy for appendicitis and visualization and diagnosis of many of the other causes of abdominal pain that can mimic appendicitis. *The radiographic findings of appendicitis on CT* include a dilated (>6 mm), thick-walled appendix that does not fill with enteric contrast or air as well as surrounding fat stranding to suggest inflammation (**Figs. 3A** and **B**). CT demonstrated a sensitivity of 0.94 and a specificity of 0.95.



FIGS. 2A TO D: Ultrasonography findings of acute appendicitis. (A) Thickening of the appendiceal wall and increased blood flow (ring of fire appearance); (B) Loss of wall compressibility; (C) Increased echogenicity of the surrounding fat; (D) Loculated pericecal fluid. ***(For color version, see plate 11)***



FIGS. 3A AND B: Computed tomography findings of acute appendicitis. (A) These include a dilated (>6 mm), thick-walled appendix that does not fill with enteric contrast or (B) Air as well as surrounding fat stranding to suggest inflammation.

Mural stratification referring to the layers of enhancement and edema within the wall is known as target sign.

APPENDICITIS IN SPECIAL POPULATION

Children

Appendicitis most commonly affects children aged 10–19 years. Infants aged 0–4 months have the lowest incidence, but up to two thirds will present with perforation. In children with an equivocal history and physical examination, imaging with either a CT scan or US can significantly reduce the negative appendectomy rate. As with adults, both CT and US have been shown to be highly accurate in diagnosing appendicitis in children, although a CT scan is believed to have a higher specificity and sensitivity.

Elderly

Because of a diminished inflammatory response, the elderly can present with less impressive symptoms and physical signs, longer duration of symptoms, and decreased leukocytosis. Perforation is thus more common, occurring in as many as 50% of patients older than 65 years of age. A prompt CT scan is advocated when the diagnosis is in dilemma.

Pregnancy

The diagnosis can be challenging, as nausea, anorexia, and abdominal pain may be symptoms of both appendicitis and normal pregnancy. The gravid uterus can displace the abdominal viscera, shifting the location of appendix. It can occur in any trimester, with perhaps a slight increase in frequency in the second trimester. Perforation is more common in the third trimester. US is accurate in pregnancy and is a useful first radiological tool. Rectal contrast CT has also been shown to be highly accurate. Although ionizing radiation has risks to the fetus, the radiation from a typical abdominopelvic CT is below the threshold of 5 rad at which teratogenic effects can be seen. Additionally, magnetic resonance imaging (MRI) has been recently used to aid in the diagnosis of appendicitis in the pregnant patient when US results are equivocal. To date, however, no adverse effects of MRI on the developing fetus have been reported.

Immunocompromise

The immunocompromised state alters the response to acute infection and wound healing. Appendicitis affects all types of patients and must be considered in those who have undergone organ transplant, are receiving chemotherapy, or are infected with the human immunodeficiency virus (HIV).

TREATMENT

Nonoperative or Medical Management

Appendicitis has long been a surgically treated disease; recently, few studies of nonsurgical management dot the surgical literature. Based on a higher rate of failure with antibiotics alone, nonoperative management of acute appendicitis has not been recommended. Nevertheless, antibiotic treatment may be a useful temporizing measure in environments with no surgical expertise. Intravenous antibiotics have been shown to reduce the incidence of postoperative wound infection and intra-abdominal abscess. Antibiotics should be administered 30 minutes prior to skin incision. As the typical flora of appendix resembles that of colon, a second-generation cephalosporin or a combination of antibiotics directed at gram negatives and anaerobes will suffice. In nonperforated appendicitis, a single preoperative dose, and in cases of perforation, an extended course of at least 5 days of antibiotics are advocated.

Operative Management: Open or Laparoscopic Appendectomy

Once the diagnosis of appendicitis is confirmed, the surgeon must decide whether to perform an open or laparoscopic appendectomy. Meta-analysis and systematic reviews have addressed the controversy. Based on the data available, one cannot convincingly recommend either open or laparoscopic appendectomy over the other. One situation in which laparoscopic appendectomy may be advisable is when the diagnosis of appendicitis is in doubt.

Open Appendectomy

If an open approach is chosen, the surgeon must then decide on the location and type of incision. If a mass representing

the inflamed appendix can be palpated, the incision must be centered at that location. If the appendix cannot be visualized, it can be located by following the teniae coli of the cecum to the cecal base. Care should be taken to avoid perforation of appendix, with spillage of pus or enteric contents into the abdomen. In excising the appendix, the surgeon must decide whether or not to invert the appendiceal stump. Recent studies show no advantages to appendiceal stump inversion. No matter how the appendix is divided, the residual appendiceal stump should be no longer than 3 mm to minimize the possibility of stump appendicitis in the future. If the base of the cecum is also inflamed but there is sufficient uninflamed cecum between the appendix and the ileocecal valve, an appendectomy with partial cecectomy can be performed using a stapling device.

Laparoscopic Appendectomy

Multiple port placements for laparoscopic appendectomy exist. The authors utilize a three-port technique, with one umbilical and one suprapubic port and the third port can be placed in either the left lower quadrant or RLQ. The appendix should be placed in a retrieval bag and removed through the umbilical port site to minimize the risk of wound infection (**Figs. 4A** to **D**).

Postoperative Care

Patients with nonperforated appendicitis require a shorter (24–48 h) hospital stay. Postoperative care for both the laparoscopic and the open approaches is similar. Patients can be started on a clear liquid diet after 4 hours, and their diet can be advanced as tolerated. Patients can be discharged when they tolerate a regular diet.

SPECIAL CONSIDERATIONS DURING APPENDECTOMY

Perforated Appendicitis

When appendicitis progresses to perforation, management depends on the nature of the perforation. If perforation is contained, it can lead to a mass or phlegmon or may result in a pus-filled abscess cavity. Appendectomy proceeds as described earlier. Peritoneal drains are not necessary, as they do not reduce the incidence of wound infection or abscess, but the final decision is of the operating surgeon. Patients are often continued on broad-spectrum antibiotics for 5–7 days and should remain in hospital until they tolerate a regular diet.

In patients with a solid inflammatory mass in the RLQ, without evidence of abscess cavity, suggesting a phlegmon, appendectomy can be difficult due to dense adhesions and inflammation.

In such circumstances, to reduce potential complications, many support an initially nonoperative approach. Conservative treatment failure, as evidenced by bowel obstruction, sepsis, persistent pain, or leukocytosis, requires immediate appendectomy.

Normal Appendix

Because of the difficulty in diagnosing appendicitis, it is not uncommon for a normal appendix to be found at appendectomy. This can occur >15% of the time, with considerably higher percentage in infants, the elderly, and young women. For many reasons, it is advisable to remove the grossly normal appendix. When a normal appendix is discovered at appendectomy, it is important to search for other possible causes of the patient's symptoms.

Interval Appendectomy

Factors to be considered when advising patients on interval appendectomy include a relatively low incidence of future appendicitis (8–10% and often associated with an appendicolith) and a morbidity associated with an interval appendectomy of approximately 11%.

Chronic or Recurrent Appendicitis

Patients do not present with the typical symptoms of acute appendicitis. Instead, they complain of recurrent and infrequent RLQ pain. When questioned, they may describe an initial episode with more classic symptoms of acute

appendicitis, with no treatment delivered. Because the diagnosis is often uncertain preoperatively, laparoscopy is a useful tool to allow exploration of the abdomen.

RECENT ADVANCES

Literature Review

Appendectomy versus antibiotic treatment for acute appendicitis, a Cochrane review, was prepared and maintained by the Cochrane Collaboration and published in the Cochrane Library 2011, Issue 11. Authors conclude that appendectomy remains the standard treatment for acute appendicitis. Antibiotic treatment might be used as an alternative treatment in a good-quality randomized controlled trial (RCT) or in specific patients or conditions where surgery is contraindicated.

New data show that pure transvaginal appendectomy is emerging as a safe and well-tolerated procedure for women with acute nonperforated appendicitis that reduces the burden of pain and has faster recovery times when compared with laparoscopic approaches.

Guidelines

The American College of Surgeons, the Society for Surgery of the Alimentary Tract, and the World Society of Emergency Surgery all describe appendectomy (either laparoscopic or open) as the treatment of choice for appendicitis. Regarding an antibiotic-first strategy, the American College of Surgeons patient information guide indicates that it "may be effective, but there is higher chance of recurrence"; the Society for Surgery of the Alimentary Tract patient care guidelines suggest that it is "not a widely accepted treatment"; and the World Society of Emergency Surgery states that "this conservative approach features high rates of recurrence and is therefore inferior to the appendectomy.... Nonoperative antibiotic treatment may be used as an alternative for specific patients for whom surgery is contraindicated."

SUMMARY

Appendicitis is one of the common causes of abdominal pain of less than a week duration presenting to the emergency department. Appendicitis can occur at any age. In spite of advances in imaging accuracy, appendicitis remains a high-risk disease for delayed or missed diagnosis, because of its varied presentation, absence pathognomonic sign or symptom, and poor predictive value of associated laboratory testing. Appendicitis continues to be a high risk for missed and delayed diagnosis, especially in extremes of young and elderly. Delayed or missed diagnosis in the emergency department and ruptured appendix are the important causes for increase in morbidity and mortality. No specific history, physical finding, or laboratory test can make the definitive diagnosis of appendicitis. US is helpful when positive but not accurate in excluding appendicitis or identifying the rupture. CT is accurate and also helpful in identifying the other causes of abdominal pain. Combination of findings can increase the likelihood of disease diagnosis and is helpful in further management. An algorithmic approach is helpful for evaluation of patients with suspected acute appendicitis (**Flowchart 1**).

104
CHAPTER

Anorectal Diseases

Ashok Kumar Puranik, Devendra Richhariya

INTRODUCTION

Anorectal diseases are sensitive in nature and the patient often presents in the later stage of the disease because he may feel embarrassed while giving history. An emergency physician should be aware of the presenting features, onset, frequency, character, recurrence, and systemic manifestation of various anorectal diseases. Physical examination requires proper positioning of the patient, adequate lighting, and visualization. Digital rectal examination (DRE) and anoscopy are helpful in further evaluation. It is important for the emergency physician to be more familiar with history and clinical findings of various anorectal complaints. The anorectal junction is the point where the rectosigmoid part of the intestine joins the skin (**Fig. 1**). This transition area is called dentate line, and 1–2 cm distal to the dentate line is the anal canal and distal to the anal canal is the anal verge which consists of skin, hair follicle glands, and subcutaneous tissue. The rectum above the dentate line is supplied by the superior hemorrhoidal artery and below the dentate line is supplied by the middle and inferior hemorrhoidal arteries.

HEMORRHOIDS

Hemorrhoidal disease is one of the most chronic diseases in the history of mankind. Ancient texts date back to Babylonian, Egyptian, Greek, and Hebrew cultures. Although very few people have died after hemorrhoids, this chapter will guide the practitioners in following a more humane approach to treat hemorrhoidal disease patients.

Pathophysiology

Hemorrhoids are submucosal cushions containing venules, arterioles, and smooth muscle fibers in the anal canal. These cushions are primarily located at right anterolateral (11 o'clock), right posterolateral (7 o'clock), and left lateral (3 o'clock) positions. Hemorrhoids are thought to have a role in anal continence and they aid in complete closure of anal canal at rest. Hemorrhoidal disease occurs as a result of abnormality in the constituents of these cushions leading to bleeding which may or may not be associated with the prolapse of the hemorrhoidal tissue. This can occur as a result of excessive strain, chronic constipation due to low-fiber diet, and increased internal anal sphincter tone. Diarrhea may also cause hemorrhoids because of recurrent straining. Pregnancy is also a significant risk factor for hemorrhoids, which can be reversed after delivery.

Classification of Hemorrhoids

Hemorrhoids are classified on the basis of their presence below (external hemorrhoids) and above (internal hemorrhoids) the dentate line (**Fig. 2**).

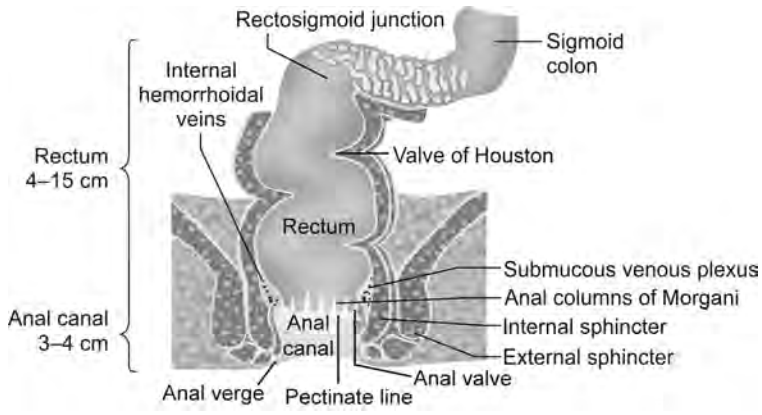

FIG. 1: Anatomy of the anorectal area.

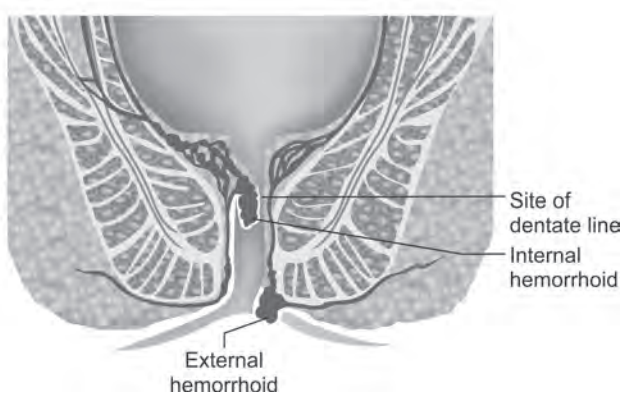

FIG. 2: Anatomy of external and internal hemorrhoids.

TABLE 1: Standard classification of internal hemorrhoids.	
Grade 1	Bleeding only
Grade 2	Prolapse with spontaneous reduction
Grade 3	Prolapse requiring manual reduction
Grade 4	Prolapsed and cannot be reduced (are at high risk for strangulation)

- *External hemorrhoids*: These are located distal to the dentate line and are covered by anoderm and because anoderm is highly innervated, the thrombosis of external hemorrhoids can be extremely painful. So, external hemorrhoids should not be ligated or excised without adequate anesthesia. Skin tag at anal verge often represents the thrombosed, fibrotic external hemorrhoids. It can cause itching and difficulty in maintaining hygiene. Treatment of external hemorrhoids and skin tag is only indicated for symptomatic relief.
- *Internal hemorrhoids*: These are located proximal to the dentate line and are covered by insensate anorectal mucosa. Internal hemorrhoids can bleed and prolapse but are rarely painful. They can become painful if severe thrombosis and necrosis occur which are usually related to severe prolapse, incarceration, and strangulation. Internal hemorrhoids are further classified clinically as given in **Table 1**.
- *Combined internal and external hemorrhoids*: These are located at the dentate line and have features of both external and internal hemorrhoids. Hemorrhoidectomy is often needed for this type of hemorrhoid.

Clinical Features

Bleeding and protrusion are the most important symptoms of hemorrhoids. Bleeding from hemorrhoids is typically bright red, either on toilet paper or into the commode after bowel movements; this is usually painless. If it is painful, then most of the time it is associated with fissure-in-ano. Although bleeding is the most common symptom, anemia is rare in these patients. Feeling of rectal fullness and perineal irritation are also associated features. Thrombosed external hemorrhoids can present as blue tender mass. Internal hemorrhoids are generally not visualized or palpated on rectal examination unless they are enlarged, prolapsed, and thrombosed.

Examination

The preferred position for examination is left lateral position with knees drawn up toward the chest as high as possible. This approach allows the patient relative comfort and the ability to clearly inspect the perineal skin and perform DRE unless he/she is thrombosed. On proctoscopy, hemorrhoids are seen as masses prolapsing into the scope.

Treatment

Medical Management/Conservative Management

Bleeding from grades 1 and II often improves by giving bulk laxatives, such as psyllium and stool softeners, and avoidance of straining. It is very important to increase the daily water intake along with fibers. Failure of conservative management is an indication for some surgical intervention.

Sclerotherapy

It was first advocated by Mitchell in 1871. The principle of sclerotherapy is scaring of submucosa which results in atrophy and fixation of the hemorrhoidal complex to the wall of the anal canal. A variety of solutions are available such as 5% phenol, sodium morrhuate, and sodium tetradecyl sulfate (STD). The procedure is performed in a patient with left lateral decubitus position. An anoscope is inserted to identify symptomatic hemorrhoids; then 1–2 mL of sclerosant is injected into the submucosal plane using a 25-gauge spinal needle. Before injection, the syringe should be aspirated to avoid intravascular injection. Accidental injection into the prostate in a male is very painful as it causes chemical prostatitis. Not more than two hemorrhoids should be injected in one sitting to avoid anal stenosis.

Rubber Band Ligation

Barron was the first to describe hemorrhoidal banding using a rubber band in 1963. It is often applied in patients with grade II and III hemorrhoids. The mucosa over the hemorrhoids, 1–2 cm above the dentate line, is grasped and pulled into the rubber band applicator. The procedure is usually well tolerated if the band is applied above the dentate line. It is important to ask the patient if he/she experiences any pain before deployment of the band. If he/she has pain before deployment of the band, it will worsen after banding. Other complications of banding include urinary retention, infection, and bleeding. Urinary retention occurs in nearly 1% of patients. Necrotizing infection is an uncommon but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the anal canal under anesthesia. Treatment includes debridement of necrotic tissue, drainage of associated abscess, and broad-spectrum antibiotics. Bleeding may occur 7–10 days after banding when ligated pedicles necrosed and sloughed. Bleeding is usually self-limiting, but persisted bleeding may require examination under anesthesia and outer ligation of the pedicle.

Infrared Coagulation and Ultroid (Direct Current) Therapy

The infrared coagulation technique uses a tungsten–halogen lamp that generates heat for 1.5 seconds leading to destruction

of mucosa and submucosal hemorrhoids. Ultroid uses direct current and is applied for 10 minutes over the hemorrhoidal complex.

Excisional Hemorrhoidectomy

Excisional hemorrhoidectomy requires a mutual decision by the physician and the patient. The physician must explain that medical and nonexcisional options are either not appropriate or law failed. The usual clinical symptoms that require surgical excision are frequent prolapse and anal seepage or hemorrhoids making anal hygiene difficult to maintain.

Milligan and Morgan Hemorrhoidectomy (Open Hemorrhoidectomy)

It was originally described in 1973 and is widely practiced in Europe. In this procedure, the entire enlarged hemorrhoidal complex is excised with ligation of the vascular pedicle and preservation of the intervening anoderm. While dissecting, the internal anal sphincter should be brushed away to preserve it. The wound is left open and allowed to heal by secondary intention.

Ferguson Hemorrhoidectomy (Closed Hemorrhoidectomy)

This technique was proposed as an alternative to open hemorrhoidectomy, as open hemorrhoidectomy has prolonged discomfort and morbidity. In this technique, an hourglass-shaped excision of internal and external hemorrhoids is done with ligation of the vascular pedicle. The center of the hourglass is anoderm. After excision, the wound is closed by an absorbable suture. It is crucial to identify the internal and external anal sphincters and preserve them. In this technique, all the primary hemorrhoids can be removed in a single sitting, although care should be taken to avoid resecting a large area of perianal skin to avoid postoperative anal stenosis.

Whitehead Hemorrhoidectomy

This technique was devised in 1982 to excise internal hemorrhoids circumferentially and relocate the prolapsed dentate line which is often a component of prolapsed hemorrhoids. In this technique, the enlarged internal hemorrhoids are excised circumferentially just proximal to the dentate line and after excision the rectal mucosa is advanced and sutured to the dentate line. But this technique has been abandoned by most surgeons because of its complications such as anal stenosis and mucosal ectropion (Whitehead's deformity).

Procedure for Prolapsed Anal Hemorrhoids or Stapled Hemorrhoidectomy

The term procedure for prolapsed hemorrhoids (PPH) has largely replaced the term stapled hemorrhoidectomy (SH) because in this procedure, the hemorrhoid tissue is not excised; instead, the redundant mucosa is fixed above the dentate line. In this procedure, a short segment of rectal mucosa proximal to the dentate line is removed circumferentially using a circular stapler. This causes the ligation of feeding venules of the hemorrhoid plexus along with fixation of redundant mucosa higher in the anal canal. But this technique is only appropriate for internal hemorrhoids and cannot be used for external or combined hemorrhoids.

Complications of Hemorrhoidectomy

Postoperative pain is the most common complication following hemorrhoidectomy. It is usually managed by oral/intravenous (IV) narcotics, nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, topical analgesics, and comfort measures such as sitz bath.

Urinary retention is another common complication after hemorrhoidectomy and occurs in 10–50% of patients. The incidence can be reduced by minimizing the intraoperative and perioperative IV fluids and providing adequate analgesics.

Fecal impaction is also a complication of postoperative pain which can be minimized by adequate analgesia and liberal use of laxatives.

Bleeding is also a common complication after hemorrhoidectomy. A small amount of blood with stool is suspected, but massive bleed requires urgent examination and pedicle ligation under anesthesia in the operation theater (OT). Bleeding can occur after 7–10 days when necrotic mucosa overlying the vascular pedicle sloughs, although some of the patients can be safely observed; however if the bleeding is massive, it may require examination and suture ligation of the vessel in the OT.

Infection is a rare complication after hemorrhoidectomy but necrotizing soft-tissue infection, mostly in immunocompromised individuals, can be devastating. Severe pain, fever, and urinary retention are the early signs of such infection. In this condition, emergency examination and debridement should be done under anesthesia. Long-term complications include anal stenosis and ectropion (after Whitehead's hemorrhoidectomy).

ANAL FISSURE

Anal fissure is a tear in anoderm distal to the dentate line, which may be acute or chronic. Acute fissure is a simple laceration, whereas a chronic anal fissure is an ulceration with scarred edges and visible internal sphincter muscles at its base with anal tag and hypertrophied papilla at the dentate line. Anal fissure almost always occurs in midline with posterior location predominance (90% in women and 99% in men). Fissures located at other than these sites often indicate some serious systemic pathology such as Crohn's disease, human immunodeficiency virus (HIV), leukemia, and other immune deficiency syndromes.

Etiology

The etiology of anal fissure is probably trauma because of passing hard stool or prolonged diarrhea. Prior anal injury or surgery leading to stenosis, stricture, or scarring is a predisposing factor. Various theories about the cause have been proposed; among them, the theory of vascular anatomy of the internal anal sphincter is most compelling. In 1989, Klosterhalfen et al. reported the anatomical detail of the branches of the inferior hemorrhoidal artery. In this study, they found that in 85% of cadaveric specimens, the posterior commissure of anal canal was not directly perfused; rather they received blood supply from end arterioles. So, there is poor perfusion of mucosa in the posterior midline along with this sphincteric spasm and hypertonicity which is common in this disease and may further decrease blood flow in the posterior midline. Schouten et al. have shown a correlation between increased anal tone and decreased vascularity by using a laser Doppler flowmeter.

Infections also cause anal fissure over the last century. Sexually transmitted infections and infections associated with an immunocompromised state may be a cause of anal fissure. Chancroid, herpes virus, and cytomegalovirus usually present as multiple superficial ulcers, while syphilitic ulcers have purulent discharge with granulation at the base. So, it is very important to properly diagnose the disease because treatment of these conditions is different.

Diagnosis

A burning pain or tearing pain while defecation is the most common symptom of anal fissure. Bleeding is usually only detected on toilet paper. Pain may last for minutes to hours. The examination should be gentle by separating the buttocks. Patients are often intolerant to DRE and proctoscopy. Topical anesthesia does not provide free examination. Atypical location of fissure requires more intensive history-taking and investigation to rule out Crohn's disease, HIV, and other immunodeficiency diseases.

Management

Nonsurgical Management

- *Conservative management*: The first-line treatment for simple, acute fissures-in-ano is warm sitz bath with stool softeners. Warm water reduces the discomfort by muscle relaxation, while stool softeners prevent trauma to the mucosa by loosening the stool. Stool softeners, such as psyllium, bran, and fiber, draw water and retain it in stool, thus making it soft. Furthermore, bran has been shown to be effective in preventing recurrence of acute anal fissure. Topical creams and steroids have a limited role in management and are not routinely recommended. This conservative management successfully heal 90% of acute fissure and 40% of chronic fissure.
- *Nitroglycerine*: It is a nitric oxide donor and nitric oxide is a potent smooth muscle relaxant, leading to vasodilatation. In view of etiology of anal fissure: Increase in anal tone and poor vascularity in posterior anal canal, nitric oxide provide immediate relief (5 min) of pain and spasm and also promote healing of fissure.

Headache is a significant side effect of nitroglycerine, which limits its use. Other side effects are orthostatic hypotension, syncopal attack, and tachyphylaxis. These are uncommon side effects.

- *Calcium channel blockers*: Nifedipine and diltiazem can be used as agents of "chemical sphincterotomy." Topical nifedipine reduces sending anal tone and then facilitates healing and relieves pain. About 2% topical diltiazem is equally effective as nitroglycerine. Topical diltiazem can heal up to 75% of anal fissures that have failed to heal by nitroglycerine alone. This class of drug supersedes nitroglycerine in the treatment of chronic anal fissure because of better effectiveness and better side-effect profile.
- *Botulinum toxin (Botox)*: Another alternative for "chemical sphincterotomy" is botulinum toxin A, an exotoxin produced by *Clostridium botulinum* that prevents the release of acetylcholine from presynaptic vesicles leading to muscle paralysis. It is an effective treatment option for chronic anal fissures. In one study, 75% of chronic anal fissures healed at 8 weeks with no recurrence in 16 months' follow-up. Complications of this form of treatment are infrequent and include transient incontinence, mainly flatus and perianal hematoma formation.

Surgical Management

Lateral internal anal partial sphincterotomy (LIS) is done in patients who fail to respond to nonsurgical management options. This procedure was originally described by Eisenhammer in 1951 as a midline posterior incision through the fissure. But subsequent studies found problems with wound healing and formation of a "keyhole" deformity. "Keyhole" deformity is a persistent groove in the midline after the posterior division of sphincter; it causes problems such as anal seepage and incontinence. Subsequent modifications to this procedure lead to repositioning of the incision to the right or left lateral position, which has effectively eliminated the complication of this deformity. *Fissurectomy* is the excision of the anal fissure. This procedure results in a defect in anoderm, which can be covered with a rotational or advancement flap to avoid "keyhole" deformity.

Calibrated balloon dilation is also an effective technique for the management of chronic anal fissures. A study comparing LIS with pneumatic balloon dilation found the healing rate of fissures to be 83.3% in the pneumatic balloon dilation group and 92% in the LIS group. At 24 months' follow-up, incontinence was 0 in the pneumatic balloon dilation group and 16% in the LIS group. So, pneumatic balloon dilation is also a safe and efficacious method.

ANORECTAL ABSCESS

Anorectal suppuration can present with acute or chronic manifestation. Anorectal abscess forms the acute presentation and anal fistula represents the chronic form. Depending on the anatomical location of abscess, the etiology and management vary (**Fig. 3**).

Etiopathogenesis

The most widely accepted theory for the development of anorectal suppuration is the cryptoglandular theory of anal

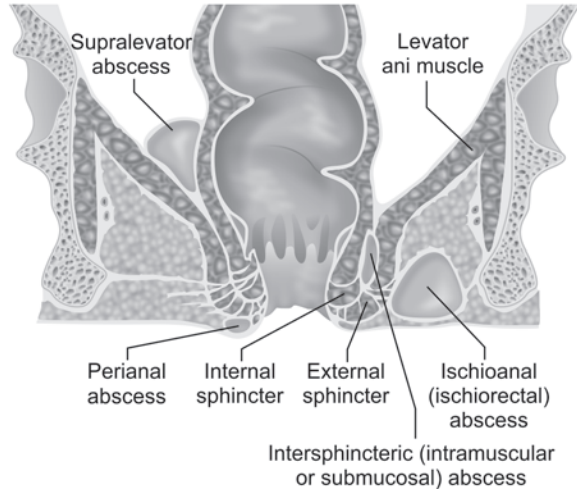

FIG. 3: Anorectal abscess.

sepsis. Anal glands are located in the intersphincteric space and their ducts traverse the internal sphincter and open into the anal crypts at the level of dentate line. Blockage of ducts with fecal bacterial plugging leads to infection of anal glands and abscess formation. The abscess usually originates in the intersphincteric space and can remain isolated or spread vertically upward or downward, horizontally or circumferentially, to any of the perianal or perirectal spaces. Other factors include immunodeficiency due to malignancy (anorectal/hematological) or HIV infection, tuberculosis, actinomycosis, trauma, foreign body, postoperative infection, inflammatory bowel disease, hidradenitis suppurativa, intra-abdominal pathology (in supralevator abscess), etc. Both aerobic and anaerobic bacteria are implicated. Most common aerobes include *Staphylococcus aureus*, *Streptococcus*, *Escherichia coli,* etc., and anaerobes include *Bacteroides fragilis*, *Peptostreptococcus*, *Clostridium,* etc. Recently, Methicillin-resistant *Staphylococcus aureus* strains have also been identified in some abscesses in immunocompromised and recurrent cases.

Types of Anorectal Abscess

Anorectal abscess is classified based on anatomical location into:

- Intersphincteric abscess
- Perianal abscess
- Ischiorectal abscess
- Postanal abscess and horseshoe extension
- Supralevator abscess

Intersphincteric Abscess

Intersphincteric space is found between internal and external anal sphincters. Intersphincteric abscesses are usually difficult to diagnose due to no visible evidence of inflammation (hidden abscess). They present with severe anal pain that may preclude a DRE. Examination under general anesthesia is usually required for diagnosis. Management is by draining the abscess via posterior internal sphincterotomy.

Perianal Abscess

Intersphincteric abscess may spread vertically downward to the perianal space. Perianal abscesses constitute the most common (60%) type of anorectal abscesses. They present with painful swelling at the anal verge. The incision for drainage is placed close to the anal verge, and a disc of skin is usually removed to prevent premature closure. Care must be taken to prevent damage of the underlying sphincter muscle. No packing is required. Sitz bath is initiated from the next day.

Ischiorectal Abscess

Intersphincteric abscess may spread laterally beyond the external sphincter to involve the ischiorectal space. The ischiorectal space is bounded medially by the external sphincter, laterally by the ischium, superiorly by levator ani, and inferiorly by the transverse perianal septum. Ischiorectal abscess may expand slowly till the roof of fossa without much signs and later present with a large, indurated mass in buttock. Simple ischiorectal abscesses are drained through an incision in the overlying skin. Vigorous debridement of abscess cavity is usually avoided to prevent injury to the inferior rectal branch of the internal pudendal nerve, which supplies the external anal sphincter and levator ani muscles.

Postanal Abscess and Horseshoe Extension

Deep postanal space lies posterior to anus and anterior to sacrum, deeper to the anococcygeal ligament, and superficial to the levator ani muscles. Trans-sphincteric extension of an intersphincteric abscess to the posterior midline forms a postanal abscess. They usually present with tenderness posterior to anus without obvious signs of inflammation (hidden abscess) and can be diagnosed by needle aspiration or examination under general anesthesia. A horseshoe abscess is produced when the ischiorectal abscess of one side spreads to the contralateral side via the deep postanal space. It is managed by a modified Hanley procedure in which a posterior midline incision is made over the postanal abscess by incising the anococcygeal ligament, and counter-drainage incisions are made over each ischiorectal space.

Supralevator Abscess

The supralevator space lies superior to levator ani and lateral to rectum and communicates posteriorly. Supralevator abscess occurs following an upward extension of the intersphincteric abscess or secondary to intra-abdominal or pelvic pathology such as appendicitis, diverticulitis, pelvic inflammatory disease, and ruptured viscus. An indurated, bulging mass is found above the anorectal ring on DRE. Management of supralevator abscess depends on its etiology. If it is secondary to upward extension of the intersphincteric abscess, drainage is performed internally through the rectum. Drainage through the ischiorectal fossa is avoided in such cases to prevent the formation of a complicated suprasphincteric fistula. If the abscess is secondary to ischiorectal abscess, then the incision is placed over the ischiorectal fossa and this may lead to the formation of an extrasphincteric fistula. Abscesses secondary to intra-abdominal or pelvic pathology require treatment of the underlying condition and direct drainage of the abscess transabdominally.

Clinical Presentation

The presentation varies depending on the anatomical location. Classically, patients present with severe anal pain out of proportion to physical examination findings. Some patients, especially immunocompromised, may present with fever, urinary retention, or life-threatening sepsis. 20–33% of patients provide a history of previous anorectal suppuration. A palpable mass may be found in the perianal area or by DRE, depending on the location of abscess. Tenderness may be present; however, fluctuation is very rarely elicited in the perianal region. Sometimes, no signs of inflammation may be found, especially in hidden abscesses.

Diagnosis

Diagnosis is made clinically by local examination. Examination under general anesthesia may be required in complex, deep-seated abscesses and in immunocompromised. Pelvic imaging studies such as computed tomography (CT), magnetic resonance imaging (MRI), and fistulography are usually indicated in complex and recurrent abscesses following inadequate drainage, immunosuppression, presence of fistula, etc.

Management

Management consists of incision and drainage of abscess, usually under local anesthesia, as an office procedure. Complex abscesses may require exploration and drainage under general anesthesia. Timely management is required to prevent extensive necrosis and life-threatening sepsis, especially in immunocompromised. Antibiotics and abscess culture are indicated if there is a history of immunosuppression, associated systemic illness such as diabetes mellitus, extensive cellulitis, etc. Biopsy to rule out leukemic infiltration is also performed.

ANAL FISTULA

Anal fistula is a chronic manifestation of anorectal abscess. In simple words, anal fistula represents a communication between the anal canal and the perineal skin. The most common cause of anorectal abscess is infection of the anal glands. This is called cryptoglandular theory of anal sepsis. Fecal bacterial plugging of the duct of the anal glands leads to infection in the gland and subsequently abscess formation, leading to anal fistula. Other etiological factors include trauma, Crohn's disease, malignancy, radiation, and unusual infections such as tuberculosis, chlamydia, or actinomycosis. These factors should be considered in the complex, recurrent, or nonhealing fistula.

Classification of Anal Fistula

The classification done by Park et al. in 1967 is the most commonly used classification system, which is as follows:

- *Intersphincteric*: The fistula is confined to the inter-sphincteric plane.
- *Trans-sphincteric*: The fistula traverses the external sphincter, communicating with the ischiorectal fossa.
- *Suprasphincteric*: The fistula extends cephalad over the external sphincter and perforates the levator ani.
- *Extrasphincteric*: The fistula extends from the rectum to the perianal skin, external to the sphincter apparatus.

Clinical Features

Most patients have a history of perineal abscess. Patients usually present with complaints of purulent discharge from the external opening in the perineal region. This discharge is usually intermittent. Classically, the symptom of discharge may also be associated with build-up of pain, mild fever, and pain on defecation, followed by mucopurulent discharge with relief of pain.

Physical Examination

On careful examination of the perineal region, an external opening is often easily seen. It can be identified as a small pit surrounded by localized fibrosis. Active discharge may or may not be present. On DRE, the internal opening may be felt as an indurated nodule or a small area most often at the level of dentate line. The indurated tract may also be palpable. If the external opening is close to the anal verge, the fistula is usually intersphincteric. Trans-sphincteric and other complex fistulas usually open far away from the anal verge. At times, there could be multiple external openings due to multiple complex fistula tracts. This condition is called watering-can perineum.

Clinical examination described nearly 100 years ago by Goodsall and Miles tells about the internal opening in relation to the external opening. The rule states that the external opening anterior to the imaginary transverse line in the coronal plane most likely communicates with an internal opening lying at the end of a radial line drawn to the nearest crypt at the dentate line. If the external opening is posterior to this line, the internal opening will most likely be located in the posterior midline following a curved tract. Exception to this is an anterior opening more than 3 cm away from the anal verge and the presence of multiple external openings. The internal opening in this condition will most likely be in the posterior midline.

Investigations

Sigmoidoscopy and colonoscopy: Sigmoidoscopy should be performed in all patients with anorectal fistula to rule out associated conditions such as neoplasm, inflammatory bowel disease, or secondary tract in the rectum.

Fistulography: It may be done in patients with recurrent fistulas when the prior procedure has failed to identify the internal opening. In this procedure, the external opening is cannulated through which contrast material is injected with minimal pressure, and multiple X-ray images are taken at different angles. However, a study by Kuijpers and Schulpen found that fistulography is unreliable when compared to intraoperative findings. They also found that it gives high false-positive results, and this leads to unnecessary and harmful surgical exploration.

Anorectal ultrasonography: It can delineate the muscle anatomy of anal sphincters and its relation to the fistula tract. Internal opening is usually not identified, but it can be accurate in localization of the fistula tract and/or abscess. The injection of hydrogen peroxide into the tract acts as an image enhancer and is helpful in detecting the complex fistula. Now, three-dimensional endoanal ultrasonography can reliably and accurately diagnose fistula-in-ano with or without hydrogen peroxide enhancement.

Magnetic resonance imaging: MRI is an accurate method of imaging an anal fistula disease. With great accuracy, it can identify the internal opening dose of the fistula tract and its external opening. MRI is particularly very useful in cases of complex fistula and secondary extension of tract. In a study by Beets-Tan et al., the sensitivity of MRI done preoperatively is 100% and specificity is 86%. When combined with endoanal ultrasound, the accuracy of diagnosis is further enhanced.

Computed tomography: The use of CT scan is limited in diagnosis of fistula-in-ano because of its poor visualization of levators and sphincteric complex.

Anorectal manometry: Manometry helps in identifying the patients who are at a greater risk of postoperative incontinence. This can help in tailoring the surgical management for improved clinical and surgical outcomes. This is especially indicated in patients requiring a division of the substantial portion of anal sphincter for its cure, in multipara women, and in women with a history of forceps delivery, third-degree perineal tear, and prolonged second stage of labor.

Fistuloscopy: This, done by using urethroscopy, is a helpful technique in the intraoperative evaluation of fistula openings,

identifying tracts, and iatrogenic tracts. Newer flexible ureteroscopes are in developmental stages. This could be of great help in diagnosing and treating an anal fistula.

Treatment

The treatment and outcome of an anal fistula depend on various factors such as classification of fistula, identification of internal and external openings, course of the fistulous tract, and amount of the sphincter involved. The external opening is usually visible as an indurated, elevated, granulomatous tissue with purulent discharge. The identification of the internal opening is difficult. Injection of hydrogen peroxide and methylene blue mixture is helpful identification of the internal opening. A simple intersphincteric fistula can be managed by fistulectomy (opening the tract) followed by curettage, and the wound is left open to heal by secondary intention.

Treatment of fistula that involves <30% of sphincter complex can be treated by sphincterotomy without having much risk of incontinence. A fistula that involves >30% of sphincter or high intersphincteric fistulas usually require placement of seton. It is placed loosely through the tract to facilitate drainage of any sepsis and to preserve the sphincter. Later, it can be converted to cutting seton which is periodically tightened to cut through the involved sphincter and to promote fibrosis. This avoids the resulting incontinence.

Other methods for a complex anal fistula include fibrin glue and porcine-derived fistula plug. Both are biological products used for fistula healing without division of the sphincter complex. They cause healing of the tract by providing an extracellular matrix which serves as a scaffold which allows cellular ingrowth and remodeling leading to tract obliteration. Successful obliteration of the tract by fibrin glue was seen in 14–60% of cases. A high fistula or persistent fistula can be treated by sliding advancement flap of mucosa, submucosa, and circular muscle to cover the internal opening.

The new technique in treatment of anal fistula is LIFT (ligation of intersphincteric fistula tract). In this technique, dissection is done in the intersphincteric plane, and the fistula tract is identified and ligated. This leads to obliteration of the communication with the anal canal. The success rate of this technique is 60–94%.

PILONIDAL DISEASE

Pilonidal disease is a condition of the intergluteal cleft in which hair containing sinus or abscess develops. The sinus may be a single tract or may be branched. It can spread laterally which emerges as granulation tissue-lined openings over the skin, usually in midline. The incidence of pilonidal sinus is 26 per 100,000 people. The morbidity associated with this disease is high due to its nature, wound complications after surgery, and high recurrence rate, thus generating a challenge for the surgeon.

Etiopathogenesis

Pilonidal disease was first described by M Hodges in 1880 as a sinus containing nest of hair. Earlier, it was considered to be of congenital origin. Gage in 1935 proposed that sinus disease was secondary to anomalous embryonic development of the medullary canal. Many theories thereafter have attributed pilonidal disease to be more of an acquired disease. Hardaway noted that pilonidal disease was "apparently much common in the military service than in civilian life." He attributed this to the poor hygienic conditions. He postulated that compression and irritation of the coccyx during field activities, such as jeep driving, was the cause of the disease. Thus, it was also called "jeep disease." Patey and Scarff in 1946 compared the histology of congenital dermoid and pilonidal sinus. He noted that the dermoid had epithelialized tracts while the pilonidal sinus had granulation tissue-lined tracts which were formed by foreign body granulomatous reaction to surface hairs. Hair follicles are almost never seen in the wall of the sinus. Dead hair is usually present within the sinus cavity. Bascom further explained that a vacuum force is created by the intergluteal cleft that directs hair into the subcutaneous tissue. This forms the basis behind Bascom cleft lift procedure.

Karydaki in 1992 described three main factors for the development of pilonidal disease. The factors are: (1) Invasion of loose hair, (2) Hair embedding, and (3) Vulnerability of the affected skin. These factors were considered in the Karydakis flap reconstruction where a more resistant gluteal skin flap was used. These theories suggest that pilonidal disease is caused due to local irritation from embedded loose cut hairs. The presence of the interdigital pilonidal disease in hairdressers and of the pilonidal disease in other sites such as umbilicus supports the acquired nature of the disease. Rarely, a carcinoma can arise from a chronic pilonidal disease.

Histologically, the pilonidal sinus tract is lined by chronic granulation tissue. The midline pits have a squamous epithelial lining whereas the tract has no epithelium. Foreign body giant cells are seen associated with hair shafts within a background of chronic granulation tissue. Microbiology gram-negative and anaerobes are mostly seen in pilonidal disease. In recurrent disease, gram-positive and aerobic bacteria are present.

Clinical Presentation

Pilonidal disease is seen 2.2 times more frequently in men as compared to women. It is seen in the second to third decade of life. Rarely it occurs in <15 or >40 years of age.

Risk factors include obesity, degree of hair growth, family history of pilonidal disease, local trauma, sedentary occupation, and dark-haired individuals. It is more commonly seen in whites and non-Hispanic populations. It is rarely seen in Asian and Pacific populations.

In 50% of pilonidal diseases, acute presentation is seen. In acute cases, the pilonidal disease presents as an abscess. It is present over the sacrococcygeal region causing pain over the area, fluctuating mass with overlying cellulitis on examination. It lies just cephalad to the midline pit above the gluteal cleft.

In chronic cases, a cavity develops which drains into single or multiple sinuses. These sinuses are located in the midline and lie between the sacrococcygeal joint and the tip of the coccyx. The cavity and sinus openings usually run cephalad, thus differentiating it from a perianal fistula.

Diagnosis

Pilonidal disease is a clinical diagnosis due to its characteristic appearance. Differential diagnosis includes hidradenitis suppurativa, furuncle, perianal abscess or fistula, sacral osteomyelitis, syphilis, tuberculosis, and actinomycosis. Malignant degeneration can occur in 0.1% cases. Squamous cell carcinoma is most commonly seen. It occurs in middle-

aged men with long-standing disease. Hence, histopathological evaluation of an excised specimen is necessary.

Treatment

Earlier when pilonidal disease was considered to be of congenital origin, complete excision of sinus tract up to the sacral fascia was done. With recent theories suggesting an acquired form of disease, complete resection with primary closure is done attending to the offending tissue and the underlying mechanism. The goal of treatment is complete wound healing with minimum morbidity and low recurrence rate. In a Cochrane review, there is no clear benefit of primary closure over an open approach with regard to healing time and infection rates. Primary closure techniques where the incision is placed laterally are considered best. Taking all factors into consideration, an individualized approach should be adopted by the surgeon for treatment of the pilonidal disease.

Acute Pilonidal Abscess

A definitive resection with abscess excision results in higher recurrence rates; hence, a stages approach is used. It can be done in an outpatient setting in the emergency room. Prone jackknife position is given and buttocks are taped apart. A paramedian longitudinal incision is made over the abscess. All debris and hair are curetted from the cavity. Unroofing and fulguration of the tract are done. Sitz bath has to be done daily to maintain hygiene. The wound is evaluated weekly to check for healing and to ensure that it is free of debris and hair. The retained hair is a major factor for nonhealing and recurrence. This procedure has a recurrence rate of 2%.

Chronic Pilonidal Disease

Chronic pilonidal disease is seen in 15–40% of patients treated for acute abscess. Recurrence following previous surgeries is also high. There is no single ideal technique for the treatment of pilonidal sinus. Various techniques are available for the treatment. Antibiotics against anaerobic bacteria may improve healing as suggested in some studies.

Conservative Approach

It consists of hair control by shaving or laser therapy, maintaining perineal hygiene. Limited lateral incision and drainage of abscess are required.

Midline Follicle Excision and Lateral Drainage—Bascom Technique

In this technique, the midline sinus pits are excised using a fine scalpel blade up to the presacral cavity and left open. An incision is made laterally 1 cm from the midline to expose the presacral cavity deep to the pits. The cavity is opened, and debridement of necrotic material, hair, and granulation tissue is done. The wound is then left for secondary healing. Frequent follow-up is required for hair removal. The advantages of this technique are minimal morbidity and a short healing time. In modified Bascom's technique, the midline excised pits are closed using a nonabsorbable suture. The lateral incision helps in curetting out the granulation tissue and hairs. It also releases the midline skin from the presacral fascia, thus preventing tethering. In the modified technique, it prevents any tension on the primary closure of the pits. Fibrin glue can be applied after excision and curettage of the sinus tract.

Incision and Curettage with Marsupialization or Saucerization

In this technique, the sinus tract is identified and deroofing of the tract is done along with curettage. The fistula probe is used to identify secondary tracts which are also deroofed. In saucerization, the skin edge is beveled to allow drainage. In marsupialization, the skin is sutured to the base of the wound. Negative pressure wound therapy can be used over the raw area to improve healing. This procedure has a recurrence rate of 1–19%, low complication rate, short operative time, and early return to work.

Excision with or without Closure

The pilonidal sinus along with the surrounding inflammatory tissue is excised up to the sacral fascia. The wound can then be primarily closed or left open for secondary healing. Data from a meta-analysis suggest rapid healing with primary closure as compared to secondary healing. There is no difference in infection rates between the two techniques. The recurrence rate was, however, lower in secondary healing. In midline and lateral incision comparison studies, lateral incisions had better healing rates, lower infection rate, and lower recurrence rates.

Karydakis Flap

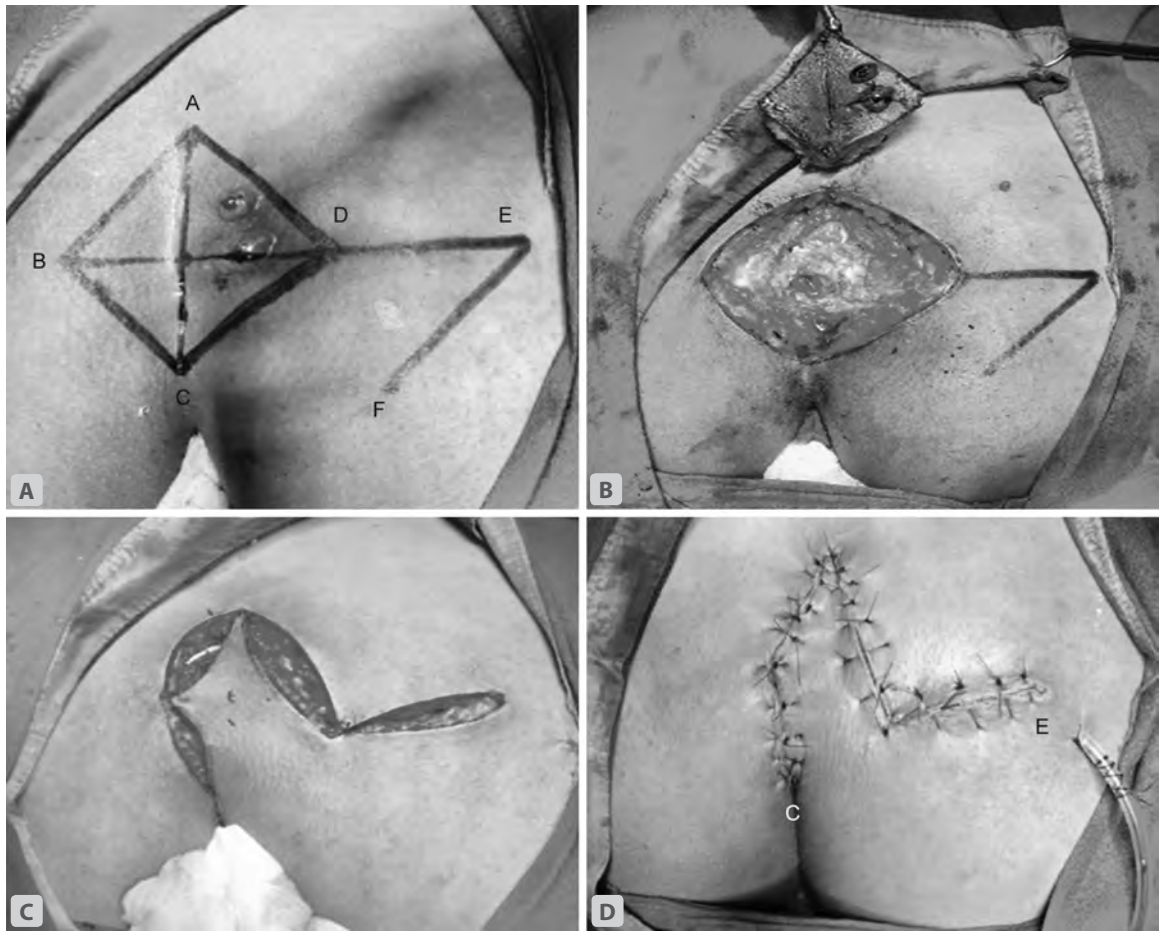
In this technique, an elliptical incision is given. Skin and subcutaneous fat are excised up to the fascia. The ellipse is placed away from the midline. The medial side should just cross the midline and should include the diseased tissue. The medial end is then mobilized by undercutting. Sutures are then placed between the limit of undercutting and the sacral fascia in the midline. This creates a shallow midline sulcus. The subcutaneous tissue is then closed by interrupted sutures after placing a suction drain. The skin is then closed using interrupted sutures. As a result, the incision line lies lateral to midline. This technique cannot be used in bilateral sinus disease.

Limberg Flap

A rhomboid area containing the diseased tissue is marked. The flap that will be utilized for cover is also marked prior to incision. Points A, B, C, D, E, F are marked as shown in **Figure 4**. Line A–C should lie in the midline. C should lie toward the perianal region. Line B–D should intersect line A–C at right angles. Line B–D is extended up to point E. The length of D–E should be equal to A–B. The length of E–F should be equal to A–D and parallel to D–C. Rhomboid excision of the diseased tissue is then done. The flap is then raised containing the skin and subcutaneous tissue up to the fascia. The flap is then rotated over the defect. Point E is sutured to point A. A suction drain is placed. Subcutaneous tissue and skin are then closed by interrupted suture.

Cleft Lift Procedure

This technique is used for a chronic, nonhealing midline wound. The midline wound is excised in a triangular shape. A full-thickness skin flap is raised to overlap the skin edges of



FIGS. 4A TO D: (A) Rhomboid excision with Limberg flap. (B) Rhomboid area to be excised and flap to be taken is marked. (C) Rhomboid excision of diseased tissue is done. (D) Flap created and fixed at points A, B, C, D suction drain in situ. ***(For color version, see plate 12)***

the wound on the opposite side. The skin is then closed over a suction drain. As a result, the superior gluteal cleft is eliminated and incision is displaced laterally.

Recurrent Pilonidal Disease

These patients require a radical approach. A wide excision of the tract along with the diseased tissue is done. It results in creation of a large defect. This defect can then be closed by Z-plasty, V-Y flap, rhomboid excision and Limberg flap, Karydakis flap, or cleft lift procedure. This procedure carries higher morbidity.

RECTAL PROLAPSE

Protrusion of rectal wall through anal orifice is termed rectal prolapse. It is relatively rare condition and malnourished children and elderly mostly affected. Elderly females commonly present with another pelvic organ involvement, e.g., uterine, vaginal prolapse, rectocele urethrocele, or enterocele. The risk factors associated with rectal prolapse are constipation, recurrent or massive diarrhea, fecal incontinence, and rectal ulcers.

Most common complaints are fullness of rectal area; associated symptoms are pain, constipation, and abdominal pain. Careful examination is required by the emergency physician as this condition is misdiagnosed as prolapsed hemorrhoids. Management strategies depend on careful evaluation of incarceration, thrombosis, and strangulation and depend on the presence of ischemia. If signs of ischemia are present, prolapse should be reduced by the surgeon in the operating room. Manual reduction can be attempted in the emergency department (ED) if signs of ischemia are not present. Gentle pressure is sufficient to reduce the prolapse, if edema is present; application of granulated sugar (which causes desiccation of mucosa) can reduce the edema. Once reduction is successful, the patient can be discharged home with follow-up in the surgery outpatient department. Stool softener fiber supplements should be prescribed to the patient with instruction to stay well hydrated to avoid constipation.

RECTAL TRAUMA/FOREIGN BODY

Rectal trauma is less common, mostly due to penetrating injuries, shooting, and road traffic accident. Rectal blunt injury is less common than penetrating injury.

Rectal trauma may occur due to foreign bodies also but is less reported to the ED. The incidence of rectal foreign bodies is reported due to voluntary insertion for sexual stimulation and autoeroticism; however, sexual assault is also reported. Prisoners and psychiatric patients can also hide sharp objects or drugs in their rectum. Obtaining history from a patient with rectal foreign bodies is quite difficult; rectal fullness, rectal pain, rectal bleeding, abdominal discomfort, and constipation are common complaints.

Rectal trauma or rectal foreign body need clinical as well as radiological assessment. Secondary survey is also necessary to assess pelvic fracture, peroneal or transpelvic injuries, and rectal or urethral bleeding. Assessment of rectal trauma with higher sensitivity is possible with rigid proctosigmoidoscopy which also detects extraperitoneal injuries. A CT scan with contrast is the gold standard with high sensitivity and specificity for detecting rectal trauma. *There are five grades of rectal injury* are described by the American Association of Surgery for Trauma (Grade I: Contusion/partial thickness laceration, Grades II–IV: Laceration of varying degree from <50% of circumference to full thickness, Grade V: Devascularized segment).

A plain radiograph has poor sensitivity and specificity and is only helpful in detecting the foreign body. Lateral and anteroposterior plain radiology film is sufficient to detect a rectal foreign body. The number, size, shape, location, and orientation of foreign body can be detected. Colonic perforation, bowel obstruction, hemorrhage, deep mucosal tear, abscess, and peritonitis are the complications of a rectal foreign body.

The general surgeon should be consulted for rectal trauma as multiple concomitant injuries may need attention. Rectal foreign bodies above the rectosigmoid junction should be removed by the surgeon. If a rectal foreign body is palpable on rectal examination, the emergency physician may attempt to remove it. Enema and anal dilatation followed by digital extraction can be attempted. 1% lidocaine or 0.5% of bupivacaine can be used during extraction to relax the anal sphincter. An anoscope or sigmoidoscope is helpful in direct visualization of foreign objects and also prevents iatrogenic injuries. Foreign bodies are difficult to extract by the trans-anal route if the size of the object is >10 cm, it is a sharp object, it has slipped to sigmoid, or it is older than 2 days. Proctosigmoidoscopy should be arranged and performed after removal of foreign body to assess bleeding by mucosal tear bowel injury and residual foreign bodies. The patient should be observed in the ED if a mucosal tear is confirmed.

PROCTITIS

Proctitis is present with nonspecific features such as irritation, itching, burning, and tenesmus and is characterized by inflammation of the rectal mucosa within 15 cm of the dentate line. Proctitis can be acute or chronic and secondary to various other diseases, e.g., sexually transmitted diseases, radiation, medication (antibiotics), autoimmune diseases (Crohn's disease, ulcerative colitis, celiac), iatrogenic (chemicals, trauma, rectal instrumentation), and idiopathic. In response to various irritants, the inflammatory process develops, e.g., loss of mucosal cell, eosinophilia, and endothelial edema. Acute reaction progresses to fibrosis of connective tissue, arteriolar endarteritis, and tissue ischemia leading to bleeding, ulceration, stricture, and fistula. The patient presents with nonspecific complaints and nonspecific examination findings such as mucosal erythema and mucosal friability. Symptomatic supportive care is important in proctitis. Sitz bath, antispasmodic medication, stool softener, and high-fiber diet are recommended. Treatment should be started if any systemic cause of proctitis is identified. Antibiotics (infectious cause), antiviral (viral etiology), and steroids (autoimmune/radiation cause) can be prescribed by the gastroenterologist/colorectal surgeon on follow-up.

PRURITUS ANI

The burning and itching sensation in the perianal region is pruritus ani. After hemorrhoids, it is the most common condition and most of the people do not take medical advice for this condition. 50–90% of cases are primary or idiopathic (no obvious cause), and secondary causes are given in **Table 2**. The problem starts with mild itching and burning which progress to intolerant soreness and itchiness and lead to scratching and excoriation causing skin injury (stage 0: normal skin, stage 1: red and inflamed skin, stage 2: white and lichenified skin, stage 3: lichenified skin, coarse ridges, and may ulcerate).

For primary and idiopathic pruritus ani, symptomatic treatment is started. Maintain dry clean and intact perineal skin. Loose-fitting undergarments are advised. Inflammation is reduced by zinc oxide and corticosteroid topical barriers. Medicated soap and topical anesthesia are discouraged. Treatment of the underlying cause should be initiated for secondary pruritus ani. Intractable pruritus ani is treated with low-dose capsaicin cream. Severe and resistant cases are treated with methylene blue injection (in the sensory nerve bundle of the perineal area), sclerotherapy, radiation therapy, and surgical procedures.

PROCTALGIA FUGAX

Proctalgia fugax is a gastrointestinal disorder that causes severe, self-limiting anorectal pain usually lasting 5 seconds to 90 minutes. Patients experience this fleeting and recurring pain over weeks, with no pain between episodes. Although this is a diagnosis of exclusion in the ED, it is important to be aware of the condition. It has several triggers, including sexual activity, stress, constipation, defecation, and menstruation. This disease affects women more than men, most commonly between the ages of 30 and 60 years, with a prevalence of 4–18% in the general population. Proctalgia fugax is thought to be caused by spasm of the internal anal sphincter or compression of the pudendal nerve. Given the fleeting nature of the pain, patients usually do not require medications; however, those with severe symptoms might get relief with topical treatments such as nitroglycerin or diltiazem. Nonpharmacologic agents, such as biofeedback, have been shown to be effective as well.

TABLE 2: Secondary causes of pruritus ani.

Mechanical	Anal fissure, fistula, hemorrhoids, trauma, tight undergarment, unhygienic conditions, vaginal discharge
Dermatitis	Eczema, psoriasis, lichen planus, erythema multiforme
Infections	Pinworm, *Candida*, sexually transmitted disease
Systemic	Diabetes, cholestasis, renal failure, leukemia, HIV, vitamin A, D, and iron deficiency, obesity
Inflammatory	Inflammatory bowel disease
Malignancy	Squamous cell carcinoma, melanoma
Medication	Colchicine, neomycin
Dietary	Tea, coffee, soda, chocolate

SUMMARY

Emergency Physician may get patients of anorectal complaints emergency department. Most of these complaints can be managed conservatively because they are benign and; however, clinicians must be aware that there are a few anorectal emergencies can progress and present as complication. The history and physical examination are important so that critical disorders can be recognized and specific treatment plans can be initiated early. It is important to maintain a broad differential diagnosis of anorectal disease to distinguish benign from serious anorectal disease and its complications. Thorough history and physical can help distinguish between different types of anorectal complaints. Most anorectal complaints can be managed conservatively, but it is imperative to know when to consult surgeons.

105 CHAPTER

Vascular Abdominal Emergencies

Devendra Richhariya

INTRODUCTION

An emergency physician should be ready to consider the uncommon diagnoses while managing abdominal emergencies or a patient with nausea, vomiting, and diarrhea or a patient with abdominal, back, or flank pain. Abdominal vascular emergencies in the differential diagnosis should be considered. Vascular abdominal emergencies are not common and on the basis of clinical findings, they are also difficult to identify and a high index of suspicion is required which when present are often catastrophic. Most of the conditions are time-sensitive, putting perfusion of critical organs (e.g., the bowel) at risk, thus leading to the potential for ischemia, infarction, and translocation of enteric microbes, bacteremia, and sepsis. Aneurysmal dilation of the aorta with rupture leads to rapid hypovolemic shock and death if not diagnosed. Most of the vascular emergencies of abdomen require surgical intervention; diagnostic testing should be performed along with resuscitation, consultation, and involvement of the vascular or general surgeon.

VASCULAR ABDOMINAL ANATOMY

The aorta gives rise to several paired and unpaired vessels within the abdomen. The adrenal, renal, and gonadal arteries are paired arteries and supply blood to respective organs. Most of the digestive tract is supplied by unpaired branches [celiac artery, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA)]. The celiac trunk gives rise to three branches (splenic, left gastric, and common hepatic arteries) which supply the foregut structures from the distal esophagus to the second part of the duodenum, the spleen, the liver, and parts of the pancreas (**Fig. 1**). The SMA typically arises at the approximate level of the first lumbar vertebra about 1 cm below the celiac trunk. The SMA gives rise to several branches that supply the midgut structures extending from the second part of the duodenum to the distal third of the transverse colon (**Fig. 2**). The venous system of the gastrointestinal tract differs from the arterial system in that, rather than draining into the inferior vena cava (IVC), it passes via the portal vein into the liver. Blood passes through the hepatic lobules into the

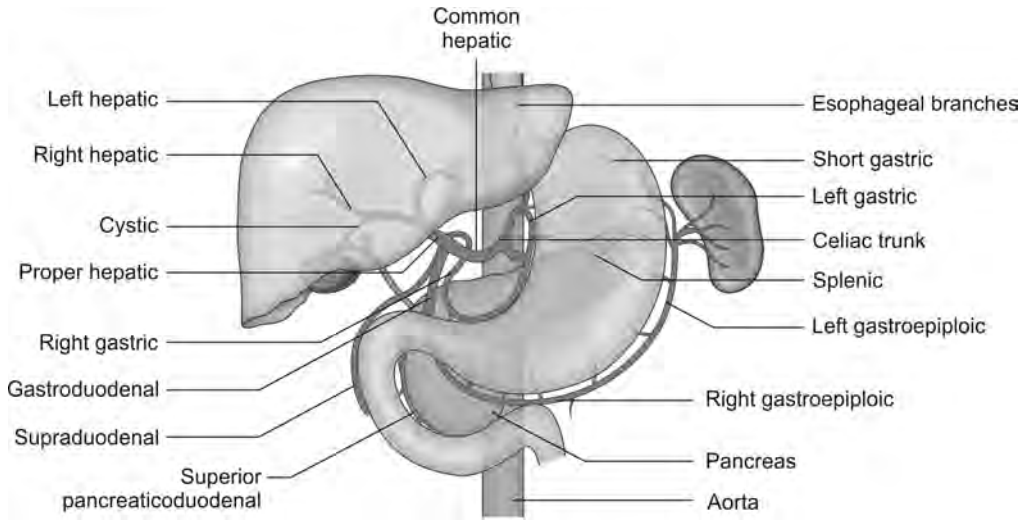

FIG. 1: Celiac trunk and its three major branches: the splenic, left gastric, and common hepatic.

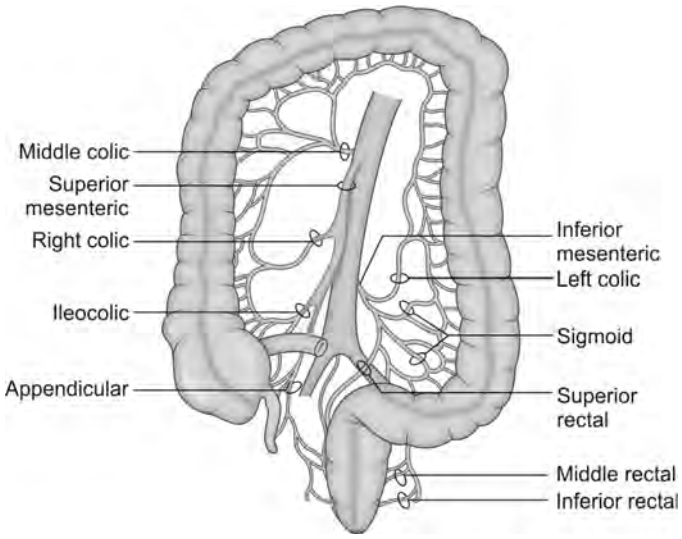

FIG. 2: Superior and inferior mesenteric arteries and their anastomotic connections.

hepatic veins, which pass into the IVC. Pathologic conditions (e.g., cirrhosis, obstruction, thrombosis) that obstruct portal flow cause anastomoses to form between systemic and portal vessels in tissues that are at the watershed junction between the two systems. When anastomoses become very large, they are named varices and locations are at the lower esophagus, the umbilicus, and the rectum.

ABDOMINAL VASCULAR THROMBOSES

Aortic Thrombosis

Acute occlusive aortic thrombosis is a rare condition that is lethal if not diagnosed. Aneurysmal disease, dissection, or severe atherosclerotic disease is associated with nonocclusive aortic thrombosis which is more common. Other conditions associated with aortic thrombotic disease include diabetes, cardiomyopathy, blunt and penetrating abdominal trauma, spinal surgery, polycythemia, thrombocytosis, nephrotic syndrome, exogenous estrogen, the classic hypercoagulable conditions (protein C and S deficiency, factor V Leiden deficiency, antithrombin III deficiency), malignancy, use of some chemotherapeutic agents, antiphospholipid antibody syndrome, and history of aortic grafting. Because of the large diameter of the aorta, emboli (typically from the left ventricle) rarely lead to aortic occlusion. Patients with an acute thrombotic event typically present with symptoms of lower extremity ischemia: bilateral lower extremity, pulselessness, pallor, pain, paresthesia, and possible paralysis. Mesenteric ischemia may also be present. Occlusion of the artery of Adamkiewicz causes spinal cord infarction. Signs of the anterior spinal artery syndrome include paralysis, and both light touch and pinprick sensations are lost but vibratory sensation and proprioception are preserved. The Leriche syndrome results from chronic obstruction of the distal aorta leading to chronic ischemia of the pelvis and lower extremities. This syndrome clinically presents in men, with a triad of symptoms: claudication, absence of lower limb pulses, and erectile dysfunction. Emergent consultation with a vascular surgeon is required in acute ischemia resulting from aortic occlusive disease. Most patients require hospitalization for observation, initiation of anticoagulant, or antiplatelet agents.

Renal Artery Thrombosis

Renal artery thrombosis is also rare and seen in the 30–50-year age group due to development of a clot in situ in existing atherosclerotic lesions. Post renal transplantation thrombosis is a known complication because of the surgical anastomoses and immunosuppressive drugs. Intra-aortic catheter or balloon pump placement, intravenous (IV) cocaine use, and renal angiography are also risk factors. Clinical features of acute renal artery occlusion consist of flank pain, which may be associated with hypertension. The patient may present with nausea, vomiting, and upper abdominal pain on the affected side and hematuria may occur in some patients. An untreated occlusion of the renal artery leads to renal infarction; the serum lactate dehydrogenase (LDH) is typically increased in renal infarction. When renal colic is suspected, unenhanced computed tomography (CT) is helpful in differentiating features of renal artery thrombosis from those of renal colic. Duplex ultrasound is the preferred initial test in the renal transplant recipient. Trauma may also be the cause of renal artery occlusion. Blunt trauma to the abdomen can lead to compression of the artery as well as dissection and thrombosis. Patients typically require surgical revascularization, and the timeliness of this intervention is linked with improved outcomes. Nontraumatic thrombosis is treated with surgical revascularization or sometimes thrombolysis.

Renal Vein Thrombosis

Renal vein thrombosis may be either an acute or a chronic process. Diagnosis depends on a high level of clinical suspicion, because the clinical findings mimic those of renal colic, renal artery occlusion, and pyelonephritis. Acute thrombosis clinically presents as flank pain along with nausea and vomiting. Hematuria and proteinuria may also be noted. Chronic thrombosis may not be clinically evident until the development of complications such as impaired renal function or pulmonary embolism. The left renal vein is affected more often than the right, but up to two thirds of patients have bilateral thrombosis. In contrast to occlusive arterial disease, renal vein thrombosis is also a disease of children and neonates. In the setting of severe volume depletion, dehydration, or sustained hypotension, blood flow is shunted from the renal vein, leading to sluggish flow that may eventually lead to the formation of a clot. In children, a palpable mass in the flank may be present because of the enlargement of the kidney on the affected side. The problem in children, clinically present as a triad of symptoms, includes a palpable mass, gross hematuria, and thrombocytopenia. The risk factors for thrombosis of the renal vein are hypercoagulable, post-transplant, and postoperative states. Blunt trauma and infection may also play a role in the development of thrombosis. The most common disease associated with the development of renal vein thrombosis is the nephrotic syndrome. Patients have direct loss of protein S and antithrombin III in their urine. With excessive proteinuria, the liver is stimulated to produce new proteins, many of which are prothrombotic.

Color Doppler sonography should be used to evaluate the flow in the graft in post-transplant patients. In the rest of the patients, the CT scan is the diagnostic study of choice. IV contrast

should be administered to visualize the vascular structures. In addition to visualizing the thrombus, the kidney on the affected side is typically engorged because of impaired venous drainage. Delayed images show a persistent enhancement from the contrast on CT scan because of the limited venous outflow. Medical management with systemic anticoagulation is the usual treatment for renal vein thrombosis. Patients with, or at risk for, a severe disease (e.g., extensive clot progressing to the IVC, renal failure, bilateral disease, renal transplant) may be candidates for systemic or catheter-directed thrombolytic therapy.

Portal Vein Thrombosis

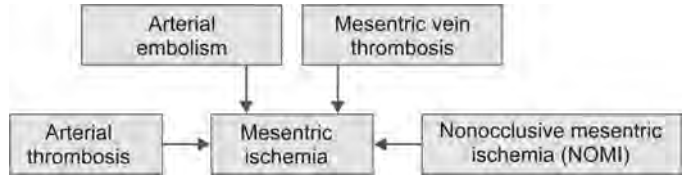
The risk of developing portal vein thrombosis in the general population is very low (<1%). Mostly, it is seen with cirrhotic patients; other risk factors associated with portal vein thrombosis are adjacent inflammatory conditions (e.g., pancreatitis, cholecystitis, diverticulitis, inflammatory bowel disease, appendicitis), malignancies (local or systemic), or hypercoagulable conditions (especially sepsis). Mortality caused by portal vein thrombosis itself is low; however, these patients frequently have other significant comorbidities that combine to give them poor outcomes with this condition. The mechanism by which cirrhosis leads to portal vein thrombosis is not clear. It is believed that decreased portal blood flow, periportal inflammation and fibrosis, and impaired production of anticoagulation factors lead to thrombosis. Portal vein thrombosis in children and neonates is associated with an intra-abdominal infection, including umbilical infections. In the acute phase, several compensatory mechanisms occur, including dilation of the hepatic artery to increase blood supply, development of variceal collaterals between the portal and systemic venous systems, and collateral cavernoma formation.

Acute portal vein thrombosis may present with abdominal pain (which may be localized in the right upper quadrant but is frequently diffuse), nausea, and fever. Signs of intestinal ischemia, which is a secondary effect of acute portal vein thrombosis, may also be present. With chronic thrombosis, patients may remain clinically silent until the secondary effects of the thrombosis occur. These effects include worsening hepatic function, worsening portal hypertension, and hematemesis from esophageal varices. Ultrasound with Doppler is the diagnostic modality of choice for portal vein thrombosis. The absence of flow within the lumen and, in some cases, the presence of a cavernoma identify the disease. If a suspicion exists for extension of the clot into the mesenteric venous system, CT with IV contrast is indicated to evaluate the vasculature and intestines.

Patients with portal vein thrombosis without complications of bleeding or intestinal ischemia are managed with systemic anticoagulation. Empiric thrombolytic therapy in cases of acute thrombosis may be indicated in severely ill patients in consultation with a gastroenterologist, although there may be significant complication rates. Thrombolytics are also considered when standard anticoagulation does not lead to recanalization. A transjugular intrahepatic portosystemic shunt (TIPS) procedure may be considered in patients having liver transplants or as an alternative to thrombolytic therapy.

ISCHEMIC BOWEL

Ischemic bowel can be caused by any one of the four mechanisms (**Flowchart 1**): (1) Arterial thrombosis, (2) Arterial embolism, (3) Venous thrombosis, or (4) Nonocclusive mesenteric ischemia (NOMI). Survival rates vary depending on the mechanism. The overall mortality is as high as 60–80%, especially with delays in diagnosis or in presentation of >24 hours and worse survival rates in older patients, in those who are not candidates for bowel resection, and in those whose cause is NOMI.



FLOWCHART 1: Mechanism of developing the mesenteric ischemia (ischemic bowel).

Mesenteric ischemia is categorized as occlusive or nonocclusive in origin. Occlusive mesenteric ischemia involves either the SMA or the superior mesenteric vein (SMV). Arterial occlusion may be embolic or thrombotic in origin. Mesenteric ischemia and ischemic colitis are different clinical entities. Patients with mesenteric ischemia typically present with abdominal pain. Patients with ischemic colitis present with lower gastrointestinal bleeding and are less likely to report abdominal pain as the primary complaint. Angiography is not indicated in cases of ischemic colitis. Predisposing cardiac conditions include arrhythmia (most commonly atrial fibrillation), myocardial infarction, cardiomyopathy, recent angiography, valvular disorder (e.g., rheumatic valve disease), or ventricular aneurysm. Following surgical embolectomy, the mortality from analyzed results from four decades is 54%.

Thrombotic Occlusion of the Mesenteric Artery

Atherosclerosis is the major cause of arterial thrombosis leading to ischemia of the SMA and is the cause of mesenteric ischemia in 25% of patients. The onset of pain is usually more insidious and may be initially intermittent and eventually become constant. Other causative factors are hypercoagulability, estrogen therapy, and prolonged hypotension. Patients with chronic ischemia may present with intestinal angina (typically epigastric pain precipitated by eating) and describe fear of food and ensuing weight loss. Chronic mesenteric ischemia is usually caused by atherosclerosis and is more common in women and smokers. It is also associated with radiation.

Thrombotic Occlusion of the Mesenteric Vein

About 10–15% of mesenteric ischemia cases are associated with mesenteric venous thrombosis. The risk factors for mesenteric venous thrombosis include oral contraceptives or estrogen therapy, malignancy, hypercoagulability, portal hypertension, portal vein thrombosis or other deep vein thrombosis, sickle cell disease, clotting disorders, hepatitis, pancreatitis, coagulopathic states, sepsis, cigarette smoking, prior abdominal surgery, and alcohol use. Mesenteric venous thrombosis cases (20%) are found to be idiopathic also. Patients may present in a subacute fashion with abdominal pain and diarrhea. Clinical findings are likely to be more severe, with frank peritonitis and bleeding in patients with extensive transmural ischemia. With chronic mesenteric

vein thrombosis, the collateral circulation usually allows for adequate venous drainage, limiting symptoms, and consequent secondary effects of portal hypertension and varix formation. Mesenteric venous thrombosis is usually diagnosed by CT with IV contrast. Most mesenteric venous ischemia is treated nonoperatively with anticoagulation. Thrombolytic therapy for portal vein thrombosis should be considered in relation to risk–benefit profile and in consultation with a gastroenterologist.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia is defined as ischemia in the absence of identifiable occlusive lesions in the splanchnic arteries or veins. Risk factors associated with NOMI are hypotension, hypovolemia, heart failure, or sepsis, leading to hypoperfusion vasoconstriction, hypotension, and hypoperfusion. Medications associated with NOMI include cocaine, digitalis (splanchnic vasoconstriction), ergot alkaloids and vasopressors, a constricting agent, and β-blockers.

Clinical Findings

Abdominal pain is the chief complaint in most patients with mesenteric ischemia, followed by associated nausea, vomiting, and diarrhea. Pain caused by embolic disease is often acute in onset and the patient may have associated nausea, vomiting, or diarrhea (both may be either bloody or without blood). Bleeding per rectum is reported in 14–16% of cases. Mild abdominal tenderness may be found on examination. As ischemia progress, patients may become hypotensive.

Laboratory Evaluation

There is no single specific test for the diagnosis of mesenteric ischemia. Mesenteric ischemia is commonly associated with anion gap acidosis, leukocytosis, and hemoconcentration. Increased lactate is associated with poor prognosis.

Diagnostic Imaging

Deciding on the most appropriate diagnostic imaging test for mesenteric ischemia is challenging. Plain abdominal radiographs, CT, ultrasound, magnetic resonance imaging (MRI), multislice CT angiography, and angiography are all radiographic modalities that can be considered. Plain radiographs may show pathognomonic findings of mesenteric ischemia (e.g., thumb-printing or bowel loop thickening). Often, these are useful as a first test to evaluate for obstruction or free air though findings are nonspecific. Abdominal radiographs have low sensitivity for the detection of air in the splanchnic vascular system. If portal gas is identified, mesenteric ischemia is the most likely diagnosis and emergent surgical intervention is indicated.

Doppler ultrasound has limited usefulness in the acute and emergent evaluation of mesenteric ischemia. MRI is a time-consuming and costly measure whose accuracy is unconfirmed; CT with IV contrast may show vascular opacification in the vessel lumen as with SMA thrombosis. Dilated loops of bowel, air-fluid levels, and changes in bowel wall enhancement or a combination of these, are nonspecific findings but may indicate more advanced stages of mesenteric ischemia. In the late stage of ischemia, a CT scan shows thickened bowel and air in the bowel wall or pneumatosis intestinalis (**Fig. 3**).

Angiography is still the gold standard in the diagnosis of mesenteric ischemia, but multidetector CT angiography may emerge as a preferred imaging modality because of its ability to assess the bowel wall. When angiography is performed, a catheter is left in the SMA for the administration of vasodilators or papaverine, which is particularly useful in embolic mesenteric ischemia.

Treatment

All patients require hemodynamic monitoring, resuscitation, IV fluid, broad-spectrum antibiotic administration, and pain management. Emergent surgical consultation and emergent laparotomy are required if peritoneal signs in acute ischemia are present, and the patient should not be given anything to eat or drink by mouth. Heparin therapy should be initiated if there is no contraindication, and vasopressors should be avoided. A patient with mesenteric ischemia caused by embolic phenomena would require surgical intervention for embolectomy, excision of the infarcted bowel, and consideration of intra-arterial papaverine. The patient with an arterial thrombus is a candidate for similar interventions: thrombectomy and revascularization. Similarly, if the patient has mesenteric venous thrombosis, thrombectomy and excision of the gangrenous bowel may be indicated, and heparin therapy should be initiated. Patients with NOMI should have the underlying cause treated as well as resection of the affected segment of bowel (**Fig. 4**). Prognosis of mesentric ischemia is depends on various factors which are shown in **Figure 5**.

ANEURYSM

A vascular aneurysm is defined by the focal dilatation of an artery to at least 1.5 times its normal diameter. All the three layers of the vessel wall—intima, media, and adventitia—are involved in a true aneurysm; otherwise the dilated segment is referred to as a pseudoaneurysm. There is a broad spectrum of disease severity associated with arterial aneurysms in the abdominal cavity. The patient may remain asymptomatic lifelong or may present with incidental findings during routine health check-ups or may present as catastrophic abdominal emergencies, though a earlier diagnosis of these lesions is common with the increased use of abdominal imaging modalities nowadays.

Nonocclusive mesenteric ischemia
Increased age
Presence of comorbidities

FIG. 5: Factors affecting prognosis of acute mesenteric ischemia.

Emergency physicians should be aware of the natural history of a vascular aneurysm as well as its management if it ruptures.

Abdominal Aortic Aneurysm

The aorta is the most common site of an aneurysm in the abdominal cavity and anteroposterior diameter of >3.0 cm is classified as an aneurysm. Most abdominal aortic aneurysms (AAAs) occur in the infrarenal region. Most aneurysms are fusiform (not saccular), entire circumference, and all layers of the vessel are involved. The mean diameter of the infrarenal aorta is 1.66–2.16 cm in older women and 1.99–2.39 cm in older men. The most important complication of AAA is rupture, which occurs almost exclusively in aneurysms larger than 4 cm. The most important risk factors are smoking, family history of AAA, increasing age, and history of atherosclerotic disease for clinically significant aneurysms (>3.9 cm). The pathophysiology of AAA development and subsequent rupture is incompletely understood at this time. The aortic wall is made up of three layers: (1) Intima, (2) Media, and (3) Adventitia. Within the media and adventitia, elastin and collagen are the most important components for maintaining the mechanical integrity of the vessel wall. Elastin is highly concentrated in the medial layer, whereas collagen is concentrated in the adventitia. Damage to and loss of elastin fibers and an associated reduction in the density of smooth muscle cells seem to be integral to the early development of AAA, whereas collagen degradation in the adventitia might be the most important factor in rupture.

Any older patient presenting to the emergency department (ED) with the clinical findings, of abdominal pain, back pain, shock, ruptured or leaking AAA should be suspected, but the presentation of these symptoms and signs is variable. Abdominal pain or back pain are prominent features in patients with a ruptured AAA. AAA mostly ruptured into the retroperitoneal space, remaining ruptured into intraperitoneal, IVC, or duodenum. Most patients presenting to the ED are unaware of this vascular emergency. The early management of patients with suspected unstable AAA, either leaking or ruptured, should focus on rapid diagnosis and early definitive treatment. The presence of known risk factors for the disease (such as male gender, advanced age, and a history of smoking) in association with acute abdominal or back pain should raise the suspicion for an unstable AAA. Pulsatile mass on abdominal palpation has sensitivity ranging from 44 to 97%.

The most useful tool in the diagnostic evaluation of AAA in the ED is bedside ultrasonography. Ultrasound is a highly accurate test, with a sensitivity and specificity approaching 100% in detecting AAA for emergency physicians. Ultrasound can also detect free fluid in the abdomen, associated with a free intraperitoneal rupture. Sonography does not reliably differentiate between ruptured and asymptomatic aneurysms, because hemorrhage most frequently occurs in the retroperitoneal tissues, where ultrasound assessment is limited. CT is a useful imaging modality for newly diagnosed AAA asymptomatic patients to define the anatomic details of the aneurysm; it should not be considered as the initial test of choice for patients with suspected ruptured AAA and unstable patients. CT is helpful where an ultrasound is technically limited or cannot distinguish between a symptomatic and an incidental AAA. For those with a suspected ruptured AAA, aggressive resuscitation is priority, along with diagnostic measures, and consultation with a vascular surgeon should be done simultaneously. Judicious fluid and blood replacement should begin for patients in shock, with large-bore, IV lines in place; once the underlying disorder is an arterial rupture and hemorrhage is confirmed, the vascular surgeon should be involved for surgical repair. For patients with an aneurysm greater than 5.4 cm, a referral should be made to vascular surgery. For those between 4.0 and 5.4 cm, surveillance with ultrasound is recommended every 6–12 months and for those <4.0 cm, every 2–3 years is probably sufficient.

Iliac Artery Aneurysm

Iliac artery aneurysms are defined by a focal dilatation in the vessel greater than 1.5 cm. Symptoms and rupture only occur in aneurysm greater than 4 cm. The risk factors and pathophysiology associated with aneurysms at this site are similar to those for AAA. Patients with AAA also have an iliac artery aneurysm in 10–20% of cases. Isolated iliac artery aneurysms are rare but, when present, the common iliac artery is the most commonly affected site. The emergency physician should be aware that compared with AAA, iliac artery aneurysms are more likely to present with urologic symptoms consistent with renal colic and difficult to visualize with sonography. Because of increased technical difficulties associated with an operation at this site, a ruptured iliac artery aneurysm is associated with high mortality (about 60%) higher than for AAA. However, elective surgery is indicated

when the aneurysm size is greater than 3.5 cm and is strongly recommended when greater than 5 cm.

VISCERAL ARTERY ANEURYSMS

Visceral artery aneurysms, which consist of lesions in renal and splanchnic arteries, are rare and usually asymptomatic and most of the visceral artery aneurysms are detected during routine investigation into unrelated abdominal symptoms. Of those detected, splenic and hepatic artery aneurysms are by far the most common, comprising 80% of visceral artery aneurysms. The natural history is poorly understood and poorly defined clinical presentation. Multiple aneurysms are present in about one third of patients. Most patients are diagnosed or present with symptoms in the sixth decade of life. Aneurysms typically greater than 2 cm are vulnerable for rupture, so this size is often considered for surgical repair in patients with an asymptomatic disease.

Splenic Artery Aneurysm

Splenic artery aneurysm is common in all visceral artery aneurysms, about 60%, and mostly are true aneurysms. Arteriosclerosis, portal hypertension, pancreatitis, and trauma are common risk factors. There is an increased prevalence of the disease in multiparous women and with the increased use of high-resolution ultrasonography in pregnancy, these aneurysms are being detected in otherwise healthy pregnant women. Pregnancy and aneurysm size greater than 2 cm increase the risk of rupture. Ruptured aneurysms are most commonly present with abdominal pain. Shock can be delayed if the initial aneurysm rupture is contained within the lesser peritoneal sac, leading to a double-rupture phenomenon. The treatment of rupture is both resuscitative and operative, including a splenectomy. Endovascular techniques, specifically transarterial embolization, are also useful. There is no consensus on the management of asymptomatic aneurysms.

Hepatic Artery Aneurysm

The second most common visceral artery aneurysm is aneurysms of the hepatic artery comprising 20%. More than half (77%) occur in the common hepatic artery and most of the rest in the extrahepatic segment of the proper hepatic artery. These aneurysms are more common in men in contrast with splenic aneurysms (common in multiparous women). Although abdominal pain and shock suggest rupture, even unruptured hepatic artery aneurysms can be symptomatic secondary to compression on the biliary tree. About 50% of aneurysms rupture into the biliary tract and can present with the classic triad of biliary colic, hematemesis (caused by hemobilia), and jaundice. The mortality of 40% associated with rupture seems to be consistent across case series data. As with splenic artery aneurysm rupture, the treatment has historically been surgical repair; however, transarterial embolization is an increasingly used technique.

Renal Artery Aneurysm

Like other visceral artery aneurysms, renal artery aneurysms are the most common incidental findings during abdominal imaging or investigations into renovascular hypertension. This is also associated with multiparous women and is similar to splenic aneurysms. Arterial fibrodysplasia is the most common vascular disorder associated with these aneurysms. Based on case series data, about 20% are bilateral. Rupture seems to be extremely rare.

SUMMARY

When patients present with abdominal complaints in the ED, the emergency physician should consider the possibility of vascular disorders as clinical situations tend to be dangerous and time specific. In maintaining an appropriate level of suspicion and assessing a patient's risk, the factors associated with the various diseases need to be considered. If a vascular emergency is strongly suspected, the appropriate diagnostic tests should be performed promptly and a vascular surgeon should be engaged as soon as possible. Bedside ultrasonography is an invaluable tool for an emergency physician, especially in suspected ruptured or leaking AAA. CT angiography is becoming the initial imaging test of choice for abdominal vascular diseases caused by occlusive thrombosis. Many of these vascular emergencies are correctable with rapid diagnosis and appropriate resuscitation.

CHAPTER

Imaging Modalities in Genitourinary Disease

Aman Gupta

INTRODUCTION

Recent technical advances and discoveries in field of radiology have made imaging of genitourinary (GU) system exciting but challenging. The best choice for imaging the GU system is debatable but must be selected on the basis of patient's symptomatology and clinical context. There are many factors to be considered when deciding which imaging modality should be used first and include radiation exposure, patient age, patient cooperation status, sensitivity, specificity and accuracy, availability of modality, cost, and timeliness of completion. Plain film radiology is perhaps one of the quickest and most inexpensive modalities readily available with considerably less radiation exposure; however, its role is limited to urolithiasis and urinary tract calcification. Ultrasound (US) has the benefits of portability, low cost, availability, and no radiation exposure to the patient. Point-of-care ultrasound (POCUS) is one of the quickest imaging modalities available and is becoming increasingly prevalent in the emergency department, but its sensitivity and specificity depend on operator expertise. Computed tomography (CT) scans have a significant radiation exposure and is much more expensive, but allows evaluation of multiple different systems simultaneously with high degree of accuracy. Magnetic resonance imaging (MRI) has a limited role in the diagnosis of GU pathologic condition because of the fact that it is expensive, is not readily available, and longer study time. However, because of its inherent multiplanner imaging, better soft-tissue resolution and delineation capabilities plays a key role in equivocal CT or US evaluations.

CONVENTIONAL PLAIN FILM RADIOGRAPHY

Plain abdomen-supine-anterior-posterior radiography or more commonly known as kidney, ureter, and bladder (KUB) plain radiography has a low cost, ready availability, and appearance with which referring physicians are familiar but unfortunately compares unfavorably with CT. The full-length abdominal film is taken with the patient supine using a low voltage technique (60–65 kV) to maximize soft-tissue contrast in inspiration using a 14 × 17 inch cassette (for adults) positioned with the lower border at the symphysis pubis to ensure the urinary bladder and urethra are included on the film. Various outlines of anatomical structures can be detected on the KUB, including outlines of renal, psoas, and bladder, much of the axial skeleton, the bowel gas pattern, and the lung bases. A range of pathology may be occasionally detected in these structures, but overall KUB radiography is a relatively unreliable diagnostic tool and its principal use is in the assessment of urinary tract calculi. However, the reported sensitivity and specificity of plain film in detection of renal and ureteric calculus (>5 mm) is only 45–58% and 60–77%, respectively. Various factors, such as stone composition, location, and size, as well as patient body habitus and overlying bowel contents also, determine the sensitivity of the KUB for ureterolithiasis. The detection rate for stones <5 mm is low, with a sensitivity of 12% or less. Presence and/or extent of urinary tract obstruction cannot be determined by KUB. The combination of KUB and US has been proposed to improve sensitivity and specificity of stone detection, especially mid ureteric calculi. The KUB is mostly performed to follow-up a previously proven calculus or as part of an intravenous urography (IVU). There are numerous causes of calcification visible on the plain radiograph, with considerable overlap in their appearances, and a specific diagnosis is often not possible (**Table 1**).

INTRAVENOUS UROGRAPHY

The IVU, or better known as excretory urography (EU), is the classic routine investigation of uroradiology. With the advent of US and multidetector computed radiography (MDCT) its role is now much less, however, it is still widely used and accepted indications for EU are:

- To evaluate the presence or continuing presence of suspected or known ureteral obstruction.
- To assess the integrity of the urinary tract status post-trauma (including iatrogenic interventions), particularly in situations in which cross-sectional imaging is unavailable or inappropriate.
- To assess the urinary tract for suspected congenital anomalies, particularly in situations in which cross-sectional imaging is unavailable or inappropriate.
- To assess the urinary tract for lesions that may explain hematuria or infection. Evaluation of underlying

TABLE 1: Common causes of calcification on the plain radiograph.

Urinary tract	• *Renal*: Calculi, renal cell carcinoma, tuberculosis, and arterial (atheroma or aneurysm) • *Ureter*: Calculi, tuberculosis, and schistosomiasis • *Bladder*: Calculi, schistosomiasis, and transitional cell carcinoma
Outside the urinary tract	• *Musculoskeletal*: Costal cartilage calcification • *Hepatobiliary*: Gallstones and hepatic granuloma • *Pancreas*: Chronic pancreatitis • *Adrenal*: Tuberculosis and Addison's disease • *Spleen*: Granuloma • *Aorta*: Atheroma and aneurysm • *Venous*: Phlebolith • *Lymphatic*: Calcified lymph nodes • *Uterine*: Fibroid

parenchymal mass or lesion of the urothelial tract can be done by EU where cross-sectional imaging is unavailable or inappropriate.

The IVU consists of a series of plain films taken after administration of an intravenous injection of a water-soluble iodinated contrast media. Traditionally the patient for IVU is prepared with laxatives, 2–4 hours fasting, and fluid restriction prior to the procedure in order to improve opacification of the collecting system. However, it is well accepted now that dehydration is associated with an increased risk of nephrotoxicity and is thus not recommended. Also, modern nonionic contrast agents do not provoke an osmotic diuresis and the degree of opacification is unlikely to be significantly altered by dehydration.

Intravenous urography is performed with some variations in different departments. A standard procedure involves a preliminary post-micturition plain abdomen film (KUB), this should he examined to check exposure factors, centering and presence of radiopaque calculus/calcification. Intravenous water-soluble iodinated contrast is then given as bolus. The standard dose for adult is 300 mg of I_2/kg body weight. A cross-kidney film is taken 5 minutes after injection of contrast (nephrogram). Abdominal compression is then applied to inhibit ureteric drainage and promote distension of the pelvicalyceal systems, optimizing their visualization. A further cross-kidney film is taken at 12–15 minutes to demonstrate pelvicalyceal system (the pyelogram). If the 15 minutes film is satisfactory the compression is removed and a full-length film is taken immediately to demonstrate the ureters (**Fig. 1A**), followed by coned images of the bladder before and after voiding (full-bladder and post-void films). This classical series can he modified based upon findings as each radiograph is reviewed to deal with particular circumstances, to attempt to increase the sensitivity of the procedure, or to reduce the radiation dose to the patient. Some of the most frequently employed modifications are: (1) Delayed images, if there is delay in opacification of the collecting system due to significant acute obstruction. Minimum number of additional films is also necessary to perform. Traditionally concept of doubling time is applied with films taken at 0.5, 1, 2, 4, 16, and 24 hours, as necessary so that the degree of obstruction may be assessed. (2) Prone film, placing the patient prone after the 10-minute image or having the patient mobilize may assist lower ureteric filling and visualization of ureters.

Although, newer low-osmolar contrast medium is relatively safe, there is a small risk of serious anaphylactic-type hypersensitivity reactions. All radiology departments thus necessarily be equipped with emergency drugs, oxygen, resuscitation equipment, and a fulltime radiologist. Knowledge of potential adverse reactions and their treatment is essential for all technical staff in radiology department.

Intravenous urography is used as traditional modality for investigating ureteric calculi. This demonstrates the relationship of a suspected calculus on the plain film to the urinary tract, confirming its location in the collecting system. In most patients with ureteric colic, there is some degree of obstruction, manifested by increasingly dense nephrogram, delayed pyelogram, dilated pelvicalyceal system down to the calculus, with a standing column of contrast in the ureter above the calculus. During last decade, use of IVU is declining for urinary imaging. Reported sensitivity of CT for urinary stone assessment, is 100% as compared with 52–69% for IVU. CT is superior to IVU for urinary tract tumor detection, with sensitivity and specificity of 96% and 99%, respectively. Sensitivity of IVU for detection of renal masses is also much less as compared to US and CT, with reported sensitivities of only 21, 52, and 85% for masses <2, 2–3, and >3 cm, respectively. In addition, masses detected by IVU inevitably require further imaging for lesion confirmation and characterization by either US, CT or MRI.

RETROGRADE UROGRAPHY

Retrograde urography (RU) is a special radiological procedure performed by instillation of contrast medium devoid of air bubbles into a ureteric catheter placed by cystoscopy with aim to optimally opacify the pelvicalyceal system and ureter for delineation of pathologies. The role for RU has been diminished due to advancement in sonography equipment and read availability of MDCT. RU can still be useful as a problem-solving tool when filling defects are detected in the upper urinary tracts on imaging particularly if there is hematuria and/or suspicious

cytology. RU is also performed for assessment of stone disease after renal and ureteric lithotripsy and occasionally used to demonstrate lower end of an obstructed ureter (**Fig. 1B)**.

The urologist positions catheter in ureter cystoscopically and the patient is transferred to the X-ray department. Under screening control 5–20 mL of a water-soluble iodinated contrast agent is injected via catheter and spot films taken of the opacified pelvicalyceal system and ureter. After adequate images have been obtained, the ureteric catheter can be withdrawn to allow contrast injection at a site of concern. Superiority of CT over RU is not fully established by scientific evidence. Few studies available comparing CT urography (CTU) with RU have shown increased sensitivity and specificity for CT detection of urothelial tumors.

CYSTOGRAPHY

Cystography procedure is performed to assess the integrity of the bladder following trauma or surgery or to investigate suspected fistulas involving the bladder. A spot film is taken before administration of contrast followed by infusion of water-soluble iodinated contrast via suprapubic or urethral catheter under screening control. When the bladder has been filled or when extravasation is identified spot films are taken in the supine, oblique, and lateral position. In patients with a suspected vesical fistula, 250 mL of contrast can be used to maximize the chance of demonstrating the fistula. In modern trauma units, conventional contrast cystography is getting replaced by a delayed CT sequence for urinary bladder, 20 minutes after contrast in trauma patients and is reported as accurate in demonstrating extravasation.

RETROGRADE URETHROGRAPHY AND VOIDING CYSTOURETHROGRAM

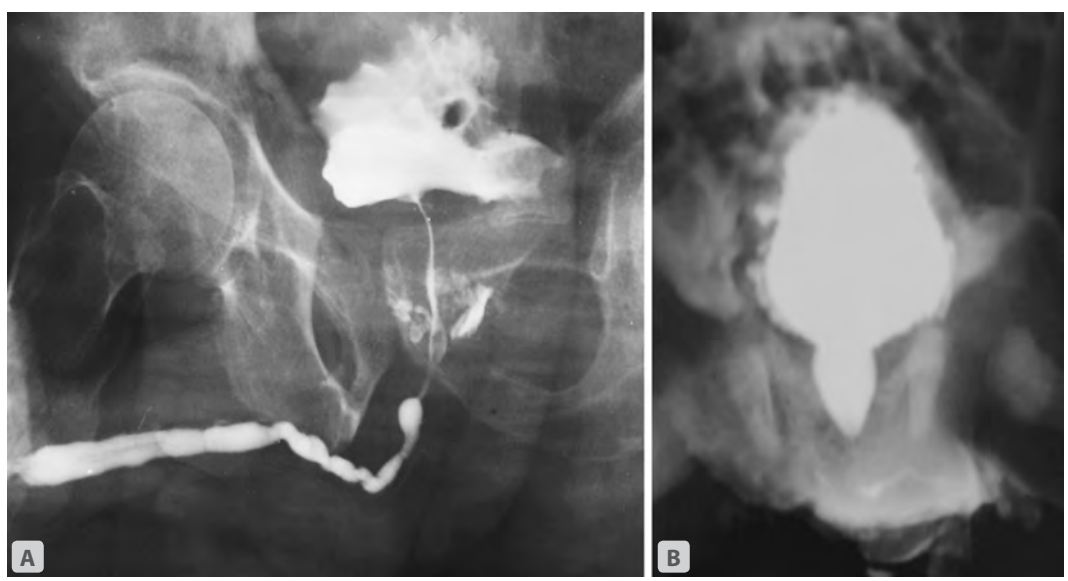
Retrograde urethrography (RUG) or ascending urethrography is used to image male anterior urethra in cases of blunt perineal trauma to assess for urethral disruption, suspected urethral stricture, and fistulas. The patient is positioned in a 45° oblique position and water-soluble iodinated contrast media is gently instilled into a stretched penis through a 12–16 gauge Foley catheter positioned with its balloon in the fossa navicularis and spot films are taken (**Fig. 2A**).

Voiding cystourethrogram (VCUG) or descending urethrography is used to image posterior urethra and demonstrate vesicoureteric reflux, particularly in pediatric patients. The bladder is initially drained of urine and later filled with water-soluble iodinated contrast medium using a Foley or suprapubic catheter. Anteroposterior and oblique bladder imaging is performed using intermittent fluoroscopy with spot images of abnormal findings. Once the bladder is filled to capacity, the urethra is imaged in profile using an oblique projection after catheter removal and during micturition in supine or while standing (**Fig. 2B**).

These procedures are less required now with advances in urethroscopy. Echo-enhanced voiding cystosonography and MR voiding cystography are also now being used for screening or follow-up in patients with known or suspected vesicoureteric reflux.

PERCUTANEOUS NEPHROSTOMY AND ANTEGRADE PYELOGRAPHY

Percutaneous nephrostomy (PCN) is mainly indicated for therapeutic purposes to drain an obstructed collecting system. Some time it is used to divert the urine flow in unobstructed systems and allow ureteric or vesical fistulas to heal. PCN tube mounted on a cannula is positioned percutaneously within the dilated collecting system under US or fluoroscopy guidance. A diagnostic nephrostogram and antegrade pyelogram (**Fig. 3**) can be performed by injecting water-soluble iodinated contrast media through nephrostomy catheter and spot films taken of the collecting system and ureter down to the level of the obstruction to assess cause, especially in patients with



FIGS. 2A AND B: (A) Retrograde urethrography in a 60-year-old male demonstrating beaded penile urethra with stricture posterior urethra; and (B) Voiding cystourethrogram in a 4-year-old male with posterior urethral valve demonstrating dilated posterior urethra with trabeculated urinary bladder wall.

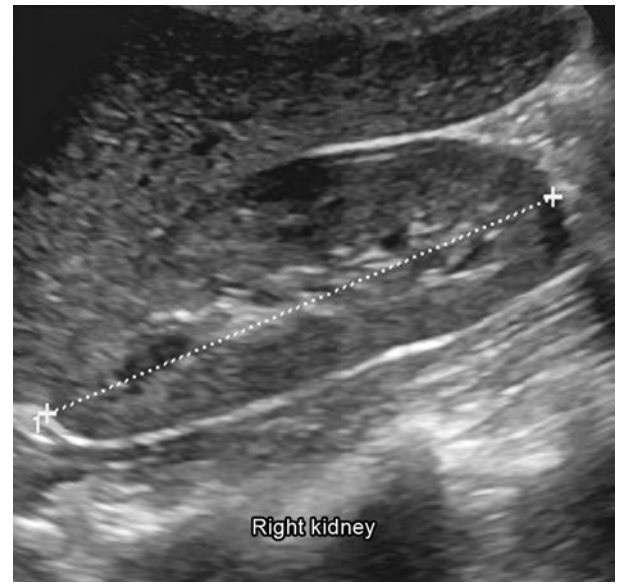

FIG. 4: Sonographic appearance of a normal adult kidney. Note renal parenchymal echotexture slightly less or equal to that of liver and dense central renal sinus echoes.

nonexcretory kidney. The most common complication of these procedures is infection and hemorrhage and appropriate precautions should be taken.

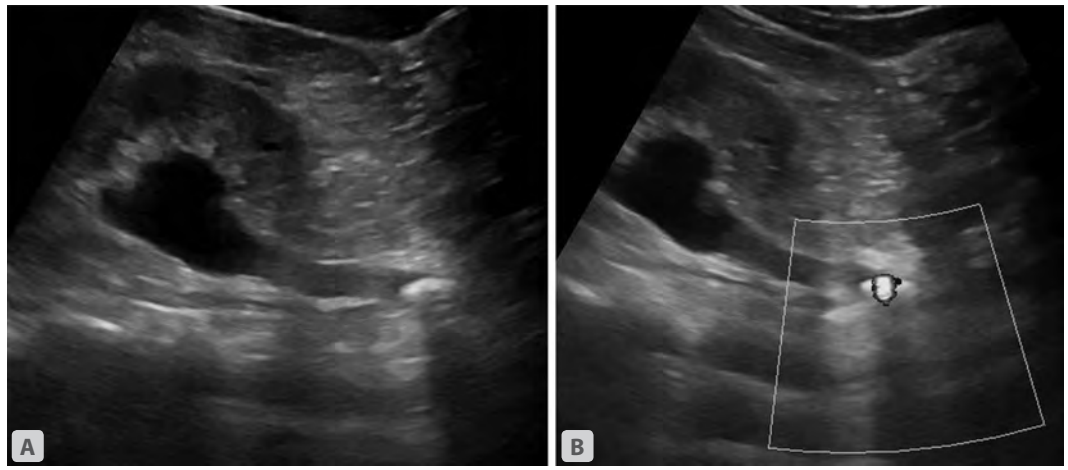
ULTRASOUND

The ready availability, portability, cost effectiveness, and absence of exposure to radiation have made US first imaging modality in the assessment and follow-up of renal diseases. US is valuable in assessment of congenital abnormalities, loin pain, hematuria, infection, tumors, and renal failure. US is very useful in determining the internal architecture of renal lesions detected on other modalities such as hyperattenuating lesions detected on MDCT, to determine whether they represent hyperdense cysts or solid lesions. US is considered safe without need for intravenous contrast or ionizing radiation, valuable in the evaluation of the postrenal transplant patient and able to safely image the structure of the graft, and its perfusion with Doppler imaging. POCUS is very popular and an increasingly growing field complementary to bedside medical examination performed by emergency physicians, unclear findings can be investigated quickly.

On US the normal adult kidneys measures in range of 9–13.5 cm. A difference in size of >1.5 cm between the two raises the possibility of unilateral disease. Renal cortex appears slightly hypoechoic in comparison to the liver and spleen. Renal cortex seen as a peripheral rim with normally inward projecting invaginations (columns of Bertin) between the medullary pyramids. In young healthy adults, cortical thickness is of the order of 2.0–3.0 cm. The renal pyramids are markedly hypoechoic as compared to the cortex in neonates and infants, becoming less hypoechoic with age and in renal parenchymal diseases with loss of corticomedullary differentiation. The central renal sinus echoes contains fat, the calyces, infundibula, part or all of the renal pelvis, blood vessels, lymphatics, and fibrous tissue (**Fig. 4**). The normal undilated ureters are not visualized on sonography, but when obstructed are seen as dilated tubular channels and mural and intraluminal pathologies can be easily picked. Urinary bladder is examined in moderately full stage; the normal wall thickness is 2–3 mm and contents anechoic. In males, the prostate and seminal vesicles are seen posterior to the bladder. In females, uterus and ovaries are evaluated either transabdominally using a sector transducer or transvaginally using an endocavitary transducer.

Ultrasound in the setting of acute flank pain may be very useful because of its inherent advantages of no ionizing radiation, availability, and portability, especially in children and pregnant patients. Urinary tract obstruction secondary to calculi is the most common cause. US usually demonstrates direct signs of obstruction of urinary tract such as hydronephrosis and hydroureter with a reasonable degree of sensitivity (95%), but at the cost of a low specificity of around 67%. Calculi on US are seen as highly echogenic foci with dense distal acoustic shadowing on grey scale and twinkling artifact on color Doppler (**Figs. 5A** and **B**).

Ultrasound is often first imaging investigation in Indian setups for suspected acute pyelonephritis (APN), although as discussed US has a low sensitivity and limited diagnostic accuracy. Features of APN on US include renal enlargement caused by generalized renal edema, renal parenchymal hypoechogenicity, loss of corticomedullary differentiation, and on dynamic scanning restricted renal movements with respiratory excursions. Hydronephrosis, either as a cause for infection or secondary to pyelonephritis, can be seen conspicuously on US. In addition, US can diagnose underlying predisposing conditions such as duplicated system or pelviureteral junction obstruction. Doppler US helpful in differentiating areas of parenchymal hypoperfusion due to arteriolar vasoconstriction and interstitial edema. Contrast-enhanced ultrasonography (CEUS) better demonstrates hypoperfusion and abscess formation.



FIGS. 5A AND B: (A) A proximal ureteric calculus on grey scale ultrasound seen as echogenic foci with posterior acoustic; and (B) Twinkling artifact on color Doppler. Note proximal hydroureteronephrosis.

DOPPLER SONOGRAPHY

Excellent noninvasive tool for evaluating renal artery (RA) hypertension and end-stage renal disease is Doppler sonography. It has high sensitivity and specificity, in the diagnosis of RA stenosis on the basis of Doppler samples obtained from extrarenal arteries combined with intrarenal waveform analysis. Benefit from therapeutic correction of RA stenosis can also be predicted by US. Patients with elevated resistive index (RI) > 0.80 show poor improvement in renal function and hypertension after revascularization.

For evaluation of acute scrotum high-resolution ultrasound (HRUS) in combination with color Doppler has become the imaging modality of choice. On gray-scale sonography, in acute phase of torsion, testis appears enlarged, spermatic cord immediately cranial to the testis and epididymis is twisted, and intrascrotal portion of the cord appears as edematous curled echogenic extratesticular mass causing a characteristic "whirlpool pattern". Color Doppler shows absent or significantly less blood flow in the affected testicle whereas in acute epididymitis/epididymo-orchitis there is thickening and enlargement of the epididymis, the echogenicity of the epididymis and testis is usually decreased with significantly increased blood flow on Doppler.

Transvaginal sonography (TVS) is imaging modality of choice in various gynecologic emergencies particularly, ectopic pregnancies, ruptured or hemorrhagic ovarian cysts, ovarian or adnexal torsions, threatened or inevitable abortions, acute salpingitis, tubo-ovarian abscess, and torsion of a pedunculated subserous myoma. A negative US helpful in excluding most of the significant pathologies. If gynecologic cause of pelvic pain is confirmed on transabdominal or TVS other imaging studies might be unnecessary, in cases where the US examination is equivocal or suboptimal CT or MRI should be considered.

COMPUTED TOMOGRAPHY

Computed tomography has a wide variety of indications, unenhanced CT is used to evaluate urinary tract stones, calcifications, hematoma, and to obtain baseline attenuation of renal masses. CT for renal parenchymal and urothelial tumor detection and characterization requires arterial and nephrographic postintravenous contrast medium acquisitions. Other common indications of CT include assessment of inflammatory and traumatic processes and RA stenosis. CT is also used to direct biopsies and the positioning of percutaneous drains.

Unenhanced CT or stone protocol CT in evaluation of the patients with urinary tract calculi has now emerged as investigation of choice and has replaced IVU in maximum institutes with reported sensitivity as high as 95% and specificity of 98%. Unenhanced CT offers several advantages over conventional IVU: (1) Obviates need of contrast media, (2) is rapid and does not require repeated imaging to determine the site of obstruction, (3) is not only more sensitive in detecting presence of calculi, but also it can detect associated obstruction. Obstruction is suggested by hydronephrosis and hydroureter above the level of the obstructing calculus and also by the presence of secondary signs of obstruction such as perirenal and periureteric fat stranding, and (4) CT has potential advantage of making alternative relevant diagnoses (diverticulitis, appendicitis, cholecystitis, epiploic appendagitis, etc.) in patients with acute abdominal pain. The major disadvantages associated with the use of unenhanced CT are exposure to ionizing radiation, its cost, and availability in peripheral centers. However, in recent years, use of low mAs stone protocol has provide comprehensive evaluation of the urinary tract with effective doses reported in a range comparable to IVU or even lower.

Contrast-enhanced computed tomography (CECT) is considered the imaging technique of choice for diagnosis or follow-up of patients with acute urinary tract infection. The reported sensitivity and specificity of CT for APN is 86.8 and 87.5%, compared with 74.3 and 56.7% for US. Plain CT detects causes of renal obstruction such as stones or soft-tissue masses. Nephrographic-phase imaging is helpful in detecting loss of corticomedullary differentiation with one or more wedge-shaped zones or streaky areas of reduced enhancement extending from the papilla through the medulla to the renal capsule. A striated nephrogram may be observed. Involvement of Gerota's fascia with extrarenal extension may also be noted. The presence of nonenhancing fluid locules within an area of APN suggests fluid liquefaction and abscess formation. APN with diffuse renal involvement causes impaired contrast excretion as per severity of infection. CT findings in patients with emphysematous pyelonephritis include parenchymal

enlargement and focal tissue necrosis, streaks of gas radiating from the papillae, gas-fluid levels, and renal and perirenal abscess.

Computed tomography urography is defined by the European Society of Urogenital Radiology as a CT optimized for renal, ureteric, and bladder examination using thin-slice, excretory-phase imaging after intravenous contrast medium administration. CTU typically consists of three imaging phases. Following unenhanced imaging, thin-section nephrographic phase imaging of the kidneys is acquired using water-soluble iodinated contrast medium. For the detection of renal parenchymal, masses nephrographic phase imaging has the highest sensitivity. Correlation with unenhanced images confirms unequivocal enhancement. The excretory or pyelographic phase is imaged 5–15 minutes after injection and covers the upper urinary tract and bladder (**Figs. 6A** and **B**). CTU protocols vary between institutions and are tailored towards the clinical problem to optimize radiation exposure and urothelial imaging. CTU is excellent modality for detection of upper urinary tract urothelial malignancies. CTU is better than IVU in detection and characterization of both intrinsic and extrinsic causes of ureteric obstruction such as mural thickening, benign and malignant strictures, retroperitoneal masses, lymphadenopathy, retroperitoneal fibrosis, and iatrogenic injury.

The radiologic evaluation of the kidneys and urinary tract in the context of trauma is guided primarily by the patient's hemodynamic status and presence or absence of hematuria. Any penetrating trauma in which direct injury to the kidneys and GU tract is suspected should be evaluated by CECT. The triphasic CT protocol in trauma should include an unenhanced phase to identify internal hemorrhage, a postcontrast corticomedullary phase to identify abnormalities in renal parenchyma, vasculature, and perfusion, and a postcontrast delayed phase obtained 5–10 minutes after contrast to identify any breech within the urinary collecting system. In circumstances where imaging is warranted but CT is contraindicated, US and unenhanced MRI should be considered.

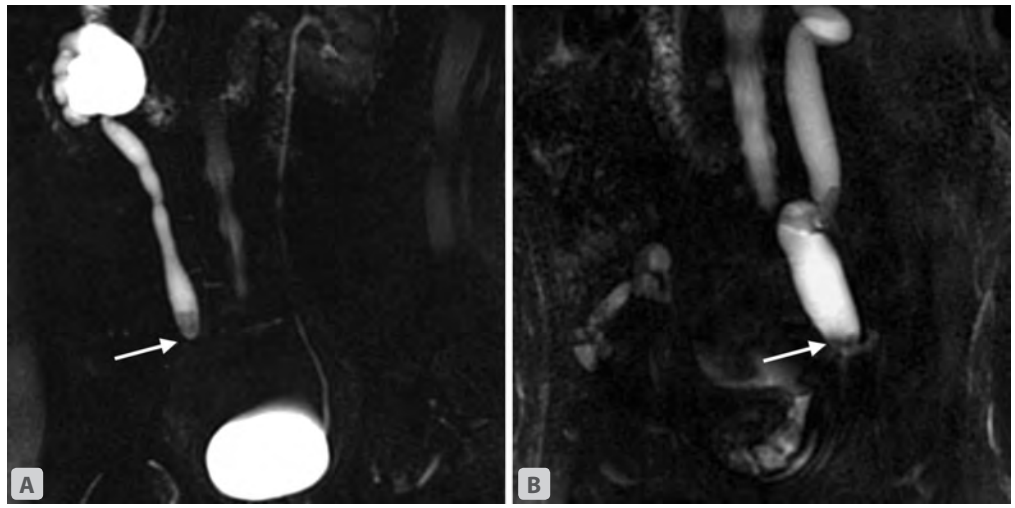
MAGNETIC RESONANCE IMAGING

Computed tomography urography, to date, has emerged as the test of choice for many urologic problems, including urolithiasis, renal masses, urinary tract infection, trauma, and obstructive uropathy. Detailed anatomy of the major portions of the urinary tract-the kidneys, intrarenal collecting systems, ureters, and bladder can be assessed by CTU. Magnetic resonance urography (MRU) may be preferred in a number of clinical scenarios and has the advantage of not using ionizing radiation and the potential to provide more functional information than CT. MRU may be preferable to CTU for performing imaging examinations of pediatric and younger patient populations, pregnant women, patients undergoing repeat assessment of the collecting systems (because of the absence of ionizing radiation), patients with history of allergic to iodinated contrast, and patients with renal dysfunction. There are two types of MR urographic techniques used to display the urinary tract:

1. Static-fluid MRU (also known as static MRU, T2-weighted MR urography, or MR hydrography), and
2. Excretory MRU (also known as T1-weighted MRU)

Static-fluid MRU treats the urinary tract as a static column of fluid and involves imaging of urine (or water) in the urinary tract by using a variety of T2-weighted pulse sequences that exploit the long T2 relaxation time of urine. Breath-hold T2-weighted MR urogram can be obtained with either thick-slab single-shot fast spin-echo (SSFSE) techniques or similar thin-section techniques. To obtain thin-section, three-dimensional (3D) respiratory-triggered sequences can be used that can be postprocessed to create volume rendered (VR) or maximum intensity projection (MIP) images of the entire urinary tract. Coronal heavily T2-weighted static-fluid MR urogram is useful for quickly identifying the level of urinary tract obstruction. Because static-fluid MRU depends on the presence of urine within the collecting systems rather than the excretory function of the kidneys, it is ideally suited for patients with dilated and obstructed collecting systems (**Figs. 7A** and **B**). For detection of periureteral fat stranding (indirect indicator of obstruction

FIGS. 6A AND B: Computed tomography urography images in patient with right staghorn calculus. (A) Thin maximum intensity projection (MIP) coronal image; and (B) Volume rendered image.



FIGS. 7A AND B: Coronal static-fluid magnetic resonance (MR) urogram shows (A) inflammatory stricture, smoothly contoured obstruction of the right ureter; and (B) malignant stricture, abrupt irregular obstruction of left distal ureter.

and tumor infiltration), fat-suppressed T2-weighted images are useful. Excretory MRU is similar to CTU and conventional IVU. Collecting systems images are taken during the excretory phase after administering gadolinium-based contrast agent intravenously. The primary imaging sequence for excretory MRU is the 3D gradient-echo sequence. Fat suppression enhances the compacity of the ureters and is recommended. Excretory T1-weighted sequences can image the kidneys in the corticomedullary, nephrographic, and excretory phases as for CTU. In obstructive uropathy, combined static fluid and excretory MRU can provide valuable information, since T2-weighted sequences demonstrate collecting system dilatation and excretory images demonstrates the ureteric tract above and below the site of obstruction and can provide an estimation of the degree of ureteric stenosis. Spin echo MRI helps differentiate blood clots and stones from tumor by demonstrating contrast enhancement on postcontrast T1-weighted imaging.

NUCLEAR MEDICINE

Nuclear medicine provides data pertaining to renal function, perfusion, and urinary tract dynamics which complements that of IVU, US, CT, and MRI. Renal perfusion and excretory functions of kidney are assessed by radioactive tracers that are excreted by the kidney, while tracers that are retained in the kidney are helpful in assessing renal anatomy. Currently the most satisfactory tracer for imaging renal anatomy is ^{99m}Tc-dimercaptosuccinic acid (DMSA); for investigating renal perfusion and excretion ^{99m}Tc-mercaptoacetyltriglycine (MAG3) is now preferred over earlier tracer excreted solely by glomerular filtration [^{99m}Tc-diethylenetriaminepentaacetate (DTPA)] or by tubular secretion (^{123}I-orthoiodohippurate).

The DMSA scintigraphy is used to locate the functioning renal tissue in renal ectopia and other congenital renal anomalies, differentiate pseudo masses, e.g., prominent columns of Bertini from true lesions such as tumors, cysts, or abscesses which appear as photon-deficient areas and to find scars or nonfunctioning areas of renal parenchyma in renal infections.

Dynamic renal studies are particularly important for the investigation of urinary tract dilatation. MAG3 and Hippuran are extracted and cleared by the renal tubules faster than the glomerular agent DTPA and so preferred for collecting system imaging in pediatric patients. DTPA is less costly and also quicker and easier to prepare than MAG3, and so it may be used in emergent situations where a rapid result is needed, particularly in respect of perfusion, e.g., renal transplant recipient with acute oliguria. A bolus injection of radiopharmaceutical is given into a peripheral vein. Rapid image acquisition is required to demonstrate the perfusion phase and for the excretion phase, sequential images are acquired for 20–30 minutes. The sensitivity of dynamic renal imaging for detecting urinary tract obstruction is maximized by increasing flow rate by giving diuretics. Analysis of the images and renogram curves obtained during the first pass of the tracer illustrate renal perfusion. Size, shape, and location of the kidneys can be assessed by taking the images obtained 3–5 minutes after injection. During the excretion phase serial images can be obtained to assess relative renal function, rate of transit of activity through the renal pelvis, drainage from the pelvis in the sitting position, and the residual bladder volume after micturition. For infants and children with suspected vesicoureteric reflux disease, indirect radionuclide cystography can be performed. After diuresis renography, the patient is placed in a sitting or standing position and the camera repositioned to include both kidneys and the bladder within the field of view. Image frames are collected during micturition and time-activity curves are derived from the region of the bladder, each kidney and along the line of each ureter. Vesicoureteric reflux is confirmed if there is an increase in kidney or ureter counts during micturition. Bladder catheterization is not required for indirect radionuclide cystography is major advantage. The disadvantage is its lack of anatomical details.

SUMMARY

The current and emerging state-of-the-art imaging modalities for evaluation of the GU system are discussed in this chapter. Numerous factors need to be taken into consideration when deciding which imaging modality should be used rather than in a single algorithm to evaluate the entire GU tract. In addition to sensitivity and specificity, availability, cost-effectiveness, and potential limitation of imaging modality are to be considered.

107 CHAPTER

Hematuria

Puneet Ahluwalia

INTRODUCTION

"Hematuria" in simple term means "blood in urine". In normal urine <3 red blood cells/high-power field (RBCs/HPF) can be present. Any hematuria with >3 RBC/HPF is marked as significant and needs further investigation and management. Isolated hematuria can sometimes be observed without any associated obvious underlying condition (e.g., cystitis and ureteral stone) or may the presenting symptoms of a serious condition like underlying malignancy in urinary tract. The causes for hematuria (and the tests needed for evaluation) vary with the age of presentation. Therefore, it is important to know the basic "workup" of the patient presenting with this symptom.

CLASSIFICATION OF HEMATURIA

Hematuria may be classified as *gross* (macroscopic hematuria or which is visible to naked eyes) or *microscopic hematuria* (detected only on urine examination).

Gross Hematuria

Gross hematuria is suspected in patients with history of passing red or brown colored urine. Patients with gross hematuria are usually frightened by the sudden onset of blood in the urine and frequently present to the emergency department for evaluation, fearing that they may be bleeding excessively. Therefore, a detailed history of consumption of any coloring agent or medications should be taken. Gross hematuria, however, with passage of clots almost always indicates a lower urinary tract source.

Microscopic Hematuria

Microscopic hematuria when blood (either RBCs or hemoglobin) is found on a laboratory urine examination or dipstick test. Repeated episodes of microscopic hematuria need evaluation. The level of investigation depends upon the risk profile of patient and the level of suspicion regarding the presence of urinary tract abnormality. Although the presence of three or more RBCs per HPF in a spun urine sediment is considered abnormal, there is no "safe" lower limit below which significant disease can be excluded.

ETIOLOGY

Hematuria can be caused by various underlying pathological conditions or the disease. Age and location of pathology in urinary tract are the main determinant for the causes of hematuria (**Table 1**). Broad range of etiological factors of hematuria needs careful evaluation when presented to emergency department. Smoking leads to urothelial malignancy and age >50 years related to bladder carcinoma.

HISTORY AND INITIAL EVALUATION

History

During the history taking of the patient with hematuria, the clinician should ask for the following clues:

- Family history of renal disease, sickle cell disease, polycystic kidney disease, and diabetes.
- Recent upper respiratory tract infection (can lead to a possible postinfectious glomerulonephritis, vasculitis, and antiglomerular basement membrane disease).
- Recent fever with pyuria and/or dysuria [indicates urinary tract infection (UTI)].
- Any recent flank pain radiating groin (suggestive of ureteral obstruction due to blood clot, calculus, and malignancy).
- History of hesitancy and dribbling in older men (suggestive of prostatic obstruction).
- Bleeding due to excessive anticoagulation. Studies suggest that chronic anticoagulation is not a cause of hematuria and patients on anticoagulants should be evaluated thoroughly to find the underlying cause of hematuria, as one will evaluate in other patients.
- Recent episode of strenuous exercise or trauma.
- Travel history to places endemic for tuberculosis or *Schistosoma haematobium*.
- Is there a history of smoking or any drug abuse?
- Hematuria in suspected analgesic abusers, diabetics, and in Afro-Americans is caused by papillary necrosis.

Initial Evaluation

In the initial evaluation of hematuria, several questions should always be asked. The answers to the following questions

TABLE 1: Etiology of hematuria.

Etiology of hematuria-related to age of patient	*Etiology of hematuria-related to pathological location*	
	Upper collecting system	***Lower collecting system***
• *Young adults and children:* Glomerulonephritis • *Over 20 years:* Nephrolithiasis • *Over 40 years:* BPH (in males) • *Over 50 years:* Malignancy • *All ages:* Urinary tract infections	• Papillary necrosis (sickle cell disease) • Renal vein thrombosis • Renal artery embolism • Benign/malignant renal mass • Glomerular bleeding (Alport's syndrome and IgA nephropathy) • Pyelonephritis • Malignant hypertension • Hydronephrosis • Polycystic kidney disease • Arteriovenous malformation • Renal or ureteric calculi • Ureteric stricture • Postsurgical complications • Trauma • Anticoagulation	• Radiation • Cystitis • Traumatic catheterization • Urethritis • Malignancy (squamous cell carcinoma and transitional cell carcinoma) • Urethral diverticulum • Trauma • Anticoagulation • Transurethral resection of the prostate

(BPH: benign prostate hypertrophy; IgA: immunoglobulin A)

will enable the urologist to target the subsequent diagnostic evaluation efficiently:

- *Gross or microscopic hematuria?* This helps the clinician to identifying any significant pathology. Patient with gross hematuria generally have significant and definitive pathology while negative evaluation in microscopic hematuria.
- *Hematuria occur in beginning or end of stream or during entire stream?* By knowing the timing of hematuria during urination one can figure out the site of origin of hematuria. Initial hematuria due to urethral inflammation, terminal hematuria due to bladder neck or prostatic urethra inflammation, and total hematuria mainly due to bladder and upper urinary tract.
- *Pain with hematuria?* Signify inflammation (cystitis) or obstruction (clots and calculi). Painful hematuria is linked with upper urinary tract hematuria with obstruction of the ureters with clots. During the passage of these clots, the patient experiences colicky flank pain similar to ureteric colic. Another painful cause of hematuria is cystitis. Gross painless hematuria is seen in patients with bladder cancer.
- *Any clots with hematuria?* If present, it is significant hematuria. Presence of any blood clots in the urine sample increases the chances of identifying any significant pathology in the patient. In case of hematuria originating from upper urinary tract, one can see the presence of vermiform (worm-shaped) blood clots. On the other hand, hematuria originating from the bladder and the prosthetic urethra the clots will be amorphous.
- *Transient or persistent hematuria?* Transient microscopic hematuria is a common problem in adults. In most patients with transient hematuria, no obvious etiology is identified. Fever, infection, trauma, and exercise are potential causes of transient hematuria. Transient hematuria can also occur with UTI (e.g., cystitis or prostatitis). In this setting, hematuria is typically accompanied by pyuria and bacteriuria and patients often complain of dysuria. Typically, benign nature of transient hematuria occurs in older patients (40 years of age) in whom even transient hematuria carries an increased risk of malignancy.

  It cannot be overemphasized that hematuria should be considered as symptom of malignancy until proved otherwise, particularly in the adults. Presence of hematuria in adults mandates immediate urologic examination. Bladder cancer is the most common cause of gross hematuria in a patient older than age 50 years.
- *Glomerular or nonglomerular hematuria?* Red or pink urine with clots with normal RBCs morphology is suggestive of extraglomerular source whereas dark red, smoky brown, or coca cola color urine with some dysmorphic RBCs suggests glomerular origin of hematuria. Also, hematuria of glomerular origin is differentiated from nonglomerular based on related significant proteinuria (>500 mg/day) and presence of cast.

Some Other Clues

- *IgA nephropathy (Berger disease)*: Children and young adult (male) having low grade fever. Hereditary nephritis, polycystic kidney disease, or sickle cell disease—family history.
- Ureteral obstruction, flank pain radiating to the groin due to a calculus or blood clot
- Prostatic obstruction, present as hesitancy and dribbling may be present in older men.
- Urinary tract infection, pyuria and dysuria may also be present in bladder malignancy.
- Recent vigorous exercise or trauma in the absence of another possible cause.
- Endometriosis of urinary tract should be suspected in women with cyclic hematuria that is most prominent during and shortly after menstruation. Contamination with menstrual blood should be ruled out by a repeat sample when menstruation has ceased.

Food and Medication

Food habits and medication history should be taken in details as they give rise to brown/red coloration of the urine (**Table 2**). Anticoagulation and drug causing nephritis cause hematuria.

TABLE 2: Food and medication which give rise to brown/red color of the urine.

Food	*Medications*	*Endogenous*
• Berries • Beets • Rhubarb • Fava beans • Paprika • Artificial food color	• Phenytoin • Nonsteroidal anti-inflammatory drugs (NSAIDs) • Rifampin • Quinine chloroquine • Phenothiazines • Nitrofurantoin • Metronidazole • Levodopa and methyldopa • Prochlorperazine • Sulfonamides	• Myoglobin • Free hemoglobin and porphyrins • Bilirubin • Melanin • Amorphous urates • *Serratia marcescens* infection

STEPWISE APPROACH FOR EVALUATION

Step I: Confirmation of Hematuria: Urine Examination

Hematuria may be due to variety of causes. Urolithiasis, UTI, neoplasms of the urinary tract (including both renal cell carcinoma and urothelial tumors), urinary tract trauma, and medical renal disease are among the more common causes.

First step in any patient presenting with suspected hematuria is to confirm the finding with urine examination. A simple and easily available *"dipstick test"* is the first step. A positive dipstick for blood in the urine most commonly indicates *any of the three conditions; hematuria, hemoglobinuria, or myoglobinuria*. Peroxidase-like activity of hemoglobin detects the presence of blood in urine and leads to change in color as per the degree and amount of oxidation.

Hemoglobinuria and myoglobinuria can be distinguished from hematuria by the microscopic examination of centrifuged urine. The diagnosis of hematuria is established by the presence of a large number of erythrocytes. Examination of the serum, in the absence of erythrocytes in urine, distinguishes hemoglobinuria from myoglobinuria. In centrifuged specimen, pink supernatant indicates hemoglobinuria. This is due to affinity of free hemoglobin in the serum to bind haptoglobin. The complex has a high molecular weight, is water insoluble and remains in the serum, causing a pink color. Once all the haptoglobin-binding sites are saturated, free hemoglobin appears in the urine. Myoglobin on the other hand is of low molecular weight and is water soluble.

Hematuria, defined as >3 RBCs/HPF, can be identified with urinary dipsticks with sensitivity of >90%. Conversely, dipstick method has a high false-positive rate for hematuria leading to lower *specificity as compared with microscopy*. Contamination of the urine specimen with menstrual blood is the most common cause of false-positive dipstick results. Increased concentration of erythrocytes and hemoglobin in dehydration with resultant high specific gravity urine is another cause of false-positive result. First morning voided specimen is also more likely to yield false-positive result due to high specific gravity. Vigorous exercise can sometimes increase the number of erythrocytes in the urine leading to false-positive results. Efficacy of dipstick in hematuria screening to identify significant urologic disease remains somewhat controversial. Confirmation of dipstick result with microscopic examination of the centrifuged urinary sediment is imperative before proceeding to more complicated studies.

Step II: Rule Out Benign Causes

History, physical examination, and laboratory examination to rule out benign causes such as infection, menstruation, vigorous exercise, medical renal disease, viral illness, trauma, or recent urological procedures. If a "benign" cause for microscopic hematuria is suspected, the patient should undergo repeat urinalysis 48 hours after cessation of the activity. In patients with bacteriuria or pyuria, a urine culture should be ordered to confirm UTI.

Step III: Baseline Renal Function: Evaluation for Primary Renal Disease

Estimate of renal function including serum creatinine, blood urea nitrogen, and calculated estimated glomerular filtration rate (eGFR) is obtained once benign causes are excluded. Contrast or gadolinium radiologic studies are contraindicated in patients with renal dysfunction. The presence of any of the parameters suggestive of renal parenchymal/glomerular disease warrants concurrent nephrology workup.

Step IV: Urological Evaluation

Urine Cytology

Urinary cytology or cystoscopy may be used. Cystoscopy is required if cytology shows malignant or atypical/suspicious cells.

Imaging

In a patient with otherwise unexplained hematuria, once nephrological or glomerular causes of bleeding are excluded, the diagnostic workup should be directed towards urological evaluation and include a search for lesions in the kidney, collecting system, ureters, bladder, or urethra. The diagnostic yield is directly proportional to age and may be higher for gross hematuria than for microscopic hematuria.

Computed Tomography Urography

It is the investigation of choice for evaluation of hematuria. Computed tomography (CT) with or without contrast is the initial imaging study of choice in hematuria of nonglomerular origin. CT has high sensitivity for detecting stones in identifying renal tumors and other nongenitourinary tract abdominal pathologies that lead to hematuria. The disadvantage of CT scan is the need of intravenous (IV) contrast and radiation exposure to the patient. CT is also not safe for pregnant females.

Magnetic Resonance Urography

For patients with relative or absolute contraindications that preclude use of multiphasic CT (such as renal insufficiency, contrast allergy, and pregnancy), magnetic resonance

urography (MRU) (without/with IV contrast) is an acceptable alternative imaging approach.

Intravenous Pyelography

Intravenous pyelography (IVP) is less sensitive in detecting kidney stones and renal masses (particularly small masses) and has largely been replaced with CT urography (CTU). In case of suspicion of upper tract involvement, a retrograde pyelography is helpful to identify the source of hematuria. Some clinicians believe that IVP is best able to characterize lesions in the urothelium. However, increasing evidence suggests detection rates for urothelial neoplasm with IVP are between 40 and 65%.

Ultrasonography

Renal ultrasound is the next best initial imaging modality in case CT is not available or contraindicated. Ultrasonography is excellent for detection and characterization of renal cysts but is less sensitive in detecting transitional cell carcinoma, small solid lesions (<3 cm), and calculi. However, the combination of ultrasonography and CT may improve the characterization of small-sized renal masses. If initial imaging modalities are inconclusive to identify the source of hematuria then cystoscopy should be planned.

Role of Cystoscopy

In Gross Hematuria

Patients who have gross (macroscopic) hematuria without any evidence of either glomerular disease or infection should undergo cystoscopy since it permits direct visualization of bladder and can detect malignant or other sources of bleeding. Cystoscopy should also be done in patients who have gross hematuria with blood clots even if they have evidence of a glomerular lesion since blood clots are virtually never associated with glomerular bleeding. The presence of blood clots in these patients suggests the concurrent presence of disease in the upper or lower collecting system.

In Microscopic Hematuria

Cystoscopy should also be done in all patients with microscopic hematuria who have no evidence of glomerular disease or other benign causes such as infection or exercise and who are at increased risk for malignancy.

Cystoscopy allows visualizing entire bladder wall for malignancy or any other abnormality. Cystoscopy may also identify the source of the bleeding among patients with gross hematuria. Moreover, cystoscopy is the only modality that permits visualization of the prostate and urethra.

UNEXPLAINED HEMATURIA

In cases of unexplained hematuria, particularly in young and middle-aged patients, glomerular disease or a stone disease is the most likely reason of isolated hematuria. In these patients with persistent isolated hematuria, evaluation with history, cystoscopy, and imaging are often not conclusive and may be normal.

FOLLOW-UP AFTER INITIAL NEGATIVE EVALUATION

Patients who have a negative evaluation for hematuria generally require follow-up with cytology, urinalysis, blood pressure monitoring, and in some cases with repeat imaging and cystoscopy. The necessity for repeat imaging and cystoscopy largely depends upon whether hematuria was transient or persistent, and upon the patient's risk for malignancy.

Follow-up of patients with transient hematuria: Patients who have even one episode of hematuria and are at high risk for malignancy require close follow-up following a negative evaluation.

Follow-up of in cases of persistent hematuria: In a patient with unexplained persistent hematuria, it is imperative to rule out the presence of an underlying malignancy. An undiagnosed carcinoma is potentially the most serious disorder in these patients. The combination of negative imaging, cytology, and cystoscopy most likely rules out the presence of a malignant pathology. However, in few patients, careful follow-up is necessary to reveal the cause of persistent hematuria. Recommended follow-up for patients with asymptomatic microhematuria includes monitoring with annual urinalysis.

1. If two consecutive annual urinalyses are negative in patients with persistent asymptomatic microhematuria, then the follow-up can be concluded.
2. Complete initial urological workup is recommended if microhematuria persists for 3–5 years.

TREATMENT

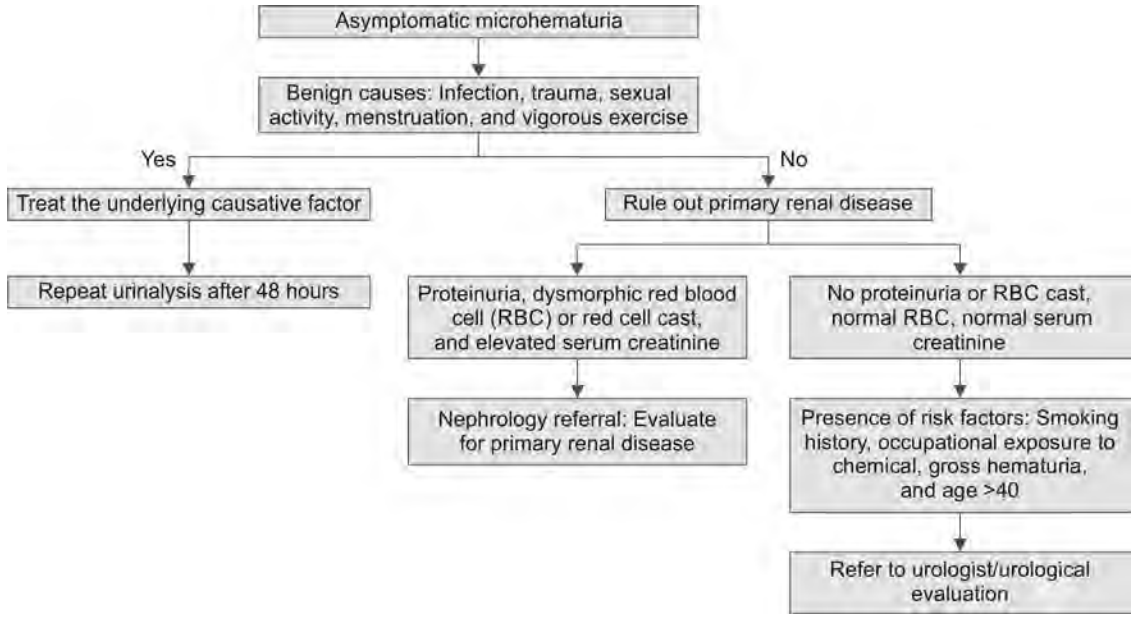
Treatment of hematuria is based on the etiology. In cases presenting to the emergency department, one should assess the hemodynamic stability of the patient first. In hemodynamically stable patients, without any life-threatening cause of hematuria, it is advised to have an outpatient follow-up. As per the recommendations of American Urological Association guideline, patients with microscopic hematuria without any benign cause should be referred to urology service for assessment of urinary tract malignancy.

Patients with gross hematuria may present to the emergency department with acute urinary retention due to bladder outlet obstruction and intravesical clot formation. This condition is treated by Foley's catheterization and may be followed by a bladder wash in consultation with the urologist.

Hemodynamically unstable patients with pain, intolerance to oral medications and fluids, and other comorbid conditions with bladder obstruction or with life-threatening cause of hematuria should be stabilized in the emergency department and are to be admitted under appropriate specialist.

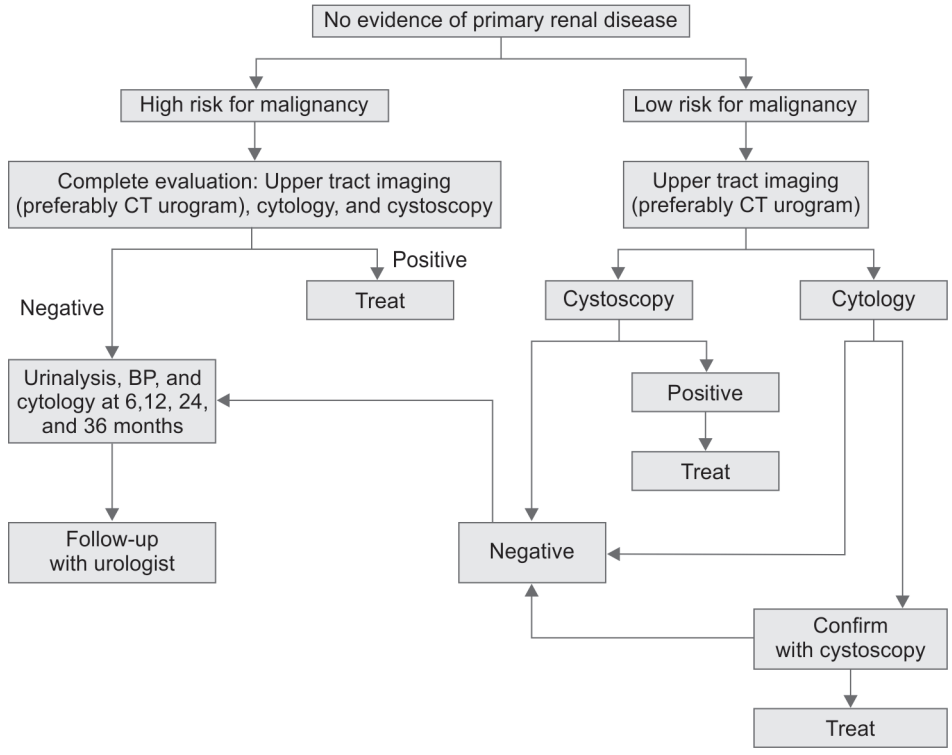
SUMMARY

The presence of RBCs in the urine is hematuria. It can be microscopic (detected by dipstick or microscopic examination) or gross (visible to naked eyes). Evaluation of asymptomatic microscopic hematuria is summarized in **Flowchart 1**. In adults, any unexplained hematuria is



Asymptomatic microhematuria
Benign causes: Infection, trauma, sexual activity, menstruation, and vigorous exercise
Yes
No
Treat the underlying causative factor
Rule out primary renal disease
Repeat urinalysis after 48 hours
Proteinuria, dysmorphic red blood cell (RBC) or red cell cast, and elevated serum creatinine
No proteinuria or RBC cast, normal RBC, normal serum creatinine
Nephrology referral: Evaluate for primary renal disease
Presence of risk factors: Smoking history, occupational exposure to chemical, gross hematuria, and age >40
Refer to urologist/urological evaluation

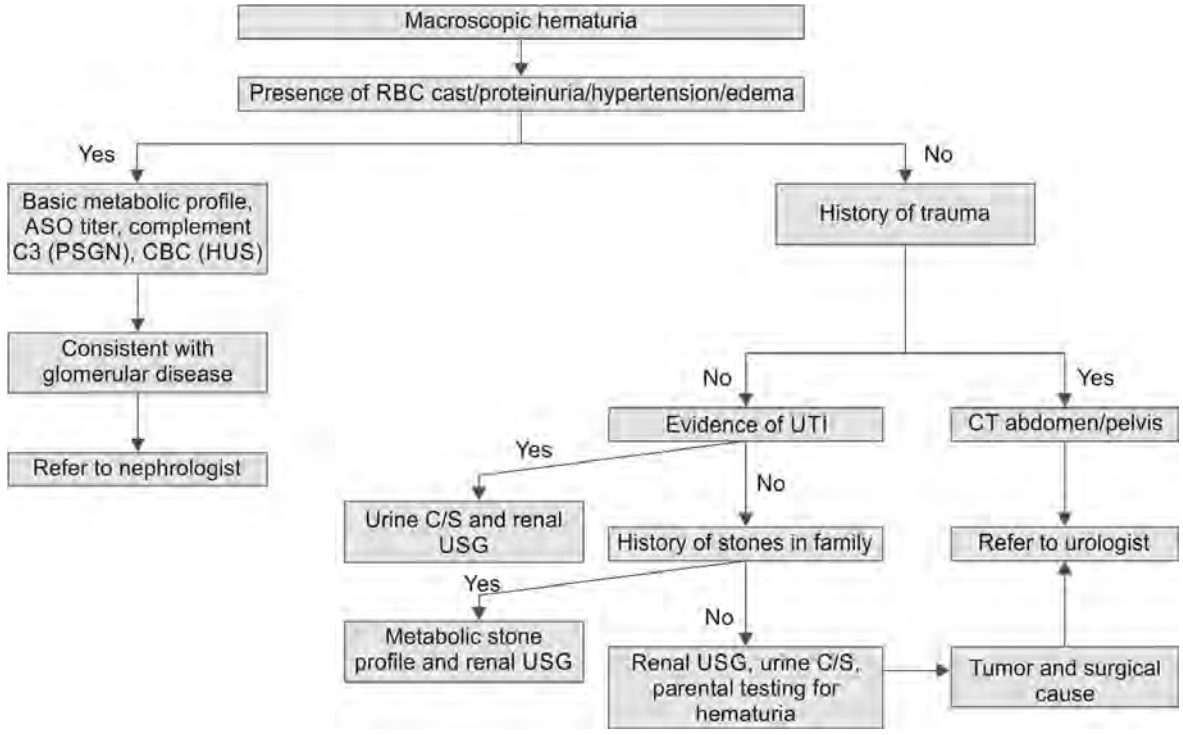
FLOWCHART 1: Evaluation of asymptomatic microscopic hematuria.



(BP: blood pressure; CT: computed tomography)

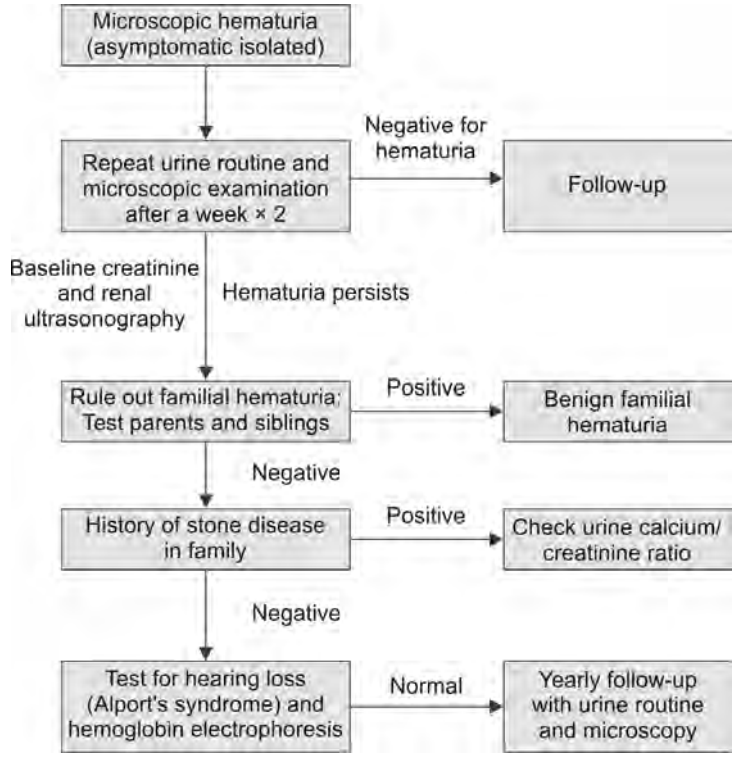
FLOWCHART 2: Urologic evaluation of hematuria.

assumed malignant until proven otherwise. Patients with gross hematuria should undergo a mandatory evaluation of the upper and lower urinary tract whereas patients with asymptomatic microscopic hematuria should have urologic evaluation upon ruling out of benign causes (**Flowchart 2**). The evaluation should include urine analysis, renal functions test, cystoscopy, renal and genitourinary ultrasonography and CT. Treatment of hematuria is based on the etiology. Hemodynamically unstable patients should be stabilized in the emergency department and are admitted for further management. Evaluation of microscopic and macroscopic hematuria is summarized in **Flowcharts 3** and **4**.



(ASO: antistreptolysin O; CBC: complete blood count; C/S: culture and sensitivity; CT: computed tomography; HUS: hemolytic uremic syndrome; PSGN: poststreptococcal glomerulonephritis; RBC: red blood cell; USG: ultrasonography; UTI: urinary tract infection)

FLOWCHART 3: Evaluation of macroscopic hematuria in children.



Microscopic hematuria (asymptomatic isolated)
Repeat urine routine and microscopic examination after a week × 2
Negative for hematuria
Follow-up
Baseline creatinine and renal ultrasonography
Hematuria persists
Rule out familial hematuria; Test parents and siblings
Positive
Benign familial hematuria
Negative
History of stone disease in family
Positive
Check urine calcium/ creatinine ratio
Negative

108 CHAPTER

Acute Urinary Retention

Puneet Ahluwalia

INTRODUCTION

Acute urinary retention (AUR) is the sudden painful inability to void, with relief of pain following drainage of bladder. It is one of the most common emergencies encountered in urology. A combination of reduced or absent urine output with lower abdominal pain is not enough to make a diagnosis of AUR. Sometimes a surgical condition with lower abdominal pain and reduced urine output due to fluid depletion, can give a false impression of AUR. Therefore, central to the diagnosis of AUR is the presence of large volume of urine. What actually defines this large volume has not been strictly described but volumes of 500–800 mL are typical. In men, the most common cause of AUR is benign prostatic hyperplasia (BPH). AUR is rarely encountered in women. It is imperative to know the etiopathogenesis and management of AUR. The present chapter focuses on both aspects.

EPIDEMIOLOGY

Acute urinary retention is common in men. The incidence increases with age, occurring most frequently in men over age 60. The reported incidence is about 0.5–2.5% person years. The risk is cumulative and increases with age. It is estimated that over a 5-year period, approximately 10% of men over the age of 70 and almost one-third of men in their 80s will develop AUR. In contrast, women rarely present with AUR. It is estimated that there are three cases of AUR per 100,000 women per year. The female-to-male incidence rate ratio is 1:13.

ETIOPATHOGENESIS

Various pathophysiologic mechanisms play a role in the development of AUR. There is no specific etiology and usually it is multifactorial. Etiologic factors responsible for AUR are divided into following broad categories.

- *Obstructive causes*: Outflow obstruction with increased urethral resistance
- *Neurogenic*: Neurologic impairment, interruption of sensory or motor innervations of the bladder.
- *Myogenic*: Inefficient detrusor muscle contraction with low bladder pressure
- *Others*: Infections drugs

Outflow Obstruction

Obstruction is the most common cause of AUR. A range of mechanical and dynamic factors are responsible for the outflow obstruction. Mechanical obstruction refers to a physical narrowing at any level in urethral channel from bladder neck to external urethral meatus. Dynamic obstruction refers to increased sphincteric activity with increased muscle tone within and around the urethra.

In men, the most common cause of obstruction is bladder outlet obstruction due to BPH. In a study of 310 men over a 2-year period, urinary retention was caused by BPH in 53% of patients. Other obstructive causes accounted for another 23%. Risk factors for developing AUR in patients with BPH include advanced age, severity of lower urinary tract symptoms (LUTS), enlarged prostate gland, and decreased urinary flow rate. Other causes of outflow obstruction in men include urethral stricture, urolithiasis, cancer prostate, phimosis, or paraphimosis and bladder cancer. Urinary retention from bladder tumors is usually caused by blood clots from intravesicular bleeding and often presents with painless hematuria.

In women, obstruction is generally secondary to anatomic distortion due to various reasons as pelvic organ prolapsed, pelvic masses, or rarely urethral diverticulum. Fecal impaction and gastrointestinal or retroperitoneal masses are large enough to cause extrinsic bladder. Neck compression can also sometimes present with retention of urine. Obstructive causes of AUR in men and women are summarized in **Table 1**.

Age

Several well-controlled studies provided considerable insights into the risk factors for AUR. Perhaps the most significant of these risk factors is age. Studies demonstrate a nearly linear increase in the age-specific incidence of AUR for men ranging in age from 40 to older than 80 years.

Lower Urinary Tract Symptoms

Increased symptom severity is associated with increased risk of AUR in several large population-based or cohort studies. The Olmsted County study focused on age, symptom severity, maximum flow rate, and prostate volume. Incidence rates per 1,000 patient-years increased from 2.6 to 9.3 for men in their

TABLE 1: Obstructive causes of acute urinary retention (AUR).

Males	*Females*	*Both*
• Benign prostatic hyperplasia • Meatal stenosis • Urethral stricture • Phimosis • Paraphimosis	• Pelvic organ prolapse (cystocele, rectocele, and uterine prolapse) • Pelvic mass (gynecologic malignancy, uterine fibroid, and ovarian cyst) • Retroverted impacted gravid uterus	• Urolithiasis (bladder stone) • Bladder tumor • Constipation with fecal impaction • Retroperitoneal mass • Gastrointestinal malignancy • Foreign body

40s to their 70s if they had mild symptoms and from 3.0 to 34.7 if they had more than mild symptoms.

Urodynamic Parameters

The relative risk increased for older men, men with moderate-to-severe symptoms (3.2 times), those with a flow rate under 12 mL/s (3.9 times) and those with a prostate volume >30 mL by transrectal ultrasound (TRUS) (3.0 times), all compared with a baseline risk of 1.0 time for the corresponding groups.

Prostate Volume and Serum Prostate-specific Antigen Levels

In the Proscar Long-Term Efficacy and Safety Study (PLESS) and Medical Therapy of Prostatic Symptoms (MTOPS) study, a linear relationship between risk of AUR and prostate volume and serum prostate-specific antigen (PSA) has been demonstrated. An analysis revealed a combination of factors such as serum PSA, frequency, symptom severity index, maximum urinary flow rate, and hesitancy as being only slightly superior to PSA alone in predicting AUR.

Neurologic Impairment

Normal functioning of the bladder and lower urinary tract depends on a complex interaction between the brain, autonomic nervous system, and somatic nerves supplying the bladder and urethra. Interruption along these pathways can result in unsustainable detrusor muscle contraction or incomplete relaxation of sphincter leading to urinary retention.

Neurogenic or neuropathic bladder is defined as any defective functioning of the bladder muscle due to impaired innervation. Urinary retention from neurologic causes occurs equally in both sexes. Although most patients with neurogenic bladder experience incontinence, a significant number might also have urinary retention. Various causes of neurogenic bladder related to spinal cord brain and autonomic nervous system are summarized in **Table 2**.

Up to 56% of patients who have suffered a stroke experience urinary retention, primarily because of detrusor hyporeflexia. In a prospective study, 23 of 80 patients with ischemic stroke developed. AUR can occur with spinal cord injuries from trauma, infarct or demyelination, epidural abscess and epidural metastasis, Guillain–Barré syndrome, diabetic neuropathy, and stroke.

TABLE 2: Causes of neurologic bladder associated with acute urinary retention (AUR).

Autonomic nervous system	*Brain*	*Spinal cord*
• Autonomic neuropathy • Diabetes mellitus • Guillain–Barré syndrome • Herpes zoster virus • Lyme disease • Pernicious anemia • Poliomyelitis • Radical pelvic surgery • Sacral agenesis • Spinal cord trauma • Tabes dorsalis	• Cerebrovascular episode • Multiple sclerosis • Brain tumor • Hydrocephalus • Parkinson's disease • Shy–Drager syndrome	• Intervertebral disk disease • Dysraphic lesions • Spina bifida occulta • Meningomyelocele • Multiple sclerosis • Spinal cord hematoma or abscess • Spinal cord trauma • Spinal stenosis • Transverse myelitis • Conus medullaris or cauda equine tumors or masses

Up to 45% of patients with diabetes mellitus and 75–100% of patients with diabetic peripheral neuropathy experience bladder dysfunction and include urinary retention. Voiding dysfunction tends to correlate with the severity of multiple sclerosis and occurs in up to 80% of patients, with urinary retention being present in approximately 20%. AUR is typically accompanied by back pain and/or other neurologic deficits.

Inefficient Detrusor Muscle

Inefficient detrusor contraction leading to AUR can be due to multiple factors including neurologic disease as above affecting the detrusor contraction or long-standing untreated obstruction leading to detrusor failure. Sometimes a precipitating event results in an acute distended bladder (e.g., with a fluid challenge, during general or epidural analgesia without an indwelling catheter). This most often occurs in patients with some unrecognized obstructive urinary symptoms at baseline.

Other Causes

Acute urinary retention is most often secondary to mechanical outflow obstruction. Other etiologies include medication, infection, trauma, and postoperative and pregnancy-related urine retention.

Medications

Multiple medications are implicated as a cause of urinary retention; most common among these are the anticholinergic and sympathomimetic drugs. These medications lead to AUR through a variety of mechanisms. Patients taking opioids and anticholinergic medications are at higher risk for AUR due to decreased bladder sensation. Anticholinergic medications also reduce detrusor contractility. Nasal decongestants that contain sympathomimetic agents increase smooth muscle tone in the region of the bladder neck. Nonsteroid inflammatory drugs are sometimes responsible for AUR. Nonsteroidal anti-inflammatory drug (NSAID)-induced urinary retention is thought to occur by inhibition of prostaglandin-mediated detrusor muscle contraction.

Infection

Infections may lead to AUR in the setting of inflammation that causes obstruction. The most common cause of infectious AUR is acute prostatitis. Acute prostatitis is usually caused by gram-negative organisms, such as *Escherichia coli* and *Proteus* species, and results in swelling of the acutely inflamed gland.

For example, an acutely-inflamed prostate gland from acute prostatitis can cause AUR, particularly in men who already have BPH. Urethritis from urinary tract infection or urethritis can cause urethral edema and can result in AUR. Genital herpes may cause AUR both from local inflammation as well as sacral nerve involvement. Other infections that have been associated with AUR include varicella zoster and vulvovaginitis, summarized in **Table 3**.

Trauma

Patients with trauma to the pelvis, urethra, or penis may develop AUR from mechanical disruption. AUR may also occur in postoperative period.

Postoperative Urinary Retention

Multiple factors as pain, traumatic instrumentation, bladder over distension, and pharmacologic agents (particularly opioid narcotics and prazosin) thought to play a role. After rectal surgery, patients will experience urinary retention up to 70% of the time. As many as 78% of patients who have had total hip arthroplasty and up to 25% of patients who have had outpatient gynecologic surgery will develop urinary retention. During hemorrhoidectomy, the use of selective pudendal nerve block rather than spinal anesthesia may decrease urinary retention.

Pregnancy-associated Urinary Retention

Urinary retention during pregnancy is usually the result of an impacted retroverted uterus obstructing the internal urethral meatus and is most often encountered at 16 weeks of gestation. In postpartum period, the incidence of AUR is reported to be 1.7–17.9%. Risk factors include nulliparity, prolonged labor, instrumental delivery, epidural anesthesia, and cesarean section. Other causes of AUR are summarized in **Table 4**.

CATEGORIES OF URINARY RETENTION

From a clinical and prognostic point of view AUR has been divided into two broad categories as spontaneous and precipitated. Precipitated AUR refers to inability to urinate after a triggering event such as nonprostate-related surgery, e.g., hemorrhoidectomy, catheterization, anesthesia, ingestion of drugs as sympathomimetic or anticholinergics or antihistaminic, and excessive fluid intake. All other episodes of AUR are classified as spontaneous AUR. The clinical significance of differentiating the two types of AUR lies in the final outcomes of these patients. In a study by Roehborn et al., after an episode of spontaneous AUR, 15% of patients had another episode of spontaneous AUR and a total of 75% underwent surgery, whereas after precipitated AUR only 9% had an episode of spontaneous AUR, and 26% underwent surgery.

CLINICAL PRESENTATION

Acute urinary retention generally presents as an inability to pass urine. It is typically associated with lower abdominal and/or suprapubic discomfort. Affected patients are often restless and may appear in considerable distress. These manifestations may be less pronounced when AUR is superimposed upon chronic urinary retention. Chronic urinary retention is often painless. Acute-on-chronic urinary retention may present with overflow incontinence. The patients may complain of incontinence rather than the inability to pass urine. Patients with AUR are likely to present initially to an emergency department or the office of a primary care clinician. Most common emergency scenarios encountered by an emergency physician are the bladder outlet obstruction caused by BPH or neurogenic bladder. Hospitalized patients may develop AUR, often related to medications or after surgical procedures.

EVALUATION

Detailed history, physical examination, and diagnostic testing can help determine the etiology of urinary retention.

History

The patient history should focus on age of presentation, sex, previous history of retention or LUTS, prostate disease (hyperplasia or cancer), pelvic or prostate surgery, radiation, or pelvic trauma. Patients will generally give history of multiple lower urinary tract voiding or storage symptoms, including frequency, urgency, nocturia, straining to void, poor urinary stream, hesitancy, sensation of incomplete bladder emptying, and intermittent urinary stream. The patient should also be asked about the presence of incontinence, hematuria, dysuria, fever, low back pain, neurologic symptoms, or rash. The physician should inquire about precipitating factors, including alcohol consumption, recent surgery, urinary tract infection, genitourinary instrumentation, constipation, large

fluid intake, cold exposure, and prolonged travel. Finally, a complete list of medications, including over the counter medications should be obtained. Younger patient age, a history of cancer or intravenous drug abuse, and the presence of back pain or neurologic symptoms suggest the possibility of spinal cord injury or compression. Therefore, a history of neurologic disease, spinal trauma or tumor, and any change in baseline neurologic status is important and should be carefully noted. However, patients with spinal pathology generally do not present primarily with AUR. These patients will most often have other signs and symptoms of spinal cord pathology with AUR being one part of clinical picture. Patients can also present with overflow incontinence and have a history of recurrent urinary tract infection (UTI). History of long-standing diabetes mellitus is also important, but most patients present with painless retention because of diabetic cystopathy. History of presence of pain in any form as restlessness or suprapubic discomfort is important as it may point towards etiology of retention. Acute urine retention of obstructive etiology is usually painful.

Physical Examination

In patients with AUR of unknown etiology, the physical examination should include the following: General physical examination including vitals, general well-being, and systemic examination. Systemic examination should focus on lower abdominal palpation. The urinary bladder may be palpable or percussible. Usually urinary bladder is percussible or palpable if it contains 150–200 mL of urine. In obese patient this may not be appreciable but deep suprapubic palpation will provoke discomfort. A digital rectal examination (DRE) should always be done in both sexes. This is important for detailed evaluation of prostate, masses, fecal impaction, perianal sensation, and rectal sphincter tone. In men, a normal prostate examination does not preclude BPH as a cause of obstruction as size of the dose not correlates the presentation. Prostatic abscess should be looked for in DRE as a hot boggy tender prostate. In women with urinary retention, it is imperative to do per vaginal examination.

In addition to the above, neurologic examination should be done in patients with suspected neurogenic bladder to test the integrity of sacral nerve roots that subserve the bladder function. This includes a general neurologic examination, as well as specific examinations related to bladder function. These include the cremasteric reflex, bulbocavernosus reflex (BCR), voluntary contractions of the pelvic floor, anal sphincter tone, and perianal sensation in the S2 to S4 dermatomes. BCR is done by squeezing the glans penis while performing a DRE. Contraction of anus felt by the examining finder indicates that afferent and efferent sacral nerves and sacral cord are intact. In females, after catheterization same reflex can be elicited by gently tugging the catheter onto the bladder neck while doing DRE, when the contraction of anus indicates integrity of afferent and efferent sacral nerves and sacral cord.

Laboratory Studies

A urine sample should be obtained and sent for urinalysis and urine culture. The urine sample is collected with standard sterile precautions after catheter insertion. The need for other laboratory testing should be determined based upon findings from the patient's history and physical examination. Most patients who present to the emergency room with concern for urinary retention have serum electrolytes and creatinine checked. These should be checked in any patient whose history suggests acute-on-chronic urinary retention, to evaluate for renal failure. Other laboratory study that may be helpful includes a complete blood count (CBC) for suspected infection. Blood gas analysis sample should be sent in patients presenting with sepsis with or without renal failure to look for metabolic acidosis. Serum PSA testing is not recommended in the setting of AUR as it is expected to be elevated during the episode.

Radiological Investigation

This includes an ultrasound kidney, ureter, bladder with prostate, and urine retention volume. Upper tracts are to be looked for hydroureteronephrosis. All these basic investigations help tailoring the emergency management of a patient presenting with AUR.

INITIAL MANAGEMENT OF ACUTE URINARY RETENTION

Urethral catheterization is the mainstay of initial management of AUR. This is for immediate decompression with relief of pain due to overdistended bladder. Standard transurethral catheters are readily available and can usually be easily inserted. If urethral catheterization is unsuccessful or contraindicated, the patient should be referred immediately to a physician trained in advanced catheterization techniques, such as placement of a firm, angulated Coude catheter or a suprapubic catheter. Record the volume drained which will confirm the diagnosis, determines the subsequent management, and provide prognostic information with regard to outcome.

Acute or Acute-on-chronic Retention

A group of elderly people are not aware of, but they actually have urine retention. This has been particularly defined as chronic retention. This has been further subdivided into low-pressure chronic retention or high-pressure chronic retention (*HPCR*). In 1984, Mitchell defined *HPCR of urine* as maintenance of voiding, with a bladder volume of >800 mL and intravesical pressure of >30 cmH_2O, often accompanied by hydronephrosis. This over the time may lead to renal failure. To the contrary low-pressure chronic retention is maintenance of voiding with a bladder volume of >800 mL, but with low normal intravesical pressure and without upper tract changes. The patient continues to void spontaneously without sensation of incomplete voiding. Often the first symptom is bed wetting and inspection of the abdomen reveals a grossly distended bladder confirmed by palpation and/or percussion. Sometimes a patient with HPCR is suddenly unable to pass urine, called as acute-on-chronic retention. Patient presents with palpable bladder, raised serum creatinine, and bilateral hydroureteronephrosis on ultrasound. On catheterization a large volume of urine is drained, often amounting to 1–2 L. As mentioned above recording of volume of urine is important as it holds differentiating two groups of patients, those with acute retention of urine with retention volume of <800 mL and those with acute-on-chronic retention with retention volume of >800 mL. All these patients may develop postobstructive diuresis and it is imperative to keep regular watch on vitals, urine output, and electrolytes.

What to do Next?

Further plan depends on the type of retention whether precipitated or spontaneous and etiology of AUR. Precipitated

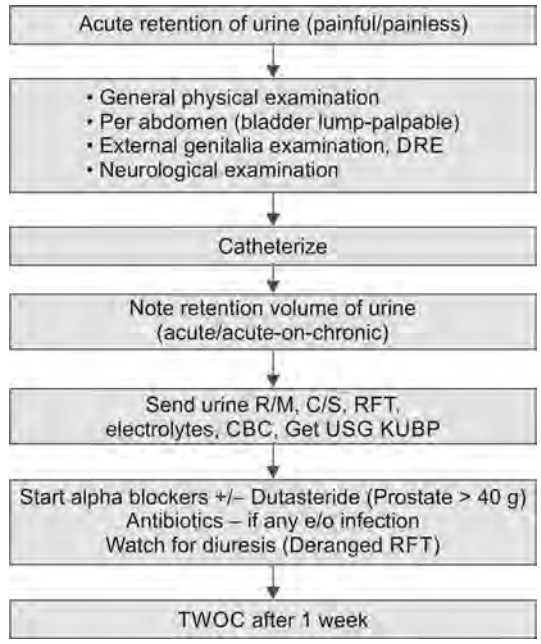
urine retention often does not recur and should be managed with a trial without catheter (TWOC) after exclusion of the precipitating factor. Spontaneous retention often recurs. In case of BPH, usually it is advisable give a TWOC and not to proceed straight to transurethral resection of the prostate (TURP).

The American Urological Association (AUA) guidelines recommend at least one attempted trial of voiding after catheter removal before considering surgical intervention. In these patients the optimal amount of time to leave a catheter in place is unknown. Up to three-fourths of men will have recurrent urinary retention within 1 week if the bladder is simply drained. One-fourth of men will void successfully after a TWOC.

Of those with successful *TWOC* about 50%, 60%, and 70% develop AUR within 1 week, 1 month, and after a year, respectively. Factors affecting the failure of TWOC are maximal flow rate of <5 mL/s, average voided volume of <150 mL.

An alpha blocker started 24–72 hours before TWOC increase the likelihood of successful voiding. The duration of alpha blockers after successful TWOC has not been determined yet. Also, it is not known whether continued use prevents further risk of AUR. Usually alpha blockers are continued after successful TWOC and finasteride or dutasteride is combined with them in case of prostate >40 g. A TWOC is clearly not indicated in patients with back pressure changes on the kidneys.

In patients with chronic urinary retention with inefficient detrusor contraction, especially those with neurogenic bladder can be managed with clean and intermittent self-catheterization. This technique is considered first-line treatment for managing urinary retention caused by neurogenic bladder and can reduce complications, such as renal failure, upper urinary tract deterioration, and urosepsis. Further definitive management of urinary retention depends upon the underlying etiology and may involve surgical and medical treatment. A basic algorithm of managing a male patient presenting with AUR is provided in **Flowchart 1**.



Acute retention of urine (painful/painless)
• General physical examination
• Per abdomen (bladder lump-palpable)
• External genitalia examination, DRE
• Neurological examination
Catheterize
Note retention volume of urine (acute/acute-on-chronic)
Send urine R/M, C/S, RFT, electrolytes, CBC, Get USG KUBP
Start alpha blockers +/– Dutasteride (Prostate > 40 g)
Antibiotics – if any e/o infection
Watch for diuresis (Deranged RFT)
TWOC after 1 week

(CBC: complete blood count; C/S: culture and sensitivity; DRE: digital rectal examination; RFT: renal function test; R/M: routine microscopy; TWOC: trial without catheter; USG KUBP: ultrasound kidney, ureter, bladder and prostate)

FLOWCHART 1: Algorithm for emergency management in case of AUR in a male patient.

SUMMARY

Benign prostatic hypertrophy (BPH) is the most common cause of AUR in men. Patient with acute retention of urine presents to ED with pain while passing the urine and usually gets relief with bladder catheterization. Lower abdominal pain and inability to pass the urine are not enough for diagnosis, nowadays better modalities are available for evaluation of causes and their management. The risk for patients diagnosed with BPH is naturally higher. In addition to serum PSA, prostate volume, maximum flow rate, and symptom severity should be considered while adopting the conservative and medical therapy. Efforts toward primary prevention of AUR are important because surgical treatment carries a higher rate of morbidity in those who are older and have more severe symptoms, larger glands, and higher PSA values.

109 CHAPTER

Acute Kidney Injury and Rhabdomyolysis

Ankit Purohit, Devendra Richhariya

INTRODUCTION

Large number of patient present to emergency department (ED) with clinical features of renal failure. Emergency physicians (EPs) role become important in the evaluation and management of renal disease. Patients with renal dysfunction, either acute or chronic, are frequently encountered in the ED. Patients may have complaints directly related to their kidney dysfunction, or they may have subtle clinical signs, and some may have no signs or symptoms of renal disease. EP must be aware about early recognition, diagnosis, prevention of further iatrogenic injury, and management of renal disease. Basic renal physiology, differential diagnosis and approach to therapy, and strategies to prevent renal injury, will be discussed in this chapter for adult patients who present to the ED with renal injury or failure. General understanding about terminology related to renal failure are *acute kidney injury (AKI):* Rapid decline in renal functions (earlier termed as "acute renal failure") *chronic kidney disease (CKD)*: Progressive persistent decline in renal function over months or years [earlier termed as "chronic renal failure" (CRF)] *end-stage renal disease (ESRD):* Minimal/absent renal function, requiring renal replacement therapy with hemodialysis or peritoneal dialysis. But, various functional and structural criteria are used to define various terminology of renal failure (**Table 1**).

PATHOPHYSIOLOGY

Four important steps in the renal function are: (1) Glomeruli receive blood flow delivered through circulation, (2) An ultrafiltrate is formed in the glomeruli and then delivered to the renal tubules, (3) Renal tubules reabsorbed the solutes and/or water, and (4) Tubular fluid (now urine) exits the tubules, draining to the renal pelvis, the ureters, and the bladder, and urine is then expelled via the urethra. Any process that interferes with any of the above four structures or steps involved in this process causes renal disease. Rapid decline in renal function give rise to AKI, and progressive decline/insult of renal function during months or years resulting CKD.

Each kidney contributes to the total glomerular filtration rate (GFR) through its approximately 1 million nephrons. The volume of fluid filtered per unit time is termed as GFR and can be calculated by measuring any steady state concentration of chemical in the blood plasma and is freely filtered by the kidney but is neither secreted nor absorbed in the kidney [GFR—(urine concentration flow)/plasma concentration].

TABLE 1: Criteria for defining AKI, AKD, CKD, and NKD.

	Duration	*Functional criteria*	*Structural criteria*
AKI	≤7 days	Increase in SCr by ≥50% within 7 days or increase in SCr by ≥0.3 mg/dL (26.5 µmol/L) within 2 days or oliguria for ≥6 h	Not defined
AKD	<3 month	AKI or GFR < 60 mL/min/1.73 m^2 or decrease in GFR by ≥35% over baseline or increase in SCr > 50% over baseline	Elevated marker of kidney damage (albuminuria, hematuria, or pyuria are most common)
CKD	>3 month	GFR < 60 mL/min/1.73 m^2	Elevated marker of kidney damage (albuminuria is most common)
NKD	NA	GFR ≥ 60 mL/min/1.73 m^2, stable GFR (no decrease by 35% within 3 months), stable SCr (no increase by 50% within 3 months or increase by 0.3 mg/dL within 2 days), no oliguria for ≥6 h	No marker of kidney damage

* NKD implies no functional or structural criteria according to the definitions for AKI, AKD, or CKD.

(AKD: acute kidney disease; AKI: acute kidney injury; CKD: chronic kidney disease; GFR: glomerular filtration rate; NKD: no kidney disease; SCr: serum creatinine)

Structural and functional changes within the kidney occur with progressive damage to nephrons. Initially, the kidney tries to maintain GFR with the remaining healthy nephrons through hyperfiltration and compensatory hypertrophy of nephron and normal clearance of plasma solutes is maintained by the kidney. If risk factors cannot be removed or physiologic insult to nephron persists and damaged nephrons cannot recover, renal reserve may be exhausted permanently. Decline in GFR, leading ultimately to oliguria, decreased urine output (UOP), or anuria, the absence of urine formation and finally renal injury and/or renal failure occurs.

Metabolism of creatine phosphate in muscle tissue and is freely filtered by the glomerulus and give rise to serum creatinine (SCr). Most laboratories, and clinical setting, use SCr as an easy and attractive index for measurement in GFR, but several drawbacks to the use of SCr as a surrogate marker for GFR. Various factors such as body mass, body composition, race, sex, total body volume, muscle metabolism, and diet influence the SCr. Apart from these nonrenal factors, significant day-to-day variations in creatinine excretion also occurs, making any single measurement SCr an imperfect measure of a patient's true renal function.

In some settings creatinine clearance (CrCl) is also used as a marker of overall renal function and an estimate of GFR. Most calculations of CrCl depend on measurement of SCr as well as a measurement of urinary creatinine concentrations (UCr) and the measured volume from a 24-hour collection of urine. In addition, certain medications (such as cimetidine and trimethoprim) may inhibit creatinine secretion. Modification of Diet in Renal Disease (MDRD) equation or the Cockcroft-Gault formula is often used in clinical research for estimations of GFR or CrCl. Both make corrections for patient variables such as age and sex. Medical calculators both online and handheld electronic devices can be used by clinicians for these formulas, values can be estimated easily, useful in ED settings.

ACUTE KIDNEY INJURY

Acute kidney injury is a common presenting problem encountered in ED associated with increased risk of mortality and often progression to CKD. AKI is more troublesome particularly in the elderly population. Derangement such as metabolic acidosis and body fluid volume disturbances are associated with AKI. The epidemiology of AKI in hospitalized or critically ill populations is well known, but in the general ED population is not well studied. The patient seen in the emergency or acute setting is often diverse with complex medical histories and without effective primary care follow-up so evidence-based approach for the management of AKI in the emergency setting is required. Most of the time, ED is the place where community-acquired AKI is identified for the first time. Thus, EP should identify, manage AKI appropriately in ED.

DEFINITION

A variety of definitions for AKI proposed in literature. In 2012, the Kidney Disease: Improving Global Outcomes (KDIGO) group defined AKI based on the UOP and the SCr concentration. This definition is an increase in SCr of ≥0.3 mg/dL within 48 hours or an increase in SCr >1.5 times baseline within 7 days or decreased UOP for 6 hours (**Table 2**). Other classification systems of AKI, such as Risk, Injury, Failure, Loss, and End-stage (RIFLE) and Acute Kidney Injury Network (AKIN), can also be used, but as per studies all three criteria are effective tools for predicting mortality without significant differences among them but advantage of KDIGO is that it covers parameters in AKIN and RIFLE.

TABLE 2: Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for acute kidney injuries (AKIs).

AKI stage	*Serum creatinine (SCr)*	*Urine output*
1	1.5–1.9 × baseline OR ≥0.3 mg/dL increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 × baseline	<0.5 mL/kg/h for >12 h
3	3.0 × baseline OR initiation of renal replacement therapy	<0.3 mL/kg/h for ≥24 h OR anuria for ≥12 h
Risk, Injury, Failure, Loss, and End-stage (RIFLE) Criteria		
1	Increase in SCr ≥150% mg/dL	<0.5 mL/kg/h for 6–12 h
2	Increase in SCr ≥200–300% mg/dL	<0.5 mL/kg/h for ≥12 h
3	Increase in Cr 300% OR creatinine >4 mg/mL with acute increase 0.5 mg/dL or initiationofrenalreplacement therapy	<0.3 mL/kg/h for ≥24 h OR anuria for ≥12 h

Source: Data from Moore PK, Hsu RK, Liu KD. Management of acute kidney injury: core curriculum 2018. Am J Kidney Dis. 2018;72(1):136-48.

Acute kidney injury is defined as a sudden reduction in kidney function that is characterized by a diminished GFR as manifested by an increased SCr or reduced UOP. AKI is further divided into three categories: (1) *Prerenal,* a kidney blood flow decrease; (2) *Intrarenal,* or kidney parenchymal injury; and (3) *Postrenal,* or urine flow obstruction. Intrarenal AKI is subdivided again on the basis of part of the kidney is involved: glomeruli, vasculature, or interstitium. Treatment of AKI depends on the causes and type of insult, so finding the source of AKI is important. As earlier discussed, SCr concentration is not accurate, for assessment of patients with AKI. CrCl is better tool for assessing AKI as it measures effectiveness of the glomeruli to filter creatinine from the plasma and is a close approximation of the GFR. Dilution, volume overload states, and reductions of creatinine production during the acute phases of an illness are confounding factors during estimation of SCr values. In critical and acute care settings, patient's body muscle mass is also fluctuate which alters the relative SCr levels. For these reasons, and to apply steady-state kinetics more accurately, other biomarkers (**Table 3**) are being studied as potential surrogates for acute kidney function such as serum cystatin C, neutrophil gelatinase-associated lipocalin (NGAL), and kidney injury molecule-1 (KIM-1). However, in the acute setting, SCr remains the most validated estimation of GFR to determine kidney function.

RISK FACTORS AND CAUSES FOR ACUTE KIDNEY INJURY

Emergency physician should assess risk factors in all patients of AKI, but particularly those in critical condition. Risk factors

TABLE 3: Several novel biomarkers for AKI.

Biomarker	*Function affected/ evaluated*	*Use*
Cystatin C (serum)	Marker of glomerular filtration	• Shows good accuracy for early diagnosis of AKI • Seems to be particularly useful in patients with sepsis
NGAL (serum)	Marker of renal tubular inflammation	Correlates well with acute changes in SCr
IL-18 (urine)	Marker of renal tubular inflammation	• Facilitates the diagnosis of AKI • Marked increased in patients with acute tubular necrosis • Predicts mortality
KIM-1 (urine)	Marker of injury to the proximal tubule, especially following ischemic insult	May be highly effective at distinguishing acute tubular necrosis from other types of renal injury

(AKI: acute kidney injury; IL-18: interleukin-18; KIM-1: kidney injury molecule-1; NGAL: neutrophil gelatinase-associated lipocalin; SCr: serum creatinine)

for developing AKI are multiple, well-studied, and well-defined. In comparison to younger patients, elderly patients (65 years or older) are more prone to AKI and have a poorer prognosis, despite advances in treatments, such as dialysis. Chronic underlying diseases, such as hypertension, diabetes, congestive heart failure, atherosclerosis, CKD, and obstructive (postrenal) uropathy, volume depletion, surgical procedures, sepsis or acute infections, and nephrotoxic agents are notable medical conditions that place patients at higher risk for developing AKI.

In patients with these risk factors who go on to develop AKI, there have been significant differences in further complications, such as delay discharging from hospital, ventilator use, and concomitant diseases.

Prerenal azotemia or acute tubular necrosis (ATN) is the main cause of AKI in >75% of patients. Body fluid losses, fluid sequestration, decreased cardiac output, or renal artery narrowing are causes for *prerenal failure*. ATN, interstitial, glomerular, and small vessel disease *are the causes for intrarenal failure*. *Postrenal causes* are those secondary to obstruction. Ultrasound can assess for masses, hydronephrosis, ureteral dilatation, and the absence of ureteral jets entering the bladder. Causes of AKI are given in **Table 4**.

TABLE 4: Causes of acute kidney injury.

Prerenal	• Low systemic volume (*congestive heart failure and liver failure)* • Hypovolemia • Low cardiac output • Dysfunctional kidney autoregulation • ACE inhibitors • Angiotensin receptor blockers • Nonsteroidal anti-inflammatory drugs • *Causes of poor renal perfusion leading to prerenal acute kidney injury:* ○ Volume depletion (diuretics, diarrhea, blood loss anemia, osmotic diuresis, diuretic overuse, burns, and vomiting) • *Decreased arterial pressure:* ○ *Medication*: NSAIDs, cyclosporine, tacrolimus, and angiotensin receptor blocker ○ Cardiorenal syndrome and hepatorenal syndrome ○ Intra-abdominal hypertension and systemic vasodilation: Sepsis
Intrarenal	• *Glomerular:* ○ Postinfections ○ Glomerulonephritis • *Tubular:* ○ Ischemia • *Nephrotoxins:* Endogenous toxins such as calcium, uric acid, hemolysis, rhabdomyolysis, contrast media, and chemotoxic agents • *Interstitial:* ○ *Medications*: Aminoglycosides, cephalosporin, penicillin ○ *Infection*: *Streptococcus* and Epstein–Barr virus ○ *Systemic disease*: Lupus and sarcoidosis • *Vascular:* ○ Renal thrombosis ○ Malignant hypertension
Postrenal	• Bladder obstruction • Prostate enlargement • Urinary retention • Malignancy • Bilateral obstructive nephrolithiasis • Obstruction of single functioning kidney

(ACE: angiotensin-converting enzyme; NSAIDs: nonsteroidal anti-inflammatory drugs)

Acute Glomerulonephritis

Glomerulonephritis, caused by autoimmune damage to the kidneys themselves, one of the intrinsic causes of AKI and progress to inflammatory changes leading to renal failure due to subsequent fibrosis of the glomerular apparatus. Nephrotic and nephritic syndromes are the presentations of this disease. Clinical features of nephritic syndrome include hematuria, proteinuria, decreased renal function, and high blood pressure. Hematuria/proteinuria is the common presentation of intrinsic renal disease and is often overlooked by EP and critical consideration in managing patients appropriately. Even mild rise in kidney function laboratory values, high blood pressure, or urinary issues can give rise to rapid deterioration of renal function if not identified or managed quickly. Progression to chronic renal failure from acute glomerulonephritis syndromes can be prevented with prompt and early management.

In poststreptococcal glomerulonephritis, antibodies formed against streptococcal antigen adhere to glomeruli at the time of infection. Complement and coagulation cascades initiated by inflammatory pathways, which leads to cell lysis, fibrin deposition, and ultimately damage to the native

structure of the glomeruli. In the long term, permanent scarring and damage of glomeruli occurs due to intraglomerular hypertension and destruction of the normal anatomy. The description of other various types of acute glomerulonephritis, e.g., postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, microscopic polyangiitis, and lupus nephritis are out of the scope of this chapter. The laboratory studies such as complement levels are not very important in the emergency setting. Meanwhile EP should focus on clinical presentations, especially in patients who present with nephrotic syndrome: hypertension, periorbital swelling, or lower leg edema, and AKI. Several types of acute glomerulonephritis or nephrotic syndrome manifest more in pediatric patients so consider appropriate age groups also in the ED. Young children between 2 and 12 years old, more often in boys than girls, are most commonly have postinfectious glomerulonephritis. Postinfection glomerulonephritis is suspected in a patient complained of a sore throat or skin infection, typically 1–12 weeks before presentation. Wegener granulomatosis or microscopic polyangiitis may presents with respiratory infections, purpura, and arthritis with signs of nephritic syndrome.

There are two main modalities of treatment for acute glomerulonephritis, supportive care (blood pressure control and dialysis) and immunosuppressive therapies to counteract the autoimmune cascade causing intrinsic renal damage. Blood pressure control is important in slowing down the decline of GFR or proteinuria. Angiotensin-converting enzyme (ACE) inhibitors have antiproteinuric and antifibrotic effects and are typically used in the chronic phase (i.e., CKD). Use of diuretics and management of hyperkalemia, acidosis, uremia, and fluid overload are the other supportive measures though these supportive measures do not reverse the underlying pathophysiology. Immunosuppressive treatments include steroids, mycophenolate mofetil, cyclophosphamide, pulse steroids, or intravenous (IV) immunoglobulins. These therapies are often complex and require management with specialists.

Sepsis

The sepsis is the leading cause of death among patients with AKI and is responsible for >40% of mortality. A study done by Levy and colleagues demonstrated 45% of patients with AKI who died had developed sepsis. Similar findings demonstrated by Mehta and colleagues through the Program to Improve Care in Acute Renal Disease database which showed 40% of patients with AKI went on to develop sepsis. Conclusion of these studies and analyses are that patients with AKI should be closely monitored for the development of infection. It is now thought that inflammatory responses represent the dominant abnormality in sepsis-associated AKI. Currently, supportive care with fluid resuscitation remains the focus of treatment in patient with sepsis. Recently, studies comparing early goal-directed therapy have not been able to demonstrate a benefit to protocolized resuscitation with early goal-directed therapy in septic shock compared with usual care. Waechter and colleagues demonstrated that the focus of resuscitation in the first 1 hour with aggressive fluid administration and initiation of vasoactive agents within the first 6 hours have produced the best patient outcomes. Isotonic solutions should be used because there is no evidence to support the use of colloids in sepsis. Finally, vasopressin or norepinephrine (NE) either can be used as the initial vasopressor for septic shock, VANISH trial showed no difference in AKI or mortality on comparison study. There is no benefit of dopamine and its agonist for the prevention of AKI as per various studies. To reduce mortality in patients with AKI, close monitoring is required for development of infection and prompt treatment is indicated.

Drug-induced Acute Kidney Injury

Drug-induced kidney disease is frequently seen in clinical practice as a cause of renal dysfunction. Acute episodes of acute renal failure due to drugs account for nearly 20%. Drug-induced nephrotoxicity is high among older adults about 66%. Therapeutic drug-induced AKI may be classified into tubular injury, glomerular injury, interstitial injury, and crystal-induced injury. Age, diabetes, or underlying renal insufficiency coupled with drug interactions are the important risk factors and understanding about these can help prevent AKI secondary to medications. There are too many drugs to list, and many drugs work together through multiple injury pathways to cause. For example, if patients are on calcium channel blockers for their hypertension, started on a macrolide for an acute respiratory process is associated with a higher risk for hospitalization with AKI. Surveillance and real-time analysis for nephrotoxic medication in the ED by pharmacists can be done for reductions in AKI.

Normal GFR is 120 mL/min in healthy young adults, and the kidney autoregulates GFR to preserve GFR and UOP. Certain drugs can interfere with the kidney's autoregulation ability to maintain glomerular pressure and decrease GFR. Renal tubular cells play important role in reabsorbing glomerular filtrate which exposes them to high levels of circulating toxins and drugs. Aminoglycosides, contrast, and vancomycin drugs associated with AKI by impairing mitochondrial function. Urinary presence of "muddy brown casts" of epithelial cells is pathognomonic for ATN. If the cause is identified and corrected early, the overall prognosis for ATN is good.

Acute interstitial nephritis, an inflammatory injury that is often nondose related which can result from a hypersensitivity reaction. Many drugs can cause acute interstitial nephritis, including allopurinol; β-lactams, quinolones, sulfonamides, and acyclovir; diuretics (loops and thiazides); nonsteroidal anti-inflammatory drugs; proton pump inhibitors (PPIs); and ranitidine.

Proton pump inhibitors have been associated with worsening SCr, two main electrolyte abnormalities (hyponatremia and hypomagnesemia) and an increased risk for AKI. Certain medications not soluble in human urine, they precipitate in the renal tubules in the presence of risk factors such as volume depletion, underlying kidney disease, and metabolic disturbances that promote changes in urinary pH favoring AKI. Ampicillin, ciprofloxacin, sulfa drugs, indinavir, and methotrexate are the commonly prescribed drugs associated with production of crystals.

There are many drugs that can present as nephritic syndrome due to glomerular injury and inflammatory disease. Some important drugs such as bisphosphonates and hydralazine typically cause ATN. Thus, monitoring of SCr is recommended before treatment and in the setting of renal insufficiency holding therapy is required. It is very important to know that illicit drugs, specifically synthetic cannabinoids, may lead to AKI in addition to myocardial

infarction, psychosis, seizures, and hyperemesis. Interestingly, in methamphetamine- or cocaine-induced rhabdomyolysis creatinine kinase (CK) does not raise much. Acute tubular injury is the most common injury in these patients and treatment is supportive and rarely requires steroids.

Contrast-induced Acute Kidney Injury

A type of AKI that results within a few days of exposure to iodinated contrast for imaging studies is termed as contrast-induced nephropathy. After hypoperfusion and nephrotoxic drugs this is the third most common cause of new AKI in hospitalized patients. The contrast-induced nephropathy/AKI is self-limited, but associated with increased mortality and even progression to CKD. Patients with an estimated GFR < 60 mL/min/1.73 m^2 are higher risk for contrast-induced AKIs. In clinical practice, radiologists take detail relevant history about comorbidities, other nephrotoxic medications before administering potentially harmful contrast. In high-risk patient, use the lowest possible radiocontrast concentrations, administer IV hydration pre-exposure and postexposure, minimize nephrotoxic agents, and renal replacement therapy (RRT) in critical cases should be considered. It is important to screen patients for reliable follow-up.

Tepel et al. reported that oral N-acetylcysteine (600 mg twice daily) along with hydration before and after the exposure to contrast medium provide significant protection against contrast induced nephropathy as compared with hydration alone.

CLINICAL EVALUATION

Acute kidney injury induce life-threatening complications include severe metabolic acidosis; hyperkalemia; and volume overload states, such as pulmonary edema or pericardial tamponade. Targeted history and physical examination can help in identifying these complications. In the acute setting it is difficult but important to know if kidney function abnormalities are at baseline or truly represent an acute injury; a baseline kidney function is ascertained via record or sometime the patient knows his or her baseline kidney function. Ascertain the source of the injury once AKI is identified. Before considering intrarenal sources, it is important to first rule out prerenal and postrenal sources. Recent volume losses, such as hemorrhage, gastrointestinal or urinary fluid losses, and recent postoperative courses during which the patient was either hypotensive or exposed to iodinated contrast for imaging (although this is controversial) for responsible for prerenal injury. Consider obstructive postrenal sources in patients with signs of nocturia, or urinary frequency, which may be suggestive of prostatic or other obstruction and retention. In patients with reduced GFR, search for exposure to nephrotoxic agents include antibiotics, such as vancomycin; aminoglycosides; nonsteroidal anti-inflammatory drugs; and ACE inhibitors/angiotensin receptor blockers. Once iodinated radiocontrast thought to be nephrotoxic; but recent studies have shown that this association is not as strong as previously believed.

Further evaluate patients in terms of hemodynamic and volume status on physical examination. Check for dry mouth, reduced skin turgor, cool peripheral extremities, and delayed capillary refill times. Examine vital signs for evidence of shock, if present invasive hemodynamic monitoring with arterial lines, central venous pressure monitoring is required. Point of care ultrasonography of the inferior vena cava at end expiration and the internal diameter of the right ventricle at end diastole helpful in assessing hypovolemia and underfilling, respectively. These patients may require a wide range of therapies from IV fluids to diuretics or, in most critical situations, RRT.

DIAGNOSTIC TESTING

Acute kidney injury is diagnosed by evaluating laboratory values, urinalysis, urine sediment, and urine chemistries. Prerenal azotemia is considered when high ratio of blood urea nitrogen (BUN) to creatinine is observed. In this setting, urine sodium concentration of <20 mEq/L as sodium is inappropriately retained and is also indicative of prerenal cause. Ultrasound of the kidneys with postvoid bladder volumes should be performed if obstruction is suspected. Further investigation of intrarenal causes includes urine electrolytes and urine osmoles. Kidney biopsy should be performed only with the direction of the nephrologist and typically reserved for patients suspected of intrarenal cause. Kidney biopsy can be performed if etiologies include systemic lupus erythematosus, glomerulonephritis, and ATN.

Presence of renal disease can be identified by estimation of several novel biomarkers; clinical trials are currently underway to evaluate the efficacy of these markers. Several biomarkers are currently being evaluated in trials with the goal to identify a biomarker, or a panel of biomarkers, that would be helpful in the early diagnosis of AKI, and also able to differentiate between different types of renal injury, and could provide an accurate prognosis, all with a high degree of specificity and sensitivity. To that end including serum measurements of cystatin C and NGAL and urine measurements of interleukin (IL)-18 and KIM-1 are the few examples of novel biomarkers though their use is not so widespread in clinical practice. However, they may represent the future for identification and assessment of the severity of renal disease. In spite of the well-known limitations described earlier, clinicians more frequently rely on BUN and SCr at the time of presentation and compare them with baseline values (when known) to help guide diagnosis and treatment.

MANAGEMENT OF ACUTE KIDNEY INJURY IN THE EMERGENCY DEPARTMENT

Volume Status

Body is able to autoregulate blood flow to the kidneys during normal physiologic stress despite acute changes in blood pressure, but this mechanism is disrupted in AKI. Patients may present with hypervolemia, such as peripheral edema, pulmonary edema, respiratory distress, heart failure, pericardial effusion, or cardiac tamponade. To manage the complication of these conditions diuretics, fluid restriction, RRT, or appropriate procedures to alleviate the volume are used.

Conversely fluid resuscitation should be used in patients with hypovolemia because it is essential to maintain organ perfusion. Patients receiving IV fluids are a delicate issue, as they may become acutely volume overloaded. The use of vasopressors can further reduce blood flow to the kidneys. Early goal-directed therapy in patients with sepsis who received crystalloid fluids had no effect on mortality or the need for RRT as per several large trials. Several retrospective studies have

demonstrated that volume overload states associated with high mortality in critically ill patients. For this reason, volume status of the patient should be frequently monitored. Administer of IV fluid therapy is recommended if clinical history reveals large volume losses, such as vomiting and severe diarrhea, and physical examination supported hypovolemia. Patients who do not respond to fluid resuscitation consider using vasopressors. Crystalloids equilibrate solutes across cell membranes, e.g., lactated Ringer or normal saline. Colloid fluids depend on oncotic gradients to increase volume in an intravascular space, e.g., albumin, gelatine, or starches.

Several studies like Crystalloid versus Hydroxyethyl Starch Trial (CHEST) have examined crystalloids versus colloids in AKI where critical care unit patients were randomly assigned saline solution versus colloids. In the colloid group there was an increased risk of RRT. Crystalloid group overall had more incidences of AKI by RIFLE criteria driven by UOP, the colloid arm of the study had more severe AKI and therefore a trend toward RRT. Recent literature demonstrates mixed reviews on balanced fluid resuscitation versus normal saline depending on acuity of the patient. The *SMART trial* (0.9% normal saline versus balanced crystalloids lactated Ringer solution) demonstrated a marginal superiority in secondary outcomes of balanced crystalloids, particularly patients who received large volumes of resuscitation in adverse kidney events, time to discharge, and mortality in critically ill adult. Another recent study, the *SALT-ED trial*, which was essentially a negative trial in adult ED patient who received a minimal of 500 mL of IV isotonic crystalloids, showed no difference in the number of hospital-free days in both treatment groups, although the secondary outcome (incidence of major adverse kidney events at 0 day) was in favor of balanced crystalloids. There is no outstanding difference in balanced crystalloids versus normal saline; considering weaknesses of both studies from the practical point of view, one should consider balanced crystalloids in critically ill and high volume resuscitated patients. Colloids are beneficial in some specific subgroup of AKI like large volume depletion, e.g., paracentesis or end-stage liver disease. In the emergent setting, overall goal of assessing the volume status is to improve cardiac output and therefore improve tissue oxygenation. Close monitoring of urinary output and mean arterial pressure is required. In emergency department frequent clinical evaluation for pulmonary congestion and urinary output 75–100 mL/h (1-3 L total) is considered appropriate.

Hemodynamic Optimization with Vasopressor Therapy

Vasopressor administration becomes necessary to achieve adequate renal perfusion in patients who continue to have hemodynamic instability with a low MAP despite fluid resuscitation. Target an initial MAP of ≥65 mm Hg, with vasopressor administration. No specific vasopressor recommendation for the treatment and/or prevention of AKI in patients with shock but NE has been found to improve CrCl in patients with distributive shock. Renal-dose dopamine infusion to achieve renal vasodilation has not been found to reduce the incidence of AKI, need for RRT, or patient mortality. In fact, dopamine may worsen both renal perfusion and GFR. As a result, KDIGO has provided a 1A recommendation against using low-dose dopamine in patients with AKI.

Metabolic Derangements

Kidneys maintain the body's electrolyte balance and in AKI, because of reduced filtration, patients often develop hyperkalemia, hyperphosphatemia, hypocalcemia, metabolic acidosis, or symptoms of uremia and associated complications such as bleeding, pericarditis, or altered mental status. Clinical manifestations of hyperkalemia which occurs at potassium levels > 7.0 mEq/L include muscle weakness/paralysis and cardiac arrhythmias secondary to conduction abnormalities. Hyperkalemia causing conduction abnormalities is detected on electrocardiograms (ECGs). The most common ECG changes of hyperkalemia findings are tall, peaked T waves with shortened QT interval, lengthening of PR interval and QRS duration, absence of P waves, and ultimately sine wave pattern as the QRS progresses in duration. In patients with hyperkalemia and ECG changes, administration of calcium gluconate or calcium carbonate (1 g IV over minutes, repeat as needed) recommended to stabilize the cardiac membrane. Then use drugs which promote potassium ions to shift intracellularly are regular insulin (10 U IV or weight-based and administered with glucose), β-2 adrenergic agonists (nebulized albuterol), or sodium bicarbonate (50 mEq/50 mL IV). After this if the patient's volume status has been assessed and determined to be hypervolemic or euvolemic with appropriate supportive fluids one can use loop diuretics (furosemide, 40–60 mg IV) or cation resins (sodium polystyrene sulfonate, 15 g orally) to eliminate potassium in the urine and stool (**Table 5**). There is limited evidence regarding use of cation resins, such as sodium polystyrene sulfonate (Kayexalate), there are some potential untoward effects and that may outweigh benefits. Newer binding agents, such as patiromer and sodium zirconium cyclosilicate (ZS-9) are studied recently. Patiromer is a synthetic polymer of nonabsorbable beads that exchanges calcium for potassium excretion in the stool in the distal colon. A recent meta-analysis investigating patiromer and ZS-9 found that these agents were more efficacious compared with Kayexalate, although further studies are warranted to test side effects, use in specific patient populations, and medication interactions.

Sodium Bicarbonate Therapy

Administration of sodium bicarbonate in patients with AKI has been controversial. Acidemia and serum pH improved after administration of sodium bicarbonate without reversing the cause of acid production. Patients with severe metabolic acidosis may require sodium bicarbonate therapy as a temporizing measure while the clinician attempts to reverse the underlying cause. Bicarbonate therapy may be helpful in stabilizing the hemodynamic and improve vasopressor sensitivity in patients with a pH <7.1. The recently published BICAR-ICU trial (Sodium Bicarbonate Therapy for Patients with Severe Metabolic Acidemia in the Intensive Care Unit) found no difference between 28-day mortality or organ failure at 7 days between treatment and control groups. However, patients with severe AKI did show a trend toward decreased need for RRT who received bicarbonate therapy. Clinicians should be aware of some clinically significant side effects of sodium bicarbonate therapy. A transient increase in arterial partial pressure of carbon dioxide (pCO_2) can occur, as sodium bicarbonate ultimately gets metabolized to CO_2, which may be detrimental for patients with an already extreme minute ventilation.

TABLE 5: Drugs to treat hyperkalemia—dose onset duration.				
Effect	***Treatment***	***Dose***	***Onset***	***Duration***
Stabilize membrane	Calcium gluconate and calcium carbonate	10 mL intravenous (IV) over 10 min	Immediate	30–60 min
Shifters	Albuterol	10–20 mg nebulization	30 min	2 h
	Insulin	10 units IV with dextrose 25–50 g	20 min	4–6 h
	Sodium bicarbonate	150 mmol IV	Hours	Hours
Excretors	Furosemide	40–80 mg IV	15 min	2–3 h
	Sodium polystyrene	15–30 g in 15–30 mL	Hours	4–6 h
Definitive	Hemodialysis		Immediate	3 h

Blood Pressure Management

Patients with kidney disease typically present with hypertension and associated organ ischemia, patients are likely habituated to higher blood pressures. The pathophysiology of hypertension depends on the duration of disease, acute versus chronic, and type of kidney disease (i.e., vasculitis vs. intrinsic kidney disease). Adrenergic-blocking agents should be considered to control the blood pressure. Labetalol given in 20-mg IV bolus initially, followed by 20–80 mg every 10 minutes to a total dose of 300 mg. As an alternative, hydralazine, a direct arteriolar vasodilator, can be given in doses of 10-mg IV boluses. MAP should be reduced slowly, by no >20% in the 1st hour and gradually by no >15% over the subsequent 24 hours.

Volume overload is the common manifestations of acute glomerulonephritis. Volume overload is caused by sodium retention from increased reabsorption in the collecting tubules. Volume expansion suppresses the renin–angiotensin–aldosterone system and enhances release of atrial natriuretic peptide. Hypertension in acute glomerulonephritis is primarily because of volume overload so the preferred initial therapy is diuretics. Loop diuretics, such as furosemide, are particularly effective in patients with reduced GFR. Second-line therapy is ACE inhibitors because these drugs activate the otherwise pathologically suppressed renin–angiotensin–aldosterone system mechanism. *Antihypertensive medications* for AKI-induced hypertension are furosemide, lisinopril, labetalol, and hydralazine.

Diuretics

In hypervolemic states, loop diuretics are recommended because these medications not only prevent volume overload, but also minimize ischemic tubular injury by decreasing metabolic demand from the activation of the sodium-potassium-chloride cotransporter in the renal medulla. However, multiple studies did not support the benefits of diuretics in AKI. The current KDIGO recommendation is to use diuretics in only two situations, frank hypervolemia or in early AKI to promote UOP.

Glycemic Control

The kidneys play an important role in glucose excretion and insulin metabolism so patients with AKI are higher risk for severe hypoglycemia. Blood sugar concentrations should be between 110 and 149 mg/dL as per KDIGO group recommendation. These guidelines are based on Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study.

Organ Damage

Other vital organs, particularly the heart, liver, and lungs are also affected in AKI. Metabolic acidosis is known to reduce the myocardial contractility. Myocardial stunning occurs due to hypoperfusion of the heart. Complex pathophysiologic mechanism between the kidneys and liver leads to development of hepatorenal syndrome, form of kidney injury, unresponsive to fluids, in chronic liver disease that causes systemic and splanchnic vasodilation, and kidney vasoconstriction. Noncardiogenic pulmonary edema (acute respiratory distress syndrome) occurs due to renal failure. These patients often require mechanical ventilation as these conditions do not respond to fluid diuresis.

ACID-BASE DERANGEMENT IN THE CRITICALLY ILL ACUTE KIDNEY INJURY

Knowledge about patient's acid-base derangement is important before treatment initiation.

Acid-base Homeostasis

Normally kidney excrete acid load, through the Na^+/H^+ transporter, which excretes approximately 1 mEq of H^+ ions per kg per day in the urine. Any pathophysiological process which gives rise to excessive acid production, inability to reabsorb a bicarbonate buffer, or decreased H+ excretion causes metabolic acidosis occurs. Patients with AKI may present with a metabolic acidosis, often classified as either an anion gap or nonanion gap metabolic acidosis (NAGMA).

Acute kidney injury-associated NAGMA occurs due to a loss of bicarbonate without concomitant increase in exogenous acid production. Conditions associated with NAGMA are severe hypovolemia secondary to diarrhea where the large bowel has impaired ability to reabsorb bicarbonate deteriorating chronic renal dysfunction as well as renal tubular acidosis (RTA). Patients with an acute RTA have impaired bicarbonate reabsorption secondary to ion transporter dysfunction. *Anion gap metabolic acidosis (AGMA)* often precipitate because of an increased acid production and because of an acute decrease in GFR the kidneys are unable to excrete. In the critically ill most common causes of AGMA include lactic acidosis and ketoacidosis. More causes of AGMA are listed in **Table 6**.

TABLE 6: Common causes of anion gap metabolic acidosis (AGMA).

AGMA mnemonic	*Causes*
M	Methanol
U	Uremia
D	Diabetic, alcohol, and starvation ketoacidosis
P	Paracetamol/acetaminophen
I	Isoniazid, iron ingestion, and inborn error of metabolism
L	Lactic acidosis
E	Ethanol and ethylene glycol
S	Salicylates

Lactic acidosis is the most common AGMA encountered in critically ill patient. Poor tissue perfusion and inadequate oxygen delivery causes lactate production. Lactate generation precipitate metabolic acidosis that can cause myocardial depression, catecholamine resistance, and progressive vasodilatory shock. Despite a maximum level of plasma catecholamines (released in response to hypoperfusion) and inappropriate activation of other vasodilatory mechanisms, vascular wall smooth muscle is unable to constrict, *vasodilatory shock* occurs. Sodium bicarbonate or dialysis may be helpful in correction of the acidic environment and improve patient's vasodilatory shock, transiently but effective treatment should be focused on reversing the inciting event.

RENAL REPLACEMENT THERAPY

Renal replacement therapy or dialysis is the ultimate treatment for severe AKI leading to critical life-threatening derangements, such as volume overload, acidosis, hyperkalemia, and toxin accumulation. In dialysis, either diffusion (i.e., hemodialysis) or convection (hemofiltration), or a combination of the two techniques is used for removal of solutes and fluids from the body. The decision to start RRT exceeds the scope of core emergency medicine and initiate nephrologist consultation to consider for emergent dialysis. *Indications for emergent dialysis* (**Table 7**) are: (1) Acidosis (pH 6.5 refractory to treatment); (2) Ingestions of dialyzable drugs (salicylates, lithium, and toxic alcohols); (3) Overload (especially with hypertension and increasing oxygen requirements); (4) Uremia (bleeding, pericarditis, and encephalopathy).

Initiation of Renal Replacement Therapy

Temporary vascular access is required for initiation of RRT in critically ill patients. To facilitate emergent RRT use of a 10-French or 12-French, double-lumen, central venous dialysis catheter is placed. Emergently placed temporary nontunneled hemodialysis catheters can be placed preferentially in the right internal jugular vein under ultrasonography guidance. If the right internal jugular vein is not accessible, femoral vein access is preferred over left internal jugular vein cannulation. Temporary hemodialysis catheters in subclavian vein should be avoided because associated with higher rates of central vein stenosis, which may prevent the use of the ipsilateral arm as a site for long-term hemodialysis access (arteriovenous graft or fistula) in the future.

TABLE 7: Mnemonic for emergent hemodialysis indications.

A	*Acidemia*: Severe metabolic acidosis despite adequate medical optimization (pH < 7.1)
E	*Electrolytes*: Particularly hyperkalemia refractory to medical therapy
I	*Ingestion*: Poisoning by drugs that are able to be eliminated with RRT
O	*Overload*: Volume overload resulting in hypoxic respiratory failure necessitating mechanical ventilation
U	*Uremia*: Complications secondary to increased BUN (bleeding, pericarditis, and encephalopathy)

(BUN: blood urea nitrogen; RRT: renal replacement therapy)

Source: Data from Nee P, Bailey D, Todd V, Lewington AJ, Wootten AE, Sim KJ. Critical care in the emergency department: acute kidney injury. Emerg Med J. 2016;33:361-5.

Temporary hemodialysis catheter's distal tip must be located within a large central vessel in order to optimize catheter blood flow. Catheter length is an important consideration, and in general should be 12–15 cm for right internal jugular, 15–20 cm for left internal jugular, and 19–24 cm for femoral vein access. Optimal catheter placement is important for establishing an effective venovenous hemodialysis circuit to provide adequate extracorporeal blood flow for fluid and/or solute removal.

Mode of Renal Replacement Therapy

Renal replacement therapy via intermittent or continuous hemodialysis should be decided once appropriate vascular access has been obtained and confirmed in the right location. A comprehensive understanding is required about indication of hemodialysis, hemodynamic, as well as the logistics needed to initiate either mode (**Table 8**). Preferred mode of RRT for rapid removal of toxins (poisoning), electrolytes (hyperkalemia), and intravascular fluid volume is intermittent hemodialysis (iHD) which can provide external blood filtration at blood flow rates of 300–500 mL/min. A single hemodialysis session can often be completed in 2–4 hours. Before initiation of iHD hemodynamic stability is generally required. In critically ill patients with hypotension or vasopressor dependence, continuous RRT (CRRT) is preferred. CRRT is run at a much slower blood flow rate (usually 20–40 mL/kg/h) to achieve the same effects of iHD, but over a 24-hour period. It is the preferred mode of RRT in patients who have unstable hemodynamic or requires vasoactive support.

The drawbacks of CRRT are its inability to clear toxins rapidly due to its low blood flow rate, the need for anticoagulation to prevent circuit clot formation, and prolonged limitations to patient mobility, increased nursing resource burden, which includes frequently changing the CRRT machine's dialysate bath and laboratory draws.

RHABDOMYOLYSIS

Rhabdomyolysis is a syndrome characterized by skeletal muscle injury which is measured with myoglobin, CK, and lactate dehydrogenase. Muscle injury can cause significant life-threatening electrolyte disorders, acute renal injury and

muscle injury secondary to trauma, myositis, medications, and muscle dystrophies. Common conditions associated with rhabdomyolysis are shown in **Figure 1**. Hypovolemia patient are more prone for developing the renal injury. Subsequently to maintain perfusion leads to renal vasoconstriction, and muscle breakdown products filtered through renal tubules.

TABLE 8: Comparison of two common modes of dialysis.

	Intermittent hemodialysis	***Continuous RRT(CRRT)***
Indications	Ambulatory, hemodynamically stable, electrolyte, and poison clearance	Critically ill, nonambulatory
Solute transport	Diffusion	Convection
Blood flow (mL/min)	300–400	150–200
Dialysate	30	1
Efficiency	High	Low
Hemodynamic stability	Poor	Good
Duration	Average 3 h	Continuous for 24 h
Anticoagulation	Not required, secondary to high blood flow rate	Required (within CRRT filter)
Logistic	Need tap water supply, technically difficult to initiate	High workload, immobility, and costly

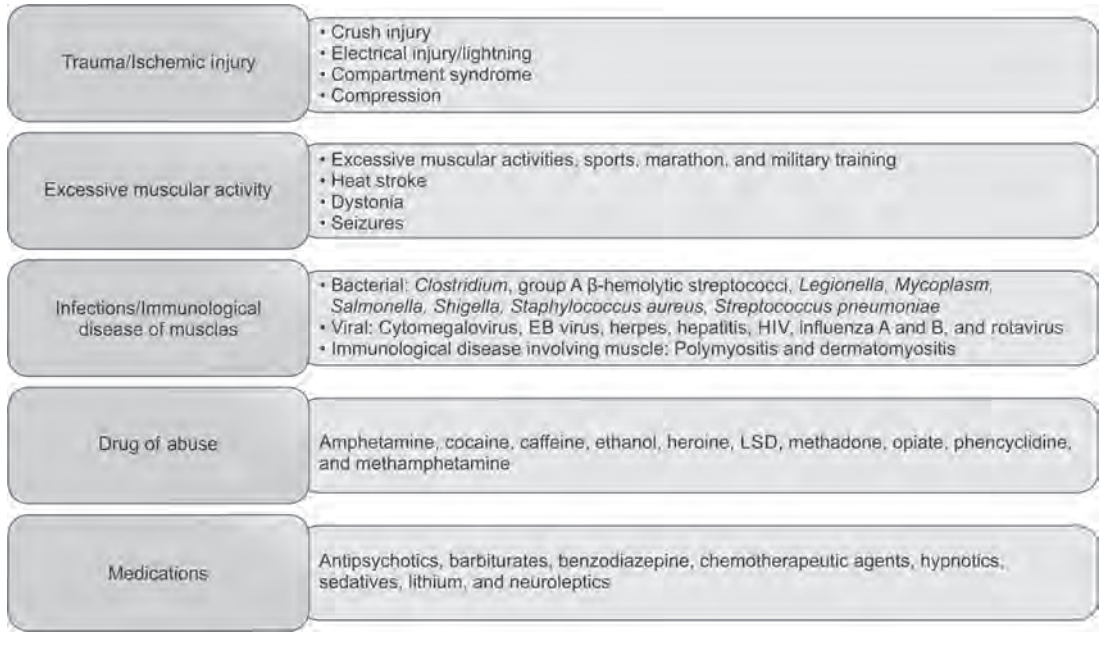
(CRRT: continuous renal replacement therapy)

Source: Data from Alvarez G, Chrusch C, Hulme T, Posadas-Calleja JG. Renal replacement therapy: a practical update. Can J Anesth. 2019;66:593-604.

Clinically, patients present with a history of myalgias, muscle weakness, and dark colored urine; occasionally nausea, vomiting, or fever may manifest. Sometime history may not be accurate and patients may present after a seizure, unknown use of medication, or variety of activity level from prolonged immobilization to running a marathon. In diagnosis, a five-time or greater increase of CK levels from upper limit of normal (1,000 IU/L) and detection of myoglobin in the urine should be taken into consideration. Myoglobin is released from damaged muscle and hem-containing protein. CK levels start rising 2–12 hours after muscle injury and peak at 24–72 hours. Studies have shown 50% chance of progression to AKI if CK levels >5,000 IU/L. The management of rhabdomyolysis in the early phase includes aggressive fluid resuscitation and electrolyte correction to improve renal perfusion and promote adequate UOP. This is important to prevent the azotemia. Consider sodium bicarbonate, 50 mmol for each 2–3 L of IV fluid therapy, although it is controversial. Balanced crystalloids or normal saline, either IV fluids may be used, as no clear benefit noted over each other. Patient should be monitored very closely because damaged muscle cells release potassium and phosphorus and RRT may be considered based on electrolyte derangements, such as hyperkalemia, hypercalcemia, anuria, hyperazotemia, or kidney injury not responding to volume resuscitation. Treatment goals include urinary output goal of 200 mL/h, urine pH > 6.5, and plasma pH 7.5. Summary of managing the rhabdomyolysis patient is as follows: Elevated CK → IV hydration with normal saline or 5% dextrose in normal saline → Goal UOP 200 mL/h, plasma pH < 7.5 → Serial evaluations for worsening AKI, electrolyte disturbances, and compartment syndrome → Consider admission for CK > 5,000 IU/L or patients at high risk for AKI.

DISPOSITION

In the acute setting, the disposition of patients with AKI is varied. These patients are at increased risk for progression



Trauma/Ischemic injury
• Crush injury
• Electrical injury/lightning
• Compartment syndrome
• Compression
Excessive muscular activity
• Excessive muscular activities, sports, marathon, and military training
• Heat stroke
• Dystonia
• Seizures
Infections/Immunological disease of muscles
• Bacterial: Clostridium, group A β-hemolytic streptococci, Legionella, Mycoplasm, Salmonella, Shigella, Staphylococcus aureus, Streptococcus pneumoniae
• Viral: Cytomegalovirus, EB virus, herpes, hepatitis, HIV, influenza A and B, and rotavirus
• Immunological disease involving muscle: Polymyositis and dermatomyositis
Drug of abuse
Amphetamine, cocaine, caffeine, ethanol, heroine, LSD, methadone, opiate, phencyclidine, and methamphetamine
Medications
Antipsychotics, barbiturates, benzodiazepine, chemotherapeutic agents, hypnotics, sedatives, lithium, and neuroleptics

(EB: Epstein–Barr; HIV: human immunodeficiency virus; LSD: lysergic acid diethylamide)

FIG. 1: Common conditions associated with rhabdomyolysis.

to CKD and increased mortality, so hospitalization of these patients is recommended to ascertain the source of insult and observe for correction of kidney function. Mostly an AKI is indicative of kidney insult either from prerenal, intrarenal, or postrenal sources. If the patient has reliable follow-up and can check their kidney function in 3 months or who have an isolated AKI and are otherwise appropriate for discharge, arrange solid follow-up. In the emergent setting, consultation to nephrology or urology services may be indicated. For life-threatening acidosis, medically unresponsive electrolyte derangements, toxic ingestion, volume overload, or uremia consultation for emergent dialysis is appropriate. Typically AKIs suspected secondary to intrinsic kidney disease, such as acute glomerulonephritis, nephrologists should be consulted. For AKI due to postrenal causes, such as obstructive nephrolithiasis consult urologist.

SUMMARY

Comprehensive overview and evidence-based acute management of kidney injuries in the ED setting is required. Prompt urgent interventions should be implemented after taking summary of causes of AKIs and performing clinical evaluations. Management of specific high-risk acute conditions, such as rhabdomyolysis and contrast-induced AKIs, and higher risk populations, such as the elderly should be kept in mind. AKI is a common diagnosis in ED with multiple complications and consequences. Treatment and management rely on early diagnosis and estimation of the cause for AKI. EP should be able to rapidly obtain a detailed history, perform a thorough physical examination, and identify high-risk elements contributing to the patient's decreased renal function. Effective treatment of critically ill patients with AKI depends on these skills. Mostly patients improve with conservative therapy, including normalizing fluid status, hemodynamic support, removal of offending agents, and addressing the patient's underlying disorder. As a temporizing intervention until the underlying disorder can be treated and reversed sodium bicarbonate therapy may be useful in patients with a severe metabolic acidosis (arterial pH < 7.1). A subgroup of patients with AKI requires initiation of emergent RRT despite aggressive medical intervention. RRT or hemodialysis is the treatment modality when conservative management fails. Type of RRT mode, appropriate temporary dialysis catheter equipment, and insertion site are the important points to address before initiation of RRT. Timely interventions that address these needs in critically ill patients with AKI are important to ensure the best long-term chances of recovery.

110
CHAPTER

End-stage Renal Disease

Devendra Richhariya

INTRODUCTION

Patients with end-stage renal disease (ESRD) present several complex management issues to emergency physicians. Timely interventions may reduce morbidity and mortality in these patients. With early identification and treatment of anemia, renal osteodystrophy, uremic malnutrition, hyperlipidemia, and cardiovascular disease, primary care physicians and nephrologists together can make significant difference toward extending and improving the lives of patients with ESRD. Two modalities of renal replacement therapy *dialytic therapy* (hemodialysis and peritoneal dialysis) and *renal transplant* is currently available for management of ESRD. For most of the patient hemodialysis is the initial therapy.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is defined as persistent or sustained damage lasting longer than 3 months and resulting in a glomerular filtration rate (GFR) of <60 mL/min/1.73 m^2 (**Table 1**). Discussion and knowledge about CKD and ESRD are important as patients with CKD are more likely to have longer hospital stays and heavy financial burden if preventive measures are not taken or disease process is not managed in early stage. Diabetes mellitus, hypertension, human immunodeficiency virus, and autoimmune and inherited diseases (including polycystic kidney disease and sickle cell disease) are the most frequent causes of CKD. Diabetes and hypertension are the most frequently encountered comorbidities associated with CKD. Incidence of renal failure is continuing to increase with increasing population of diabetes and hypertension. In emergency department, various clinical situations are presented with features of CKD which further complicate the evaluation and treatment of the patient along with emergency physician should take precaution about administration of contrast media, medication dosing, even when patients present with complaints not directly related to their kidney disease. In emergency department, patients with chronic or end-stage kidney disease frequently present with clinical features that are directly related to CKD and their complication, including fluid overload, electrolyte imbalance, or infection. Patients who already suffering from CKD, acute worsening of renal failure can occur due to several acute insults, including nephrotoxic agents, hypovolemia, and decreased renal perfusion. Any of the causes of acute kidney injury (AKI) can be superimposed on chronic renal insufficiency, leading to acute worsening of renal function. So, the role of emergency physician is to recognize the presence of the disease process in their patients and limit further renal insults during diagnosis and treatment of emergency conditions. Emergency physician frequently attending the patients who are chronically receiving renal replacement therapy (RRT) and should be prepared for complications related to CKD/ESRD and related to these procedures. So, it is worthy to discuss about RRT, including peritoneal dialysis (PD) and hemodialysis (HD) in this chapter itself. Infections, bleeding, complications related to volume management, and electrolyte abnormalities are common in patients on RRT. When patients fail to get their RRT as scheduled, complications related to fluid management and electrolyte become more problematic. Among patients with ESRD, infections due to sepsis are the leading cause of mortality. It is also important to note that a percentage of patients with ESRD on RRT proceed to renal transplantation. It is important for the emergency physician to take immediate corrective action in worsening renal function with renal transplant patient that may be caused by any of the insults that can cause AKI and that early identification of the cause and rapid treatment are crucial in the patient with only a single functioning kidney. Furthermore, acute or subacute worsening

TABLE 1: Stages of chronic renal failure.

Stage of chronic renal failure	*GFR mL/min/1.73 m^2*
Stage 1 (kidney damage not evidenced by GFR)	GFR ≥ 90
Stage 2 (mild disease)	GFR 60–89
Stage 3 (mild-to-moderate disease)	GFR 30–59
Stage 4 (moderate-to-severe disease)	GFR 15–29
Stage 5 (requirement of dialysis and kidney transplant)	GFR < 15

(GFR: glomerular filtration rate)

of renal failure in the patient with transplant may also be a sign of transplant rejection, and the patient's transplant surgeon or nephrologist should be consulted early in the course of evaluation and treatment.

END-STAGE RENAL DISEASE

End-stage renal disease is the irreversible loss of renal function, resulting in the accumulation of toxins and the loss of internal homeostasis. Uremia, the clinical syndrome resulting from ESRD, requires RRT for survival. At present, two basic modalities of RRT available: Dialytic therapy, either HD or PD and renal transplant. In the vast majority of new cases of adult ESRD initial therapy is HD, with a few patients starting PD and renal transplants. Cardiac causes account for about half of all deaths followed by infections, cerebrovascular events, and malignancy.

PATHOPHYSIOLOGY

Renal failure leads to inability to excrete about >70 chemicals from the body and accumulation of waste chemicals in uremic plasma, toxins, individually or in combination, cause uremic organ dysfunction and give rise to symptoms of uremia. Cyanate, guanidine, polyamines, and β2-microglobulin are the other potential uremic toxins apart from urea. Dialysis able to reverse not all but most of the untoward effect of the uremia because many toxins are highly protein bound and nondialyzable and many uremia-related organ dysfunctions persist after dialysis. The kidneys secrete erythropoietin and 1α-hydroxylase, which is necessary to produce the active form of vitamin D3. Because 85% of erythropoietin is produced in the kidneys, depressed level of the renal hormones $1,25(OH)_2$-vitamin D3 and erythropoietin occurs in ESRD and manifests as anemia in uremic syndrome. Vitamin D3 deficiency results in decreased gastrointestinal (GI) calcium absorption, inducing secondary hyperparathyroidism and leading to renal bone disease. Normal feedback mechanism in secretion of hormone is also disturbed in uremia leading to oversecretion of hormones. Excess free oxygen radicals are produced in uremic state, which react with carbohydrates, lipids, and amino acids to create advanced glycation end products. Thus, progressive nature of the atherosclerosis and amyloidosis is seen in ESRD patients.

CLINICAL FEATURES OF UREMIA

Uremia is a clinical syndrome consists of a group of symptoms, signs, or laboratory tests (**Table 2**). Correlation can be established between the symptoms of uremia and low GFR (8–10 mL/min/1.73 m^2). Raised blood urea nitrogen (BUN) and serum creatinine levels represent inaccurate picture of the clinical syndrome of uremia. Severity of the patient's symptoms related to uremia such as fluid overload (51%), hyperkalemia (18%), and severe acid-base disturbances are the most common reasons for emergency dialysis.

Cardiovascular Complications

Cardiovascular diseases such as coronary artery disease, left ventricular hypertrophy, and congestive heart failure are common and 10–20 times higher in ESRD and patient on dialysis. Preexisting conditions (e.g., hypertension and diabetes), uremia (e.g., uremic toxins, hyperlipidemias, homocysteine level, and hyperparathyroidism), and dialysis-related conditions (e.g., hypotension, dialysis membrane reactions, and hypoalbuminemia) are the causes responsible for cardiovascular disease in ESRD.

Cardiac Markers

Traditional misconception is markers of myocardial damage (troponins I and T) and is unreliable for diagnosis of ischemic cardiovascular disease in ESRD and dialysis patients. Troponin I and T are commonly elevated in asymptomatic HD patients and probably reflect left ventricular hypertrophy and microvascular disease, and associated with long-term risks of coronary artery disease. 20% or more dynamic rise and with at least one value above the 99th percentile higher baseline

TABLE 2: Clinical features of uremia.

Common uremic features	Pruritus and generalized muscle cramping
GI symptoms	Anorexia, nausea, vomiting, hiccups, altered taste, GI bleeding, ascites, diverticulitis, and diverticulosis
Cardiac	Coronary artery disease • *Hypertension*: Essential hypertension, glomerulonephritis, renal artery stenosis, and fluid overload • *Heart failure*: Fluid overload, uremic cardiomyopathy, high output, and AV fistula • *Pericarditis*: Uremic related to dialysis and pericardial tamponade
Hematologic	Anemia, reduced RBC survival, low erythropoietin level, bleeding diathesis, and humoral and cellular immune deficiency
Neurologic	• *Uremic encephalopathy*: Decrease in alertness, memory and cognition, disturbed sleep, slurred speech, asterixis, seizure, and coma • Dialysis dementia • Subdural hematoma • *Peripheral neuropathy*: Restless leg syndrome, sensorimotor neuropathy, and autonomic neuropathy
Renal bone disease	• Vitamin D deficiency and aluminum intoxication • Hyperparathyroidism • Metastatic calcification

(AV: arteriovenous; GI: gastrointestinal; RBC: red blood cell)

levels of troponin T and I, many define myocardial infarction in ESRD patient.

Hypertension

Hypertension in ESRD patient is primarily due to increased total peripheral resistance increases in blood volume, decreased vascular compliance, the vasopressor effects of native kidneys, the renin-angiotensin system, and the sympathetic nervous system. Most cases of hypertension in ESRD can be controlled with adrenergic blocking agents, angiotensin-converting enzyme inhibitors, or vasodilating agents, such as hydralazine or minoxidil.

Heart Failure

Heart failure in ESRD patients is primarily caused by hypertension, followed by coronary artery disease and valvular defects. Other causes of heart failure in ESRD patient are uremic cardiomyopathy, fluid overload, and arteriovenous fistula-related high-output failure. Natriuretic peptide levels are elevated in HD patients. Concomitant left ventricular hypertrophy and systolic dysfunction in HD patients give rise to elevated levels of natriuretic peptides. When all other causes of congestive heart failure have been excluded, uremic cardiomyopathy is diagnosed as exclusion because left ventricular dysfunction is related to ischemic heart disease, hypertension, and hypoalbuminemia in most uremic patients. Dialysis rarely improves left ventricular function in uremic patients with congestive heart failure.

Pulmonary Edema

Fluid overload is common cause of pulmonary edema in ESRD patient. Supplemental oxygen, bilevel positive airway pressure, nitrates, and angiotensin-converting enzyme inhibitors are the main therapies for pulmonary edema. Loop diuretics, such as furosemide [(60–100 mg intravenous (IV)], may be beneficial due to short-lived vasodilatory actions even in those with minimal urine output. HD is the definitive treatment for fluid overload in ESRD patients.

Cardiac Tamponade

Classic findings of cardiac tamponade such as changes in mental status, hypotension, or shortness of breath may not present in any critically ill ESRD patient. Warning signs suggesting the diagnosis of tamponade increased are interdialytic weight gain, increased edema, and intradialytic hypotension. Point-of-care ultrasound is the best method to detect pericardial effusion and tamponade. Ultrasound (US)-guided bedside pericardiocentesis should be performed in hemodynamically significant and unstable patients' pericardial effusions.

Pericarditis

Pericarditis is common in uremia. Fluid overload, abnormal platelet function, and increased fibrinolysis and inflammation are the common causes of uremic pericarditis. Pericardial contents are sterile unless infected and are abundant with fibrin and inflammatory cells. Pericardial friction rubs can be heard on cardiac auscultation in uremic pericarditis, which are louder than in most other forms of pericarditis. BUN level is nearly always >60 mg/dL. Typical electrocardiogram (ECG) changes of acute pericarditis may not be present as inflammatory cells do not penetrate into the myocardium. Associated abnormalities such as left ventricular hypertrophy, ischemia, and metabolic abnormalities (e.g., hyperkalemia and hypocalcemia) can be present in ECG. Suspect infection when the ECG has features typical of acute pericarditis. Dialysis-related pericarditis is most common during inadequate dialysis or due to missed sessions or vascular access problems. HD is most commonly associated with dialysis-related pericarditis. Improved dialysis techniques have lessened the incident of dialysis-related pericarditis. Management of uremic and dialysis-related pericarditis in patients in hemodynamically stable condition is intensive dialysis. HD is preferred over PD because of the higher clearance rates of HD. HD is effective in most of the cases of dialysis-related pericarditis. Indomethacin, colchicine, and steroids are not useful for ESRD pericarditis. If pericardial effusion is not resolved within 10–14 days of HD, anterior pericardiectomy is required, and total pericardiectomy reserved for constrictive pericarditis.

Hematologic Complications

Anemia

Decreased erythropoietin, blood loss from dialysis, frequent phlebotomy, and decreased red blood cell survival times, all these cause precipitate anemia in ESRD and patient on dialysis. Factitious anemia can also be noticed in dialysis patient due to fluctuations in plasma blood volume. Anemia is treated with regular infusions of human recombinant erythropoietin (erythropoietin replacement therapy) which improves the quality of life for ESRD patients by increasing exercise capacity and tolerance.

Coagulopathy

Risks of GI tract bleeding, subdural hematomas, subcapsular liver hematomas, and intraocular bleeding are increased in ESRD patient. Several mechanisms involved with uremic bleeding are decreased platelet function, abnormal platelet-vessel wall interactions, altered von Willebrand factor, anemia, and abnormal guanidinosuccinic acid-dependent production of nitric oxide and creatine. Best predictor of clinically important defects in hemostasis is skin bleeding test. Patients receiving aspirin or warfarin are at greater risk of major bleeding. Infusions of desmopressin, 0.3 μg/kg IV/subcutaneous (SC) (benefit in 1 hour), or cryoprecipitate, 10 units given over 30 minutes (benefit in 4 hours) used to improve bleeding times. Conjugated estrogen, 25 mg IV or 6 mg/kg/day (benefit in 6 hours) and tranexamic acid are also used as an alternative is another option.

Immune Disorders

Incidence of infectious diseases is common in ESRD patients due to immunological deficiency and the HD filter membrane may exacerbate immunodeficiency by complement activation after exposure and dialysis does not improve the immune function.

Neurologic Complications

Hemodialysis patients are more prone for developing stroke, both hemorrhagic and ischemic. Subdural hematomas occur more frequently (~10 times) in dialysis patients than in the

general population. Nonspecific central neurologic symptoms associated with renal failure known as uremic encephalopathy. Uremic encephalopathy is best diagnosed after eliminating structural, vascular, infectious, toxic, and metabolic causes of neurologic dysfunction. Features of dementia are nonspecific. MRI may show basal ganglia lesions. Neurologic findings of uremic encephalopathy may improve with dialysis. Peripheral neuropathy (lower limb > upper limb) is one of the most frequent neurologic manifestations of ESRD manifest as paresthesia, reduction in deep tendon reflexes, impaired vibration sense, muscle wasting, and weakness. Autonomic dysfunction manifests as impotence, postural dizziness, gastric fullness, bowel dysfunction, and reduced sweating. Treatment with vitamins, amitriptyline, gabapentin, and carbamazepine is only marginally effective. Conventional HD has limited role in improving autonomic dysfunction; however, elevated sympathetic activity may be reduced by daily short HD and long nocturnal HD.

Renal Bone Disease

Phosphate excretion decreases, which results in increased serum phosphate levels as the GFR falls in ESRD. Metastatic calcification can occur when the calcium phosphate product [Ca^{2+} (mg/dL) × PO_4 (mg/dL)] is >70–80. Calcification of synovial membrane causes pseudogout and clinically present as joint pain. Metastatic calcification in small vessels clinically present as skin and finger necrosis, while calcifications in the cardiac and pulmonary systems become life-threatening. Treatment consists of the use of low-calcium dialysate and phosphate-binding gels.

β2-microglobulin Amyloidosis

Patients >50 years of age and on dialysis for >10 years are on high risk of developing dialysis-related amyloidosis (β2-microglobulin amyloidosis). Development of chronic inflammatory condition (deposition of advanced glycation end products) is responsible for amyloidosis. Common sites for amyloid deposits are the GI tract, bones, and joints. Complications include GI perforation, bone cysts with pathologic fractures, and arthropathies, including carpal tunnel syndrome and rotator cuff tears.

HEMODIALYSIS

Hemodialysis—Technical Aspects

Hemodialysis requires extracorporeal filter "dialyzer" substitutes for the glomerulus to produce an ultrafiltrate of plasma (**Fig. 1**). Dialyzer consists of semipermeable membrane and blood is taken and returned through the sterile tubing. Dialysis fluid is used which has electrolyte composition similar to extracellular fluid (**Table 3**). Dialysis fluid is passed in opposite direction across the outside of membrane. Pressure gradient across the hemodialyzer filter is adjusted during HD to control the amount of fluid removal (ultrafiltration). During HD, blood is removed from the vascular access site by large-bore needles (typically 15 gauge), circulated through the dialysis machine at rates of 300–500 mL/min, and returned to the patient. The dialysate usually flows at a rate of 500–800 mL/min through the dialysis filter in the direction opposite to blood flow. To prevent thrombosis at the vascular access site small amounts of IV heparin, 1,000–2,000 units, are used. HD sessions typically take 3–4 hours. Solute removal (clearance) during HD depends on the filter pore size, the amount of ultrafiltration (solute drag), and the concentration gradient across the filter (diffusion).

Vascular Access for Hemodialysis

When urgent dialysis is required, vascular access is achieved by placing the double lumen catheter in Jugular vein (preferably) subclavian vein or femoral vein.

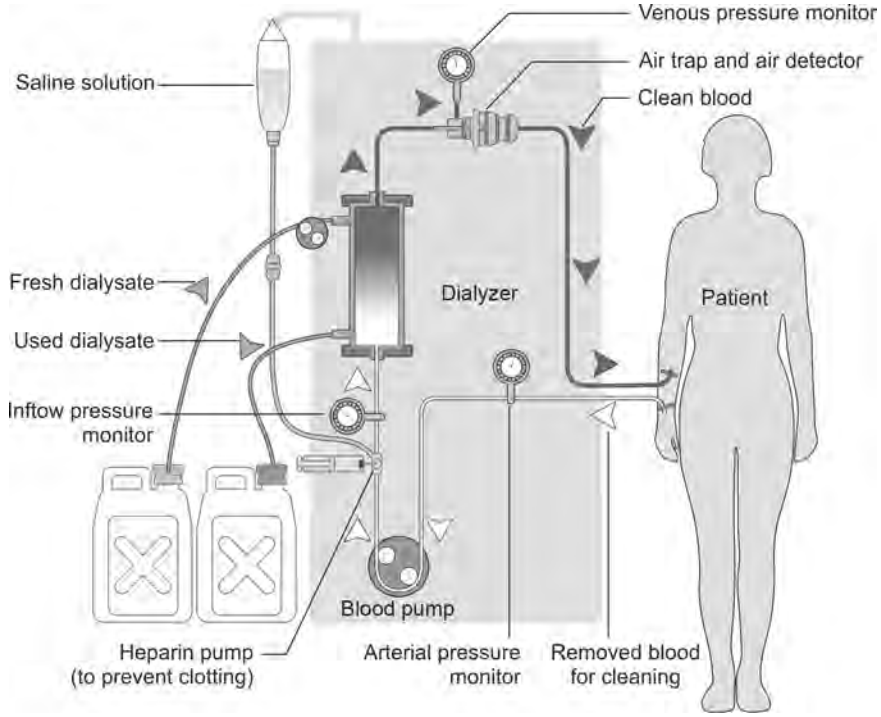

FIG. 1: Schematic diagram of hemodialysis circuit.

TABLE 3: Major electrolyte components of hemodialysate peritoneal dialysate.

Component	*Hemodialysate*	*Peritoneal dialysate*
Na	140	130–135
K	2	0
Ca	1.25	0.75–1.75
Mg	0.25	0.25–0.75
Cl	105	95–102
HCO_3	35	-
Lactate	-	35–40
Glucose	0.20	1.36–3.86

Cimino–Brescia Fistula

Cephalic vein is anastomosed to radial artery or ulnar artery is preferred as 2-year survival rate is >75%.

If arteriovenous fistula creation is not possible due to nonsuitability of native artery or vein, an interposing vascular graft made of an autologous vein, polytetrafluoroethylene (PTFE), must be used for vascular access. In comparison to natural arteriovenous fistulas, these grafts are associated with higher complication rate and shorter functional life expectancies. The third form of tunneled-cuffed catheters is also used for achieving vascular access for HD. The right internal jugular vein is the most common site for tunneled-cuffed catheter placement. Tunneled-cuffed catheters should not be removed by pulling. Vascular access-related complications lead to increased hospital stay and further complicated the HD procedure. The most common vascular access-related complications of HD are failure to provide adequate flow (300 mL/min) and infection. Thrombosis and stenosis of the vascular access are the most common causes of inadequate dialysis flow. Direct injection of alteplase can be used to treat thrombosis of vascular access and vascular surgeon opinion should be taken.

Vascular access infections occur in 2–5% of arteriovenous fistulas and approximately 10% of grafts over their functional lifetimes. Infected arteriovenous fistulas are at increased risk of bleeding. Patients with an infected access often present with fever, hypotension, or an elevated white blood cell (WBC) count. *Staphylococcus aureus* is the most common infecting organism, followed by gram-negative bacteria. Hospitalization is required to treat the vascular access infection, and vancomycin is the drug of choice (15 mg/kg or 1 g IV) because of its effectiveness against methicillin-resistant organisms and long half-life (5–7 days) in dialysis patient. An aminoglycoside (gentamicin 100 mg IV initially and after each dialysis treatment) is added if gram-negative organisms are suspected, but the patient is monitored closely because of toxicity. Other measures include removal and delayed replacement of the catheter, catheter exchange over a guidewire, and the use of antimicrobial/citrate lock solutions, although limited controlled data exist.

Bleeding

Another serious complication related to vascular access is life-threatening hemorrhage. Aneurysms, anastomosis rupture, and overanticoagulation are the possible causes of hemorrhage. Control bleeding immediately with manual pressure applied to the puncture sites for 5–10 minutes, and observe the patient for 1–2 hours if bleeding stopped. When simple methods fail to control hemorrhage or large-volume bleeding occurs, consult a vascular surgeon.

Vascular Insufficiency

In approximately 1% of all patients, vascular insufficiency of the extremity distal to the vascular access occurs. This "steal syndrome" clinically presents as exercise pain, nonhealing ulcers, and cool, pulseless digits as a result of shunting of arterial blood to the venous side of the access. Doppler US or angiography is the best diagnostic approach, consult vascular surgery and treatment is surgical.

Complications during Hemodialysis

Hypotension

The most frequent complication observed during HD is low blood pressure occurring in 50% of patient. During HD, average 1–3 L of fluid is removed over a 4-hour session, but 2 L/h fluid removal is possible. During ultrafiltration, normal blood pressure maintenance is depending on cardiovascular compensatory mechanisms and refilling of the vascular space by fluid shifts from the interstitial and intracellular compartments. Most common cause of intradialytic hypotension is excessive ultrafiltration due to underestimation of the patient's ideal blood volume (dry weight). Optimal dry weight is often clinically defined when hypotension prevents further fluid removal. Differential diagnosis of intradialytic hypotension includes myocardial dysfunction from ischemia, hypoxia, arrhythmias, and early pericardial tamponade. Other causes contribute to hypotension are abnormalities of vascular tone from sepsis or antihypertensive medications. Measures should be taken to prevent intradialytic hypotension are improving nutrition, performing ultrafiltration before dialysis, and increasing the sodium concentration of the dialysate solution. All these measures enhance the vascular refilling. The timing of intradialytic hypotension is often helpful in formulating a differential diagnosis. Causes of hypotension during early phase of dialysis session are preexisting hypovolemia, predialysis fluid losses, GI bleeding, sepsis, vomiting, diarrhea, or decreased intake of salt and water. Blood loss can occur from blood tubing or hemodialyzer filter leaks. If hypotension occurs at the end of dialysis, mostly cause is excessive ultrafiltration, but pericardial or cardiac disease can also precipitate hypotension at the end of dialysis. Orthostatic hypotension, tachycardia, dizziness, and syncope may occur due to hypotension during HD. Measure to be taken to manage intradialytic hypotension includes stopping of HD and placing the patient in the Trendelenburg position. Patient should receive salt by mouth (broth) or normal saline, 100–500 mL IV, if hypotension persists. Further extensive evaluation required if these conservative measures fail. Assessment of volume status, cardiac function, pericardial disease, infection, and GI bleeding is helpful. In an intensive care setting, further volume expansion or the administration of vasopressors to support blood pressure may require under invasive hemodynamic monitoring.

Dialysis Disequilibrium

Dialysis disequilibrium is a clinical syndrome occurring at the end of dialysis when large solute clearances occur during HD and is characterized by nausea, vomiting, and hypertension, which can progress to seizure, coma, and death. Patient's first dialysis session or during hypercatabolic states are the conditions when this clinical syndrome occurs the most. Dialysis disequilibrium may occur due to osmolar imbalance between the brain and the blood resulting in cerebral edema. Limiting solute clearance when initiating HD is the preventive measure. This condition can be managed by stopping dialysis and administering 5 mL of 10–23% sodium chloride or mannitol 0.25 g/kg IV to increase serum osmolality.

Air Embolism

When blood is pumped through an extracorporeal circuit there is always a risk of air embolism. The clinical presentation depends on the patient's body position at the time of the incident increased intracranial pressure and neurologic symptoms if patient sitting, air passes through the internal jugular vein to the cerebral circulation. Pulmonary hypertension and systemic hypotension occur in a recumbent position; air goes into the right ventricle and pulmonary circulation. Air embolism symptoms are acute dyspnea, chest tightness, and loss of consciousness, and sometimes full cardiac arrest. Signs include cyanosis and a churning sound in the heart from air bubbles in the blood. Clamp the venous blood line and place the patient supine, if air embolism is suspected. Start 100% oxygen to aid reabsorption of the air. Percutaneous aspiration of air from the right ventricle, IV administration of steroids, full heparinization, and hyperbaric oxygen treatment are the other measures for vascular air embolism.

Electrolyte Disturbance

Due to errors in mixing the dialysate concentrate with water, electrolyte abnormalities, rapid osmolar shifts may occur and manifests as hemolysis. However, hyperkalemia is the most common electrolyte disturbance that requires intervention. Hypoglycemia occurs in diabetic and nondiabetic ESRD patients. In addition to drugs, malnutrition and sepsis are important causes of hypoglycemia.

PERITONEAL DIALYSIS

Peritoneal Dialysis—Technical Aspects

Peritoneal membrane is the blood–dialysate interface in PD (**Fig. 2**). Osmotic pressure differences between the blood and dialysate determine the amount of ultrafiltration, which can be adjusted by changing the dialysate glucose concentration. Similar to HD, PD relies on the processes of clearance (solute removal) and ultrafiltration (fluid removal) as alternative to functions of the nephron. Solute removal occurs through process of diffusion. Dialysate contains 1.5% and 4.25% glucose formulations, which can be adjusted to increase or decrease ultrafiltration. Standard PD regimens consists of four exchanges daily, with 2 L of dialysate infused and left in place for several hours before draining. During the day, approximately 8 L are infused and about 10 L are drained, for a removal of approximately 2 L/day of fluid. In emergency department setting PD can be performed, over the long-term throughout the day (continuous ambulatory PD), or through multiple exchanges at night while the patient sleeps (continuous cyclic PD).

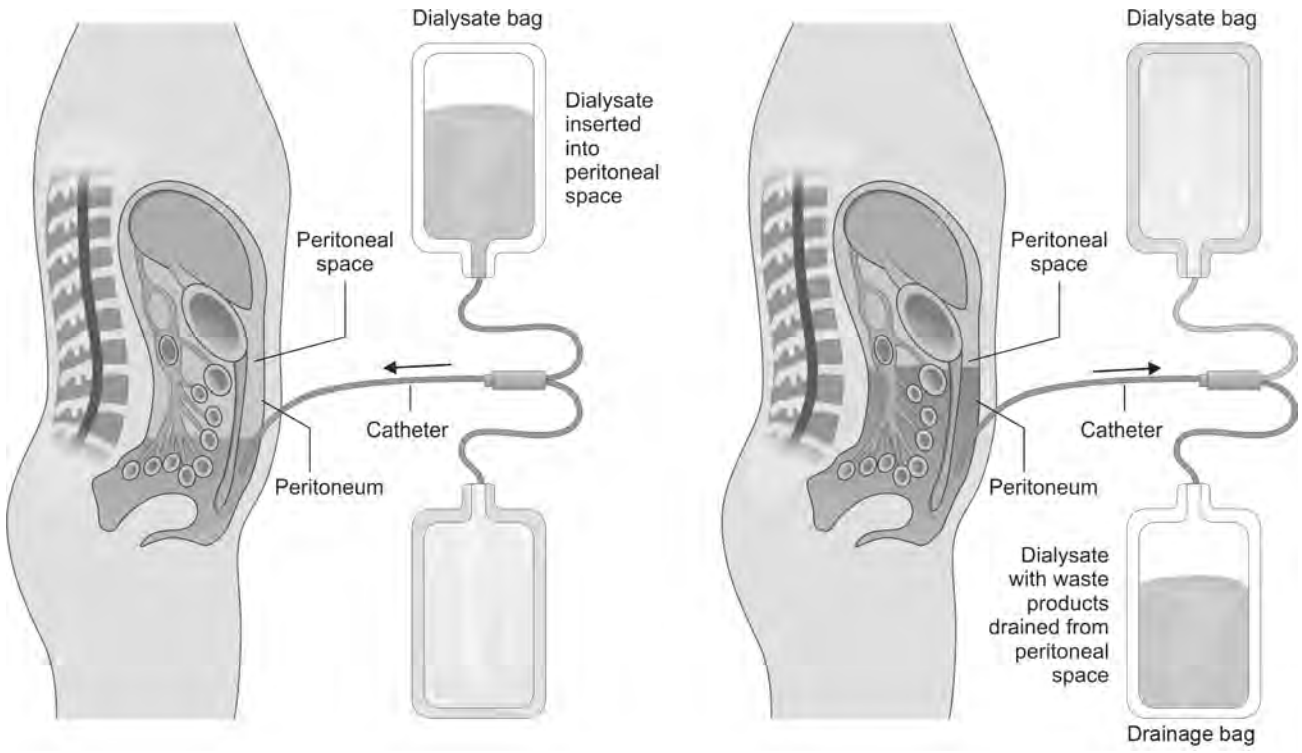

FIG. 2: Schematic diagram of peritoneal dialysis.

Complications of Continuous Ambulatory Peritoneal Dialysis

Peritonitis

Peritonitis is the most common complication of PD. Fever, abdominal pain, and rebound tenderness are the clinical presentations of peritonitis in PD patients. Cloudy effluent observed which suggests peritonitis, confirmed by Gram stain, cell count, and culture. The cell count in PD-related peritonitis is usually >100 leukocytes/mm^3 with >50% neutrophils.

Organisms isolated in PD-related peritonitis are *S. epidermidis*, *S. aureus*, *Streptococcus* species, gram-negative bacteria, anaerobic bacteria, and fungi. Empiric therapy begins with a few rapid exchanges of fluid lavage to decrease the number of inflammatory cells in the peritoneum, with added heparin (500–1,000 units/L dialysate) to decrease fibrin clot formation. A first-generation cephalosporin can be mixed with the dialysate, 500 mg/L with the first exchange and 200 mg/L with subsequent exchanges. In penicillin-allergic patients, use vancomycin 500 mg/L and maintenance doses of 50 mg/L per exchange. If seeking gram-negative coverage, add gentamicin 100 mg/L and maintenance doses of 4–8 mg/L per exchange. Recommendation is to treat for 7 days after the first negative culture results, usually resulting in a total of 10 days of therapy. Hospitalization of patient based on the patient's clinical appearance. Parenteral antibiotics are not needed.

Abdominal Wall Complications

Pain, erythema, swelling, and discharge around the PD catheter exit site suggestive of infection. *S. aureus* and *Pseudomonas aeruginosa* are the most common causative bacteria. Oral first-generation cephalosporin or ciprofloxacin started as empiric therapy as an outpatient therapy. Further follow-up of patients should be done in continuous ambulatory PD centers.

RENAL TRANSPLANT

End-stage renal diseases are increasing around the globe. Renal transplant can improve patient's quality of life and increases the survival as well. Over the past few decades living donor transplants are increasing and reducing the gap between demand and supply. Donors include those who are genetically related to the recipient or emotionally related (such as spouse, partner, or close friend). Living donation has become more acceptable with improvements in surgical nephrectomy techniques (laparoscopic and mini-open donor), reduced postoperative pain, shorter hospital stay, and faster return to work.

Causes of ESRD that can be managed by renal transplant: Diabetes mellitus, chronic glomerulonephritis, polycystic kidney, nephrosclerosis, interstitial nephritis, IgA nephropathy systemic lupus erythematosus, and Alport syndrome.

Relative contraindication for renal transplant: Comorbid conditions, age >65 years, untreated coronary artery disease, obesity, HIV infection, chronic Hepatitis B or C infection, and malignancy.

Procedure: Since the original operation described by Kuss et al. in 1951, procedure for a renal transplant is the same. The most common approach is a pelvic operation with extraperitoneal placement of the kidney. The right side is usually chosen, as the iliac vessels on the right are more superficial than on the left. The renal transplant involves three important anastomoses: the donor renal artery is anastomosed to the recipient external iliac artery (end-to-side); the donor renal vein is anastomosed to the external iliac vein (end-to-side); and the donor ureter is reimplanted to the recipient's bladder forming a ureteroneocystostomy with a JJ ureteric stent left in situ. The JJ-stent is removed 8–12 weeks postoperatively under local anaesthetic via flexible cystoscopy.

Factors affecting the renal transplant outcome: HLA matching and cross match is routine and remains fundamental of renal transplant. Graft survival is >87% when recipient and donor are HLA identical by serological and molecular methods.

Complications following the renal transplantation: Over the time techniques for renal transplant have improved so surgical complications are less. The most common surgical complication after a renal transplant is wound complications; these include wound infections, and fascial dehiscence or incisional hernias. The main medical complications in the first few weeks after transplantation are rejection and infection (**Table 4**).

Long-term follow-up after renal transplant: Depending on the type of graft, the average lifespan of a renal transplant is now 8–15 years. Lifelong regular follow-up of the transplant recipient in the transplant clinic is routine. Patients' general practitioners' role is to monitoring risk factors for cardiovascular disease and maintaining a high level of suspicion for any complication.

TABLE 4: Complications after renal transplant.

Surgical complications	*Early*: Hemorrhage • Renal artery thrombosis • Renal vein thrombosis • Recipient vasculature injury • Urine leak • Lymphocele • Wound complications
	Late: Ureteral obstruction • Transplant renal artery stenosis
Medical complications	*Early*: Acute rejection—acute cellular, antibody mediated • Infection—bacterial, viral (cytomegalovirus), fungal (pneumocystis)
	Late: Immunosuppression related—specific side effect profile, malignancy, chronic alloimmune injury • Allograft related—recurrent disease • Renal disease—anemia, bone disease • Cardiovascular disease • Infections—polyomavirus

SUMMARY

Chronic kidney disease and ESRD are recognized as a major health problem affecting considerably large population. In view of growing elderly population and increasing numbers of patients with diabetes and hypertension, prevalence of CKD patients will continue to rise. Complications associated with CKD: Anemia, hyperlipidemia, nutrition, osteodystrophy, and cardiovascular risk make the management of this medical problem unique and complex. Patients with CKD present several complex management issues to emergency physician. The staging system is significant in stratifying the patients according to disease severity and excellent tool for management of CKD and dialysis patients and recommend treatments according to disease stage. Morbidity and mortality in these patients can be reduced with early identification and treatment of anemia, renal osteodystrophy, uremic malnutrition, hyperlipidemia, and cardiovascular disease. Primary care physicians and nephrologists together are making significant strides toward extending and improving the lives of patients with chronic renal disease and ESRD.

CHAPTER

Kidney and Ureteral Stones

Devendra Richhariya

INTRODUCTION

Urinary stone disease (USD) is a generic term that refers to the presence of stones within the urinary tract, commonly known as kidney stones, urolithiasis, or nephrolithiasis. USD is a common disease in the India. Its prevalence has steadily increased in the recent decades. Based on the acute nature of presentation, kidney stones generate a large volume of emergency department (ED) visits and hospital admission. Given the frequent presentation of USD in the ED, it is essential for the emergency practitioner to have the expertise in diagnosis and the management of this disease. Terminologies related to renal stones are summarized in **Box 1**.

RISK FACTORS

The risk factors for USD are influenced by urine composition, which can be affected by many factors including dietary, systemic illness, and environment. Some are modifiable whereas others are not. Risk factors can be categorized into nondietary, dietary, and urinary. **Table 1** presents summary of risk factors.

Nondietary

Incidence of USD is more common in men (three times) than in women. The risk of USD is 2.5 times more likely if there is a family history. Prior history of USD and systemic medical conditions such as diabetes, obesity, gout, hypertension, chronic kidney disease, Crohn's disease, hyperthyroidism, primary hyperparathyroidism, sarcoidosis, and renal tubular acidosis have all been implicated in increasing the risk of USD. Environmental exposures such as living in warmer climates and certain occupations in which the individual works in higher temperature have been proposed as risk factors for development of USD. This is thought to be related to a combination of factors including insensible water loss from heat and increased vitamin D exposure from living in warmer climates and low fluid intake due to certain occupation's lack of access to bathroom leading to lower urine volume and a higher risk of stone formation.

BOX 1: Terminology related to renal stone.

Urolithiasis: Calculi in urinary tract, including kidneys, ureters, bladder, and/or urethra

Nephrolithiasis: Calculi in the kidney

Ureterolithiasis: Calculi in one or both ureters

Kidney stone: Common terminology that refers to calculi in the kidneys, but often includes calculi in the lower urinary tract as well

Dietary

The composition of urine is influenced by dietary intake and environment, and several dietary factors have been implicated in the development of USD. Nutrients that have role in USD are

TABLE 1: Risk factors of urinary stone disease.

Nonmodifiable (nondietary)	• *Family history* (2.5 times increased risk) • *Structural anatomy of urinary system*: Calyceal diverticulum, horseshoe kidney, ureterocele, vesicoureteral reflux—ureteral strictures • *Medical history*: Gastric bypass, hypertension, diabetes, metabolic syndrome, primary hyperparathyroidism, sarcoidosis, Crohn's disease, gout, renal tubular acidosis, hyperthyroidism, and multiple myeloma
Modifiable (dietary)	Low fluid intake, low calcium diet, high animal protein diet, high oxalate intake, high sodium diet, hot weather, obesity, and decreased exercise
Medication	• *Medication stones*: Indinavir, triamterene, and acyclovir • *Promote calcium stones*: Loop diuretics, acetazolamide, theophylline, and glucocorticoids • *Promote uric acid stones*: Thiazides, salicylates probenecid, and allopurinol
Urinary	Low urine volume, urine concentration, urine composition, low urine pH, hypercalciuria, hyperoxaluria, and hypocitraturia

calcium, animal protein, oxalate, sodium, sucrose, magnesium, and potassium. Certain factors such as low fluid intake, low calcium diet, high animal protein diet, and high sodium diet are known to contribute to the risk of USD. In addition, the use of certain stone-forming medications also increases the risk of stone formation. Conditions that enhance enteric oxalate absorption often in the setting of malabsorption such as patients with history of gastric bypass, bariatric surgery, and short bowel syndrome are discussed in the next section.

Urinary

Urinary stone formation is intricately related to urine composition, low urine volume, urine concentration, and urine pH. Conditions such as hypercalciuria, hyperoxaluria, and hypocitraturia all increase urinary concentration of these ions and can cause stone formation when the urine becomes supersaturated. The persistent low pH promotes the precipitation of uric acid and is associated with the formation of uric acid stones.

CAUSE

There are four main types of urinary stones, with the majority (75–90%) composed of *calcium oxalate*, followed by *uric acid* (5–20%), *calcium phosphate* (6–13%), *struvite* (2–15%), and *cystine* (0.5–1%). **Table 2** presents stone types and composition. The exact pathogenesis of stone formation is complex and involves both metabolic and environmental factors. This pathogenesis is not entirely understood, but it is clear that it is affected by urine composition. Stone formation usually starts in the kidney and is due to urinary supersaturation with free ions (e.g., calcium and oxalate in calcium oxalate stones), and this leads to the formation of crystals. It is thought that the process starts with the formation of a nucleus, which is a heterogeneous mixture of substances such as uric acid, and this forms a nidus for nucleation, around which the stone grows. Increased urinary ion excretion and decreased urine volume will favor stone formation. High urine flow rate will reduce supersaturation. However, despite similar degree of urine saturation, stones form in some people whereas not in others, and this may be due to the presence of promoters and inhibitors of crystallization in the urine.

TABLE 2: Stone composition and causes.

Stone composition	*Causes*
Calcium oxalate and calcium phosphate 90%	• Hypercalciuria (high dietary sodium and protein, hypercalcemia) • Hyperuricosuria (high purine and high protein diet) hyperoxaluria (low dietary calcium, high oxalate diet or oxalate absorption, and genetic hyperoxaluria) • Hypocitraturia (chronic metabolic acidosis and inflammatory bowel disease)
Struvite (magnesium ammonium phosphate) 2–15%	Urine infection from urea-splitting bacteria (i.e., *Proteus*, *Klebsiella*, and *Corynebacterium*), staghorn formation, and high urine pH
Uric acid 5–20%	• Hyperuricosuria (gout) • Low urine pH • Radiolucent
Cystine 1%	Cystinuria—autosomal recessive disorder of cystine, ornithine, arginine, and lysine staghorn formation
Others <1%	Medications (raltegravir, indinavir, and triamterene)

CLINICAL PRESENTATION

The classic presentation of kidney stone is an acute onset, severe unilateral flank pain radiating to the ipsilateral groin; classically it starts at night. The pain is usually episodic, lasting 20–60 minutes, and does not completely resolve before the next wave of pain. The typical patient is usually writhing in distress and unable to find a comfortable position. In contrast to the patient with acute abdomen, they do not lie still. As the stone descend into the ureter, the pain may descend to the abdomen corresponding to the location of the stone with associated dysuria, urgency, and frequency. Approximately 30% of patients will report hematuria. Patients will experience nausea and vomiting due to the shared splanchnic innervations of the renal capsule and intestine. Fever is not typically present, unless associated with infection. There are several conditions that may mimic renal colic. **Table 3** lists the most common.

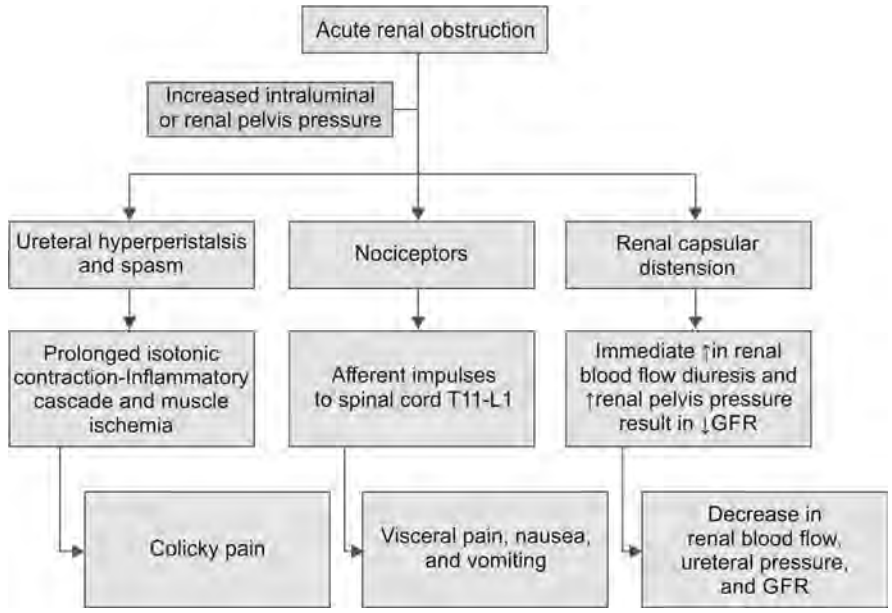
The mechanism of renal colic or the pain cycle related to kidney stones has a complex mechanism as well (**Flowchart 1**). While there is mechanical injury to the ureteral wall from the passage of kidney stones, the pain associated with urolithiasis is attributed to the obstruction of the urinary tract and the resulting increase in renal pelvic pressures leading to renal capsular distention, stimulation of nociceptors, and hyperperistalsis of the ureter.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of the USD includes a history and physical examination, evaluation of patient's risk factors and comorbid conditions, and the likelihood of an important alternate diagnosis. Typically, laboratory evaluations are done, which include a complete blood count, a metabolic panel to assess renal function, and urinalysis to assess for the presence of hematuria and infection. Confirmatory imaging is not always

TABLE 3: Renal colic mimics.

Gynecologic	Hemorrhagic cyst, dermoid cyst, endometrioma, ovarian neoplasm, ovarian torsion, fibroid, ectopic pregnancy, and pelvic inflammatory disease
Gastrointestinal	Appendicitis, diverticulitis, biliary disorders, pancreatitis, and small bowel obstruction
Urological	Pyelonephritis and urinary tract infection
Vascular	Abdominal aortic aneurysm, aortic dissection, renal artery thrombosis, renal infarction, mesenteric artery dissection or embolism, and intraperitoneal or retroperitoneal hemorrhage
Musculoskeletal	Mechanical low back pain and fractures
Miscellaneous	Herpes zoster infection (shingles)



Acute renal obstruction
Increased intraluminal or renal pelvis pressure
Ureteral hyperperistalsis and spasm
Nociceptors
Renal capsular distension
Prolonged isotonic contraction-Inflammatory cascade and muscle ischemia
Afferent impulses to spinal cord T11-L1
Immediate ↑in renal blood flow diuresis and ↑renal pelvis pressure result in ↓GFR
Colicky pain
Visceral pain, nausea, and vomiting
Decrease in renal blood flow, ureteral pressure, and GFR

(GFR: glomerular filtration rate)

FLOWCHART 1: Mechanisms of pain in renal colic.

necessary. For example, in a patient with known history of kidney stones, with a typical presentation and low likelihood of an important alternate diagnosis or complications, conservative management may be appropriate. However, in patients with no prior history of USD and with high risk for complication and alternate diagnosis, diagnostic imaging should be considered. The development of a clinical prediction rule, the STONE score, aims to evaluate the likelihood of uncomplicated ureteral stones and clinically important alternative diagnosis. This rule uses five objective criteria (gender, duration of pain, race, nausea/vomiting, and erythrocytes on urine dipstick) to categorize patients into low, moderate, and high probability of having a ureteral stone. The total score is 0–13 and is divided into three groups—low-risk: 0–5, moderate risk: 6–9, and high-risk: 10–13. This scoring system attempts to predict the likelihood of uncomplicated ureteral stones and is inversely associated with likelihood of an acutely important alternate diagnosis. This clinical prediction rule has the potential to guide decision-making regarding diagnostic imaging and treatment options. When this prediction rule was attempted to be externally validated, research found that the STONE score can aggregate patients into low-, medium-, and high-risk groups but lacks the sensitivity (53%) to allow clinicians to avoid obtaining a computed tomography (CT) scan. Further validation is required regarding the utility of this prediction rule.

IMAGING MODALITIES

When a patient presents to the ED with suspected renal colic, there is no consensus on which imaging modality should be obtained or even if imaging is necessary in the ED. The imaging is important in patient with suspected renal colic to confirm the diagnosis, obtain information about the stone size and location, diagnose complications related to USD, and rule out any potential disorders that mimic renal colic. Some physicians prefer imaging every patient who presents with suspected renal colic; others image only patients with first-time stones. CT of the abdomen and pelvis without contrast can be performed using low radiating dose scanning protocols or standard dose scanning protocols. Some clinicians reserve CT for patients who do not improve with conservative therapy or if another diagnosis is suspected. CT of the abdomen and pelvis without contrast using low-dose radiation scanning is the preferred examination for most adults. It has the highest diagnostic accuracy for renal and ureteral stones. It provides information on the stone size, location, and site of obstruction. CT scan is also useful in determining alternate diagnosis. CT of the abdomen and pelvis without contrast cannot evaluate kidney function. Ultrasound of the kidney and bladder can help diagnose renal colic indirectly by detecting hydronephrosis and the symmetry of the ureteral jets. Ultrasound can determine if a patient has unilateral or bilateral hydronephrosis and rarely can visualize presence of ureteral stones. This imaging modality is quick, noninvasive, and does not expose the patient to radiation; therefore, it is the preferred imaging modality in the pregnant patient and in recurrent nature of USD. Some clinicians prefer to obtain a CT scan after performing an ultrasound, either when an ultrasound is positive to confirm stone size and location in order to formulate a treatment plan or when an ultrasound is negative to confirm the negative test and to determine an alternate diagnosis.

Performing an ultrasound as the initial imaging test might decrease the need to order an abdominal and pelvic CT scan and thus decrease the radiation exposure to the patient. The abdominal radiography cannot detect hydronephrosis and has a sensitivity of 57% for stone detection and localization. An intravenous pyelography (IVP) involves radiographic imaging of the kidney, ureters, and the bladder before and after intravenous contrast dye is administered. It can diagnose hydronephrosis, evaluate renal function, and potentially show the position of the stone. IVP has similar sensitivity to that of ultrasound. This examination generally is not used as a first-line diagnostic imaging examination. MRI of the abdomen and pelvis is seldom used for nephrolithiasis. MRI poorly detects stones. Currently, MRI is used in nephrolithiasis in pregnant patients with hydronephrosis on ultrasound. In these patients

it can help determine the location of the obstruction, while not subjecting these patients to radiation.

MANAGEMENT AND TREATMENT

Analgesia

When a patient presents with an acute stone episode, one of the main goals is relief from pain. The pain that renal colic patients experience is from an increase in collecting system pressure and urethral spasm, which is modulated via prostaglandins. Because of this theory, nonsteroidal anti-inflammatory drugs (NSAIDs) have been the preferred drug for treatment of renal colic. NSAIDs can decrease smooth muscle tone as well as inhibit prostaglandins. NSAIDs should be avoided in patients with a history of a gastrointestinal bleed or impaired renal function. Narcotics have also been found to be helpful in the treatment of renal colic pain. Narcotics do not help with inhibiting prostaglandins, and in fact some studies found that they increase ureteric muscle tone.

Hydration and Diuretics

Patients who are dehydrated from either vomiting or decrease in oral intake should receive intravenous hydration. In theory, increase in fluid flow through the affected kidney might expedite stone passage and thus improve the patient's symptoms. Studies have been performed to prove this hypothesis by high-volume fluid hydration with or without the addition of diuretics to increase urine output. The literature in fact does not support the use of diuretics and high-volume fluid therapy in acute renal colic.

Medical Expulsion Therapy

There have been several medical expulsion therapies (METs) that have increased the passage rate of ureteral stones, which include alpha blockers, calcium channel blockers, and antispasmodic agents. Treatments that increase stone passage would benefit the patient by decreasing the need for interventional procedures. The top two METs that have been studied for the treatment of renal colic are TAMSULOSIN (an alpha-adrenoceptor antagonist, a smooth muscle relaxant drug) and nifedipine (a calcium channel blocker). In 2018, a meta-analysis of 67 trials showed a small benefit of alpha-blocker therapy with stone passage than with a placebo control. The use of MET in improving the passage of ureteral stones needs further research. At this time, there is little downside in using tamsulosin in MET, the cost of treatment is low, and there are few side effects.

Urology Consultation

Patients who are not able to be treated conservatively, due to having any one or several criteria should consult an urologist in the ED for admission and possible urgent intervention **Box 2**. Patients with an obstructing stone and urinary infection should be admitted for intravenous antibiotics and decompression of the obstruction. Patients with intractable vomiting should be admitted for intravenous hydration and supportive care. As alike, patients with intractable pain who cannot be controlled on oral agents should be admitted for supportive care. Patients with one functioning kidney should also be admitted to the hospital.

BOX 2: Admission criteria for kidney and ureteral stones.

- Urosepsis
- Intractable vomiting
- Infection with stone obstruction
- Stone size <15 mm
- Bilateral obstruction
- Single kidney or transplanted kidney with an obstruction
- Intractable pain
- Significantly elevated creatinine level

TABLE 4: Rate of spontaneous stone passage based on stone size.

Size of stone (mm)	*Rate of spontaneous passage (%)*
1	87
2–4	76
5–7	60
7–9	48
≥9	25

PROGNOSIS

Stone passage is dependent on the size, shape, and location of the kidney stone. Most stones 4 mm or less in diameter pass spontaneously. For stones >4 mm in diameter, there is a progressive decrease in the spontaneous passage rate as the size of the stone increases (**Table 4**). Shape is also important, and in particular the width of the kidney stone predicts the likelihood of spontaneous passage. In addition, stones that have reached the distal ureter are more likely to pass without intervention. Only about half of the stones in the proximal ureter are expelled spontaneously, while approximately 80% will pass if at the ureterovesicular junction. Recurrence is common. In the absence of preventive measures, the probability of recurrence of symptomatic kidney stones at 5 years is 50% and 60% by 10 years. Fortunately, the recurrence rate can be decreased by up to 50% in those treated with medication or dietary intervention. Although renal failure and permanent functional injury to the kidney are uncommon with urolithiasis. Decreases in renal blood flow begin 5–18 hours after obstruction and the degree of reversibility is unclear. Few studies suggest irreversible damage after 4 weeks of obstruction.

COMPLICATIONS

Obstruction

Patients who have a ureteral stone obstruction should have relief of obstruction within 2 weeks. Studies have shown that time to relief of obstruction and the presence of infection were the only significant predictors of outcome of long-term renal damage. If the obstruction was delayed past 2 weeks, renal outcome worsens progressively. Thus, urologists can closely monitor patients with an obstruction that does not have a concurrent infection, if they have a functioning contralateral kidney.

Infection

An infection in the presence of an obstructive stone is a urologic emergency. Antibiotics cannot be excreted unless there is relief of the obstruction. When there is a urinary tract infection with a nonobstructing stone, patients can be treated with oral antibiotics with close follow-up within 24 hours.

Stents

Patients with ureteral stents should be evaluated for obstruction, infection, and migration of the stents. This can be done by using abdominal and pelvic CT scan or a kidney, ureter, urinary bladder (KUB) ultrasound. Such patients should consult an urologist for their management and disposition.

SPECIAL CONCERNS

Pediatric

Stone disease in the pediatric population is uncommon, although its incidence is increasing especially in teens. The presentation of children with stone disease differs from that of an adult. Children usually present with a vague abdominal pain, not a unilateral colicky flank pain. Gross hematuria is present in 14–33% of patients and urinary tract infection affects 8–46% of stone pediatric patients. Ultrasound is the study of choice in the pediatric population due to concern over radiation exposure. Indications for admission are the same as for the adults. All children should be referred to an urologist and a workup for metabolic stone disease should be performed.

Pregnancy

There are anatomic and pathophysiologic changes in pregnancy that increase the risk of renal colic. There is urinary stasis secondary to compression and increase in progesterone levels. There is also hypercalciuria secondary to calcium supplementation and increase in glomerular rate. The renal ultrasound is the study of choice in pregnant patients secondary to the radiation exposure of CT scan. Narcotics are generally required for pain management because NSAIDs are contraindicated in pregnancy. METs can be safely used in pregnancy. Indications for admission are the same as for nonpregnant adults. Close follow-up with obstetrics as well as urologist is needed.

Geriatrics

The first important thing is to make the correct diagnosis. The differential diagnosis for this patient population includes acute myocardial infarction and abdominal aortic aneurysm. The average age of the first presentation for renal colic is 42 years, and it is uncommon for this first presentation to occur in patients older than 60 years. Thus, if a patient older than 60 years presents with no history of USD with symptoms that suggest renal colic, one must have high index of suspicion for an alternate diagnosis. The CT scan is the preferred imaging modality because it can evaluate both the renal collecting system and the aorta as well as other possible alternate diagnoses. The elderly population tend to have comorbid conditions and are on medications that may preclude them from the standard pain management of USD. For example, in patients who have renal failure or peptic ulcer disease, the use of NSAIDs is contraindicated.

SUMMARY

"Kidney and ureteral stones" is a frequent ED complaint. Either due to increasing identification or lifestyle changes, the prevalence of kidney and ureteral stones is increasing in all age groups. It is important for emergency physician to develop expertise in the diagnosis and acute management of this disease. The classic presentation of urolithiasis is an abrupt, unilateral flank pain that radiates to the groin. The diagnosis of urolithiasis includes a history and physical examination, evaluating the patient's risk factors, evolution of symptoms, the presence or absence of infection, and the exclusion of renal colic mimics. Noncontrast CT is the current diagnostic test of choice for ureteral stones. Most patients with acute renal colic can be managed conservatively with pain control and hydration. Emergent urological consultation in the ED is required for patients with urosepsis, renal obstruction with suspicion of a proximal urinary tract infection, acute renal failure, anuria, or intractable pain or vomiting.

112
CHAPTER

Urinary Tract Infection

Krunal Desai

INTRODUCTION

Urinary tract infection (UTI) is the most common infectious disease which affect from neonate to geriatric age group population in worldwide. Emergency physician need to evaluate wide spectrum of UTIs ranging from uncomplicated pyelonephritis, cystitis, urethritis to complicated pyelonephritis, urethritis, cystitis, or even who present with sepsis and shock. Challenges are much more while evaluating the UTI in emergency with improper history, nonavailability of culture reports, and irregular follow-up. Priorities for emergency physician while evaluating the UTI are determine whether infection is complicated or uncomplicated, necessary laboratory and imaging required, and appropriate antibiotics for patient.

DEFINITIONS AND CLASSIFICATION

Urinary tract infection described as an inflammatory process of urinary epithelium (upper or lower or both urinary tract) which is triggered by microorganism. Presence of white blood cells (WBCs) in urine is termed as pyuria, presence of bacteria in urine termed as bacteriuria.

Urinary tract infections can be classified on anatomical site, structural, and functional basis.

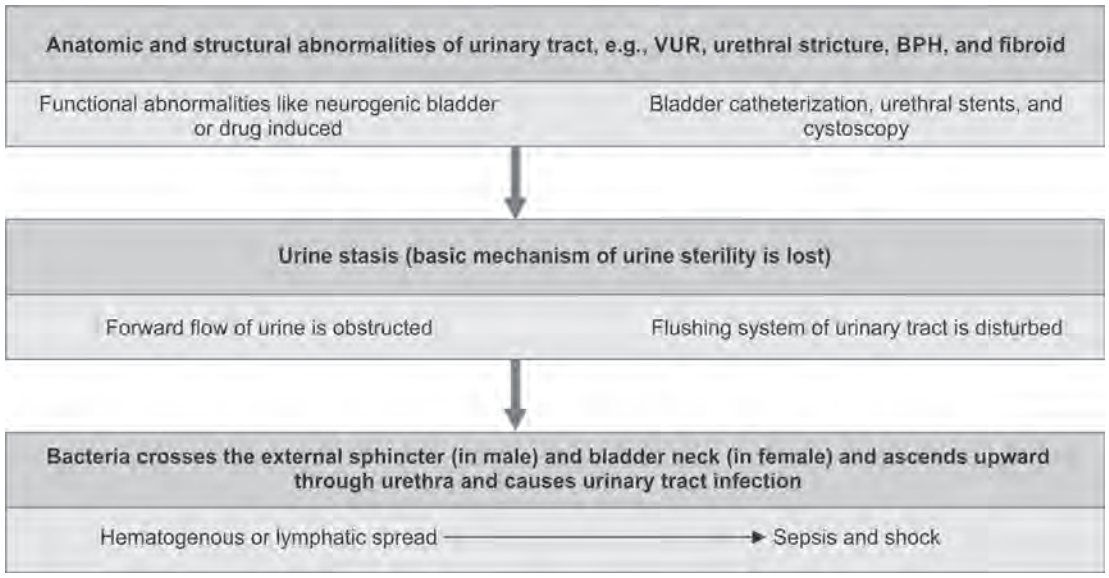
- *Upper UTI* involves ureter and kidney called as pyelonephritis.
- *Lower UTI* involves bladder called as urethritis and cystitis.
- *Uncomplicated UTI*: Uncomplicated UTI refers to occurs in young, healthy, and nonpregnant with normal structural and functional genitourinary tract.
- *Complicated UTI*: Complicated UTI refers to occurs in male, pregnant women, and any individual with structural and functional abnormality of genitourinary tract such as urolithiasis, neurogenic bladder, vesicoureteral reflux (VUR), malignancy, immunocompromised status, catheter, or stents.
- *Catheter-associated UTI (CAUTI)*: Patient with signs and symptom of UTI + presence of indwelling urinary catheter with no other source of infection.
- *Recurrent UTI*: It is defined as two uncomplicated UTIs in 6 months or three or more uncomplicated UTIs in the preceding 12 months.
- *Relapse of UTI*: It is defined as recurrence of UTI within 2 weeks of treatment completion for same organism.
- *Reinfection*: It is a recurrence of UTI with different organism than previous one.

PATHOPHYSIOLOGY

In normal situation, forward flow of urine is maintained along the urinary tract and urine remains sterile because of this flushing system of urinary tract. Urine remains sterile till external sphincter in male and till bladder neck in females. Mucosal barrier, immunological defense, and acidic nature of urine are the other factors helpful in prevention of UTI. Any disruption in anatomy, structure, and function of urinary tract leads to disruption of sterility of urine and infection. Pathophysiology of UTI is summarized in **Figure 1**. Incompetent ureterovesical valve leads to VUR and important cause of febrile UTI in children up to 24 month of age group. Spinal cord injury (SCI) patient with neurogenic bladder (dysfunction in bladder emptying) and patient with urologic surgery are also suffering from VUR. Calculi, masses or tumors either arising from urinary tract or outside like gastrointestinal tract or gynecologic structure obstruct the urine flow. Prostatic hypertrophy and urethral stricture are common causes in elderly men while fibroid, large pregnant uterus (in young female) and uterine prolapse (elderly female) are responsible for urinary obstruction. Medications such as anticholinergics, antipsychotic antidepressant, antiparkinson, and antihistamine are also responsible for urinary retention. Any instrumentation such as catheterization, cystoscopy, and transurethral surgery for stents placement and for calculi are high risk for UTI.

RISK FACTORS AND UROPATHOGENS

About half of the women experience UTI at least once in their lifetime. Lower rates of UTI are seen in men. Though elderly men are on higher risk due to prostate enlargement, use of catheterization, and debilitated state. Prior history of UTI, sexually active individual, and spermicidal use are the usual risk factors for UTI. *Escherichia coli* (75–95%) followed by *Staphylococcus saprophyticus* (5–15%) are the most common pathogens responsible for the complicated and



Anatomic and structural abnormalities of urinary tract, e.g., VUR, urethral stricture, BPH, and fibroid
Functional abnormalities like neurogenic bladder or drug induced
Bladder catheterization, urethral stents, and cystoscopy
Urine stasis (basic mechanism of urine sterility is lost)
Forward flow of urine is obstructed
Flushing system of urinary tract is disturbed
Bacteria crosses the external sphincter (in male) and bladder neck (in female) and ascends upward through urethra and causes urinary tract infection
Hematogenous or lymphatic spread
Sepsis and shock

(BPH: benign prostatic hyperplasia; VUR: vesicoureteral reflux)

FIG. 1: Pathophysiology of the urinary tract infection.

TABLE 1: Pathogens responsible for urinary tract infection (UTI).

Uncomplicated UTI	*Complicated UTI*	*Catheter-associated UTI*	*Recurrent UTI*
• *Escherichia coli* (75–95%)	• *Pseudomonas aeruginosa*	• *Proteus mirabilis*	• Antibiotic resistant *E. coli*
• *Staphylococcus saprophyticus* (5–15%)	• *Acinetobacter baumannii*	• *Candida* species	• *Enterococcus* species
• *Enterococcus* species	• *Enterococcus* species		• *Staphylococcus* species
• *Klebsiella pneumoniae*	• *Staphylococcus* species		

noncomplicated UTI. Gram-negative bacteria (*Klebsiella* and *Proteus mirabilis*) and gram-positive bacteria (*Enterococcus* and group B *Streptococcus*) can also responsible for UTI. Most common pathogens involved in complicated UTI are *Pseudomonas aeruginosa, Enterococcus faecalis*, and extended-spectrum β-lactamase (ESBL) producing bacteria. While polymicrobial and resistant organism involved in elderly men with urinary obstruction. Pathogens responsible for UTI are summarized in **Table 1**.

CLINICAL FEATURES

Urinary tract infection can present from localized symptoms to severe sepsis. In suspected case of UTI, detailed history and clinical features to classify the cause are most important. Patient can present with cystitis to urosepsis condition.

Cystitis

Cystitis is superficial infection of urinary bladder. Patient who has cystitis present with localized symptoms such as dysuria, urinary frequency, hesitancy, hematuria, or suprapubic pain. It is more common in woman than man. Usually patient with cystitis has no fever with only above-mentioned localized symptoms. It is necessary to evaluate regarding sexually transmitted disease (STD) by proper history such as urethral discharge, vaginal discharge, vaginal bleeding, new sexual partner, and sexual partner with STD. All these symptoms are more suggestive of STD than cystitis. Man, with >50 years of age, prostatic abnormality, and history of previous instrumentation can present with cystitis.

Pyelonephritis

Pyelonephritis is upper UTI which involves kidney and ureter. In contrast to cystitis, patient with pyelonephritis present with more systemic symptoms than local such as fever, vomiting, nausea, abdominal pain, and flank pain. For diagnosis of pyelonephritis, ultrasonography (USG), kidney, ureter, and bladder (KUB), or noncontrast computed tomography (NCCT KUB) should be done. Urine culture and blood culture should be sent from emergency before administration of antibiotic is ideal approach.

DIFFERENTIAL DIAGNOSIS

Being emergency physician, it is necessary to keep all differentials in mind for early confirmation, diagnosis, and management. History and clinical examination findings help to rule out all differentials and make confirm diagnosis. Common and life-threatening mimic of UTI can be differentiated as shown in **Table 2**.

DIAGNOSTIC EVALUATION

In emergency department, presumptive diagnosis of UTI by proper history and clinical examination should be confirmed by pathological-radiological investigations. Life-threatening

TABLE 2: Common and life-threatening mimic of the urinary tract infection.

Fever, nausea, vomiting, and abdominal pain	*Lower abdominal pain and urinary symptoms*
• Abdominal aortic aneurysm	• Spinal epidural abscess
• Cholecystitis	• Ectopic pregnancy
• Lower lobe pneumonia	• Ovarian torsion
• Appendicitis	• Pelvic inflammatory disease
• Diverticulitis	• Testicular torsion
	• Epididymitis/orchitis

differentials must be rule out first as mentioned above. For confirmed diagnosis of UTI, urine dipstick, routine microexamination, culture, USG are necessary. All these investigations should be used as per requirements. For urine test first most important thing is to collect urine by proper clean-catch method.

Technique for urine collection:

- Clean periurethral area, retraction of foreskin, and separation of labia: Collect midstream urine
- If patient cannot void urine: Sterile catheterization with no touch technique and collection
- If unable to catheterize patient: Suprapubic aspiration but invasive and painful

Once urine is collected, it should be analyzed as soon as possible because delay can make unreliable results.

Urine Dipstick

Urine dipstick test used in emergency department to find out presence of ketone, protein, glucose, nitrates, leukocyte esterase, bilirubin, pH, and specific gravity. For diagnosis of UTI, nitrite and leukocyte esterase test are important. Leukocyte esterase enzymes are released from WBCs, so presence of it indicates WBCs in urine. But drawback is WBCs can be vaginal source in female patients that cannot be ruled out. Results can be false positive in high glucose or protein concentration, use of glucocorticoids, and viral illness. So leukocyte esterase test has wide range of sensitivity from 70 to 95%. Other important test for UTI in emergency is nitrite test. In this test nitrates present in urine is converted to nitrite by microorganism but only by Enterobacteriaceae. So that other common organisms for UTI such as *S. Saprophyticus* and enterococci can be missed out. Nitrite test sensitivity alone is 81% but if both nitrite and leukocyte esterase positive then sensitivity increases up to 94%. False-positive results in nitrite test occur with contaminated specimen, drug, food that color urine red, and *Trichomonas* infection. False-negative results with recent antibiotic treatment, presence of glucose and protein in urine, and high specific gravity.

Urine Microscopy

After urine dipstick test, urine routine and microscopic examination are the most commonly used tests to diagnose UTI in emergency department. Urine microscopic examination provides information regarding presence of bacteria, WBC, red blood cell (RBC), and epithelial cells in urine. WBC count > 5 per high power field in symptomatic patient indicates abnormal result. If counts are less but history and clinical examination findings are suggestive of UTI, first rule out false-negative causes. Presence of WBC and RBC indicates other causes like vaginal bleeding or bleeding from genitourinary tract and do further diagnosis accordingly. Presence of epithelial cells indicates contaminated specimen.

Urine Gram Stain

Urine gram stain examination finds out gram-positive and gram-negative organism. So on that basis clinician can suspect organism and start empirical antibiotics. Major drawback is not available in most of emergency departments.

Urine Culture and Sensitivity

Urine culture and sensitivity frequently used at intensive care unit (ICU) when bedridden patient with prolong catheterization and multidrug-resistant organism in different cultures. In emergency it is used in selected patients. If patient with clinical history and examination suggestive of UTI, positive urine dipstick, microscopic examination does not need to do culture. Such patient responds well to empirical antibiotics. Patient with sepsis, male patient, pregnant, pyelonephritis, immunocompromised individual, recurrent UTI, and complicated UTI needs urine culture examination. It should be done before administration of antibiotic. Collection should be done with proper care.

Imaging

Patients with UTI generally do not need imaging in diagnostic evaluation. But in some conditions, renal imaging required to find out causes. USG KUB is primary modality of investigation. It is easy to perform, rapidly available, and can direct pathologies such as calculi, hydroureter, and kidney size and shape. CT scan is the investigation of choice for any renal pathology. It shows size, shape, pyelonephritis, calculi, obstructive changes, abscess, and emphysematous changes. In suspicious cases, CT KUB with contrast can be done to find out renal artery, vein stenosis due to thrombus or embolism.

TREATMENT

General Consideration

For treatment of UTI, first it is necessary to confirm type of UTI. There are basic steps which have to be considered by emergency physician for treatment of UTI:

- Confirm type of UTI
- Proper hydration
- Change catheter if suspect CAUTI
- Decide to admit or outpatient treatment
- Send culture reports, if indicated
- Start symptomatic treatment
- Start antibiotic as per antibiogram
- Follow-up

Principle of Antimicrobial Management

Antibiotics are typically recommended for UTI to eliminate the pathogen from the urine. While choosing the antibiotics, two important factors are important; one pathogen should

be susceptible to antibiotics and second its concentration in urine should be at high level [above the minimum inhibitory concentration (MIC)] to eliminate the pathogen. Dose adjustment of antibiotics is required in acute as well as chronic renal insufficiency. Eradication of pathogen is challenging in end-stage renal disease due to inability to maintain antimicrobial concentration in the urine. Urinary obstruction can also affect the antibiotic concentration in the urine so this should be addressed as early as possible.

Antibiotic therapy should be decided on the basis of the diagnosis, comorbidities, hemodynamic status of the patient, and the local/institutional antibiogram. While evaluating the UTI patient in emergency department urine culture is rarely available, so antibiotics should be started empirically and hospital antibiogram is useful to understand resistance pattern and antibiotic selection. History of medication allergies, compliance of the drug, cost of medication, and availability should also be considered.

Patient with hemodynamic instability and with urosepsis should be treated with intravenous (IV) fluid, vasopressors along with IV antibiotics. Proper evaluation is required in patient of urinary obstruction who presented with shock because these patients may require emergency urologic intervention. In view of source control strategies in management of UTI, percutaneous or endourologic drainage of hydronephrosis and renal abscess may require. Emphysematous pyelonephritis may require immediate partial or total nephrectomy.

Asymptomatic Bacteriuria

Condition where patient is asymptomatic but has bacteria in urine or urine culture (clean midstream catch) report is showing quantitative count of at least 10^5 cfu/mL (in single specimen for men and two consecutive specimens with same species for women). In emergency department, patient usually comes after obtaining previous report as emergency physician do not prescribe urine culture in asymptomatic patient. These groups of patients where bacteria are visualized in microscopy should be kept under observation, and usually not treated with any antimicrobial because they often clear. Pregnant women should be treated with antimicrobial for 3–7 days because of risk of preterm, low birth weight, or situation may progress to pyelonephritis.

Acute Uncomplicated Cystitis

Patient presenting with acute uncomplicated cystitis can be treated as outpatient treatment. Emergency physician should start antibiotics as per local resistance and antibiogram. Mostly drugs which get concentrated in urine considered as choice of antibiotics. There are three antibiotics which are used in treatment: Nitrofurantoin, trimethoprim-sulfamethoxazole (TMP-SMX), and ciprofloxacin.

Nitrofurantoin is used in treatment of uncomplicated cystitis because it is highly active against *E. coli* and achieves high urinary concentration. But major drawback is prolonged treatment, does not penetrate to tissue so cannot be used in pyelonephritis.

Dose: Nitrofurantoin 100 mg twice a day for 7 days.

Due to gradually increasing resistance of *E. Coli* to TMP-SMX, if local resistance <10–20% it can be used as empirical treatment in cystitis. If resistance >20%, nitrofurantoin should be considered.

Dose: TMP-SMX one DS (double strength) twice a day for 3 days.

If patient is allergic and resistance to nitrofurantoin and TMP-SMX, fluoroquinolones should be considered. As fluoroquinolones are used in multiple conditions such as pneumonia, complicated UTI, and tuberculosis, it should not be start as empirical antibiotic because of chance to develop resistance in community.

Dose: Ciprofloxacin 500 mg twice a day for 3 days.

Pyelonephritis

In most cases, infection begins as cystitis. If bacteria ascend through urinary tract and reaches infected kidney parenchyma, the condition is called pyelonephritis. Some cases also occur through hematogenous spread by *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Salmonella*, and *Candida*. Fever, vomiting, flank pain, and costovertebral angle tenderness are the presenting features. Urine culture and blood culture along with diagnostic imaging are recommended if kidney, ureteral stone, masses, abscess, and emphysematous pyelonephritis are suspected. Antibiotics and supportive care (antipyretics, antiemetics, and IV fluid) are mainstay of the treatment. While initiating the antibiotics in emergency department, coverage should include against *E. coli* which is responsible for majority of cases. Patient should be admitted if vomiting and signs of dehydration, sepsis, pregnancy, postrenal transplant, presence of calculi, urethral stent, and catheters are present.

Acute Uncomplicated Pyelonephritis

As pyelonephritis is infection on renal parenchyma, antibiotics which penetrate in tissue can be considered as initial treatment. Fluoroquinolones are initial choice of antibiotic. But being emergency physician must consider to start outpatient or inpatient treatment. Indications for admission are inability to maintain oral hydration, unable to take oral medicines, severe sepsis, acute renal failure, immunocompromised, pregnancy, etc. If patient is allergic to fluoroquinolones, oral or IV amoxicillin can be started if low local resistance to organism.

If the patient can be treated as outpatient treatment oral fluoroquinolone is initial treatment of choice.

Oral Medicines

- Ciprofloxacin 500 mg twice a day for 7 days
- Amoxicillin 500 mg three times a day for 10 days
- Cefpodoxime 200 mg twice a day for 14 days

Intravenous Medicines

- IV ciprofloxacin 400 mg twice a day for 7 days
- IV ceftriaxone 1 g once a day for 14 days

Acute Complicated Pyelonephritis

As mentioned before, patient with pyelonephritis associated with structural and functional abnormality of genitourinary tract, immunocompromised status, signs of sepsis considered as complicated pyelonephritis. These patients required as early as possible broad-spectrum IV antibiotics. Take culture before administration of antibiotics. Recently, ceftolozane/tazobactam and ceftazidime/avibactam are newer antibiotics on trial for complicated UTI.

Doses

- IV cefepime 1 g twice a day
- IV piperacillin/tazobactam 4.5 g three times a day
- IV imipenem 500 mg four times a day
- IV ciprofloxacin 400 mg twice a day
- IV vancomycin 15 mg/kg twice a day

Recurrent Urinary Tract Infection

Many patient visits emergency department with same complains of UTI frequently. Usually these patients can be managed with antibiotics according to previous culture and treatment. In these patients it is necessary to find out cause or risk factor for recurrence. Risk factors are structural and functional abnormality of genitourinary tract, new sexual partner, use of a diaphragm or spermicide. It is also necessary to find out which patients need further investigations of recurrent UTI.

Indication for further investigation of recurrent UTI:

- Prior urinary tract surgery
- Obstructive symptoms
- Prior abdominopelvic surgery
- Immunocompromised status
- Repeated pyelonephritis

Two treatment modalities can be used in recurrent UTI:

1. Postcoital antibiotics
2. Self-start therapy

Postcoital antibiotic can be started in female patients with recurrent UTI when sexual activity is risk factor for UTI. Low dose antibiotics should be started within 2 hours after coitus. TMP-SMX, ciprofloxacin, nitrofurantoin, norfloxacin, and ofloxacin are generally prescribed.

Self-start antibiotic is another modality in women who can able to recognize her symptoms of UTI. Three days course of antibiotics should be given to such patients and advised to start treatment if symptoms present. If symptom dose not resolve within 2 days then it is advised to contact physician for further treatment.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a severe necrotizing infection of renal parenchyma and perirenal space caused by *E. coli* mostly in uncontrolled diabetic patient. Emphysematous pyelonephritis considered as urologic emergency and severe spectrum of clinical pyelonephritis, with high mortality rate 20–40%. It is believed that high blood sugar in tissue provide favorable environment for *E. coli* which ferment sugar and produce carbon dioxide. Computed tomography of abdomen and pelvis is used to confirm the diagnosis. Emergency department management consists of board-spectrum antibiotics, IV fluid, and urgent urology consultation. In modern management, conservative approach of percutaneous drainage along with medical management (antibiotics) is considered. Nephrectomy may be required in severe cases.

Renal Abscess and Perinephric Abscess

Purulent infectious collection of renal parenchyma is known as renal abscess, typically caused be gram-negative bacteria and suspected when patient with pyelonephritis is not responding to antimicrobial therapy. Perinephric abscess results from rupture of cortical abscess in to perinephric space. Imaging modality of choice is computed tomography. Supportive and noninvasive approach can be opted for hemodynamically stable small abscess (3–5 cm) and can be treated with antibiotics. Antibiotic therapy should be targeted against gram-negative organism. Open or percutaneous surgical drainage is considered for larger abscess.

Catheter-associated Urinary Tract Infection

Catheter-associated UTI is one the common healthcare-associated infection and bacteriuria is observed in about 10% in catheterized individual. Urinary catheter system provides an environment for *Pseudomonas*, *Proteus*, *E. coli*, and *Enterococcus* bacterial growth. Fever, suprapubic tenderness, and sepsis hypotension are usually present. Urine culture result is obtained if CAUTI is suspected, catheter should be replaced or removed and antibiotics should be started immediately.

Spinal Cord Injury Patient and Urinary Tract Infection

Patients of SCI are more prone for UTI and most common cause of fever. Catheterization of bladder, impaired bladder emptying, and decreased fluid intake altered defense mechanism of body due to chronic illness. Decubitus ulcers are the predisposing factors for UTI in SCI patient. Fever fatigue with vague abdominal discomfort are the usual presenting feature, they are not experiencing classic feature of UTI (dysuria, frequency, and urgency) because of loss of sensation. *Enterococcus*, *Proteus*, and *Pseudomonas* are common pathogens. Aminoglycosides plus penicillin or third-generation cephalosporine is considered for UTI in patient with SCI.

Urinary Tract Infection and Sexually Transmitted Infection

Urinary tract infection and sexually transmitted infection (STI) are sometime difficult to differentiate as in both conditions symptoms like dysuria may overlap and are present in sexually active persons. STI present with vaginal discharge, lower abdominal pain, pruritus, dyspareunia, and history of multiple sexual partner. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are most common causative organisms for cervicitis, pelvic inflammatory disease, epididymitis, and prostatitis. If suspected, both UTI and STI can be treated concurrently.

Special Population

Pregnancy

Pregnant women are more prone to get UTI due to hormonal and mechanical changes during pregnancy. In pregnancy, asymptomatic bacteriuria also should be treated because there are chances to develop severe sepsis, premature labor, low birth weight, etc. Most common organism is *E. coli*. Nitrofurantoin, beta-lactam antibiotics, second- and third-generation cephalosporins are generally used for treatment. But all medicines used according to trimester and considering

its side effects. Fluoroquinolones and tetracyclines are contraindicated in pregnancy. Nitrofurantoin should be avoided in first-trimester and near-term period because of its effect on organogenesis, potential to cause hemolytic anemia in newborn. Ceftriaxone causes kernicterus by bilirubin displacement. Obstetrician opinion is necessary.

Elderly

Diagnosing and managing the UTI in elderly is challenging because of limited history and typical symptoms may not be present or not well communicated. Bacteriuria and pyuria along with nitrite positive are indicative of active infection. Initiation of antibiotics in elderly needs caution. IV antibiotics are required in UTI with sepsis or altered sensorium. Oral antibiotics should be carefully prescribed in those elderly who can be discharged home. Nitrofurantoin is usually the first choice but must be avoided in renal insufficiency.

DISPOSITION

Majority of patient of uncomplicated and few of complicated UTI can be discharged home. Pyelonephritis patient with fever, vomiting, dehydration, and hemodynamic instability need hospitalization for stabilization with IV fluid, antibiotics, antiemetics, later they can also be discharged with close follow-up.

SUMMARY

Being an emergency physician, based on clinical symptoms, history, and examination do appropriate evaluation for UTI. Use antibiotic as per hospital antibiogram and local resistant pattern. Summary of empirical use of antibiotics is given in **Table 3**. With increasing resistance pattern, it is necessary to follow recent guidelines for management of such cases.

TABLE 3: Summary of empiric antibiotic therapy in UTI.

Condition	*Antimicrobial agents*	*Dose/route*	*Duration of therapy*
Acute uncomplicated UTI	Nitrofurantoin	100 mg/oral twice/daily	5 days
	TMP-SMX	160–800 mg 1 DS/oral/twice daily	3 days
	Fosfomycin trometamol	3 g/oral	One dose
	Ciprofloxacin	500 mg/oral/twice daily	7 days
	Levofloxacin	750 mg/oral/once daily	5 days
	Amoxicillin-clavulanic acid	500–125 mg oral thrice daily	3–7 days
	Cefpodoxime	100 mg/oral/twice daily	7 days
	Cephalexin	500 mg/oral/twice daily	7 days
	Cefaclor	500 mg/oral/three times daily	7 days
	Cefuroxime	250 mg/oral/twice daily	7–10 days
Pyelonephritis (outpatient)	Ciprofloxacin	500 mg/oral/twice daily	7 days
	Levofloxacin	750 mg/oral/once daily	5 days
	Cefpodoxime	200 mg/oral/twice daily	10–14 days
	TMP+SMX (DS)	160–800 mg 1 DS/oral/twice daily	10–14 days
	Amoxicillin-clavulanic acid	875–125 mg oral thrice daily	10–14 days
	Ceftriaxone	1 g/IM or IV	One dose
	Ciprofloxacin	400 mg IV	One dose
	Gentamycin	5 mg/kg IM or IV	One dose
Pyelonephritis (inpatient)	Ciprofloxacin	400 mg IV	Every 12 hourly
	Levofloxacin	500 mg IV	Every 24 hourly
	Ceftriaxone (± aminoglycoside)	1 g IV	Every 12 hourly
	Gentamycin (± ampicillin)	5 mg/kg IV	Every 24 hourly
	Piperacillin-tazobactam (± aminoglycoside)	3.375 g IV	Every 6 hourly
	Meropenem	2 g IV	Every 8 hourly

(DS: double strength; IM: intramuscular; IV: intravenous; TMP-SMX: trimethoprim-sulfamethoxazole; UTI: urinary tract infection)

113
CHAPTER

Penile Emergencies

Puneet Ahluwalia, Devendra Richhariya

INTRODUCTION

The penis is a very sensitive organ in the body and even minor discomfort or injury to penis compels the patient to consult the physician either in outpatient or in emergency department. Emergency physician should be aware of the penis-related conditions and emergencies because delay intervention may lead ischemia and necrosis of the penis. Emergency physician should be able to manage ischemic priapism, phimosis, paraphimosis, entrapment (zipper) injury, and penile fracture. Any penile trauma should be considered as an emergency until proven otherwise. This chapter includes various penile complaints in adults, with emphasis on the most serious (penile fracture) and common conditions such as phimosis, paraphimosis, balanitis, and posthitis.

ANATOMY

The penis consists of the paired corpora cavernosa, or erectile bodies, that lie dorsal to the corpus spongiosum (**Fig. 1**). The corpus spongiosum surrounds the penile urethra. The corpora cavernosa and corpus spongiosum are wrapped in a thin connective tissue layer, the tunica albuginea. The glans is the distal head of the penis. The distal foreskin, or prepuce, in uncircumcised men lies over the glans and can be retracted proximally to expose the glans. The coronal sulcus distinguishes the glans penis from the penile shaft.

PRIAPISM

Priapism is defined as prolonged erection of the penis, generally lasting >4 hours, in the absence of sexual desire or stimulation. This medical condition was named after Priapus, an ancient Greek god of fertility and horticulture who was endowed with oversized genitalia. Ironically, one cause of priapism is prolonged effects of erectile dysfunction medications, making a pleasurable emulation of Priapus a painful one. More than one-third of patients with severe priapism may experience permanent erectile dysfunction despite treatment, resulting in obvious infertility or other emotional or functional sequelae.

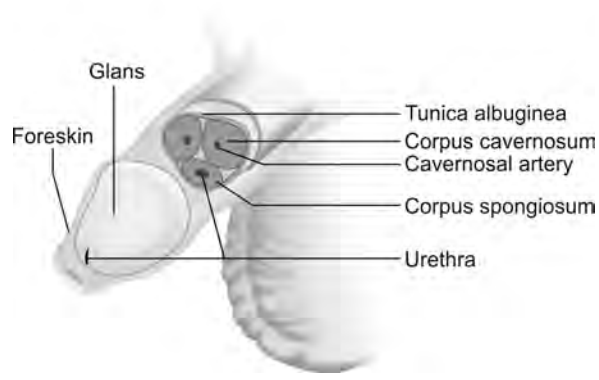

FIG. 1: Anatomy of the penis.

Etiopathogenesis

Priapism can be divided into two main categories. Ischemic priapism, also known as low-flow priapism, is the most commonly seen variant and is caused by painful venous engorgement of the corpora cavernosa and requires emergency treatment. Nonischemic (high-flow) priapism is rare and is often painless. It is caused by increased arterial inflow to the penis from traumatic arterial-cavernosal fistulae and does not require urgent treatment. Ischemic priapism can be considered as a compartment syndrome of the penis. The corpora cavernosa become engorged with stagnant, oxygen-depleted venous blood from either an intraluminal obstruction of venous blood flow or an inability of the penile muscle tissue to adequately contract and augment venous outflow. The causes of ischemic priapism are multiple and varied (**Box 1**).

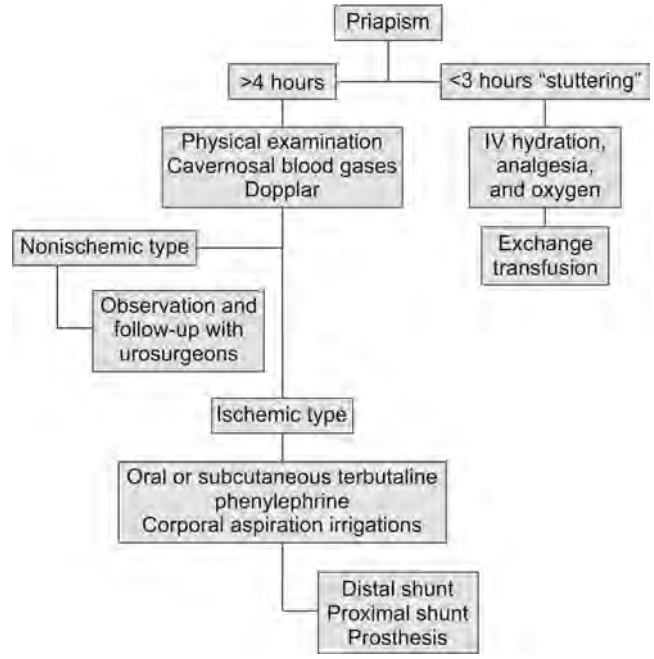
Differentiating Ischemic and Nonischemic Priapism

Evaluation of the patient with priapism may involve several steps before a final cause can be identified. *Patient history* can help differentiate between ischemic and nonischemic priapism. Ischemic priapism is painful, nontraumatic,

BOX 1: Causes of ischemic priapism.

- *Medications*
- Impotence agents; intracavernosal therapies (prostaglandin E1, papaverine, and phentolamine); and oral agents (i.e., sildenafil)
- *Antihypertensives*: Hydralazine, prazosin, doxazosin, and α-adrenergic blocking agents such as tamsulosin
- *Antidepressants*: Trazodone, fluoxetine, sertraline, and citalopram
- Antipsychotics (phenothiazines) and atypical antipsychotics (ziprasidone)
- *Substance abuse*: Cocaine, marijuana, and alcohol
- *Others*: General anesthetics, hydroxyzine, metoclopramide, omeprazole, anticoagulants, testosterone, immunosuppressants (e.g., tacrolimus), and total parenteral nutrition
- *Hematologic disorders*
- Sickle cell disease, leukemia, and myeloma
- *Central nervous system*
- *Brain*: Cerebrovascular accident
- *Spinal cord*: Spinal stenosis, spinal cord injury, lumbar disk herniation, cauda equina syndrome, spinal disk disease, epidural anesthesia, and neurosyphilis
- *Hip arthroplasty*: Presumably caused by intraoperative nerve injury
- *Others*
  - Infections, malaria, and rabies
  - Toxins—scorpion
  - Carbon monoxide and idiopathic hypertriglyceridemia

and may be associated with a history of priapism, hemoglobinopathy, or vasoactive drug use, whereas nonischemic priapism is typically painless and caused by traumatic injury. Patients with ischemic priapism often present shortly after onset of symptoms because of pain, whereas patients with nonischemic priapism may present after several hours or days of symptoms. On physical examination, ischemic priapism will present with a rigid penile shaft but soft glans. Patients with nonischemic priapism will often have a partial erection, but the entire penis, including the glans, will be firm. The presence of the *"peisis sign",* which is partial or complete resolution of the erection during compression of the perineum, may also help support the diagnosis of nonischemic priapism. Any patient presenting with the first episode of priapism and who is not known to have sickle cell disease should have a sickle cell preparation and a complete blood cell count, regardless of ethnicity. *Aspiration of the corpora cavernosa* is helpful in distinguishing ischemic from nonischemic priapism. The blood gas of ischemic priapism will be grossly dark in color and have a pH < 7.25, a partial pressure of oxygen (PaO_2) < 30 mm Hg, and a partial pressure of carbon dioxide (pCO_2) > 60 mm Hg. In contrast, corporal blood gas from nonischemic priapism will appear much closer to normal arterial blood gas, typically with a pH > 7.30, PaO_2 > 50 mm Hg, and pCO_2 < 40 mm Hg. Finally, *color duplex ultrasound* of the penis and perineum may be useful in assessing for the presence or absence of blood flow through the cavernosal arteries. Absent blood flow will confirm the diagnosis of ischemic priapism. Normal or increased blood flow will support the diagnosis of nonischemic priapism. *Arteriography* may be indicated for nonischemic priapism, but it is often performed when embolization treatment is planned rather than as an initial diagnostic modality.



FLOWCHART 1: Treatment summary of priapism.

Management

A urologic surgeon typically manages treatment of acute priapism. However, treatment for ischemic priapism will frequently need to be initiated in the emergency setting while awaiting specialty consultation **Flowchart 1**.

The classic teaching is that the initial treatment—*oral (or subcutaneous) terbutaline a ß2-adrenergic agonist,* is thought to increase venous outflow from the engorged corpora through relaxation of venous sinusoidal smooth muscle. Terbutaline has an unproven benefit. If terbutaline fails to work rapidly, the next step in the treatment of priapism is *corporal blood aspiration*, saline irrigation, and injection of α-adrenergic receptor agonist such as dilute phenylephrine. Phenylephrine should be diluted in normal saline to a concentration of 0.1–0.5 mg/mL, and 1-mL injections made every 3–5 minutes for 1 hour. Lower concentrations in smaller volumes should be used in children and patients with severe cardiovascular disease. Use of a preprocedural penile block is essential. In addition to the treatment directed at acutely relieving the symptoms, other underlying causes, if they exist, should be treated. For example, patients with sickle cell disease may benefit from intravenous fluids and supplemental inhaled oxygen. Certainly any potentially offending medications should be discontinued.

Treatment of stuttering priapism includes *preventative daily antiandrogen therapy*, such as cyproterone acetate, or gonadotropin-releasing hormone drugs, such as leuprolide, which paradoxically reduce the frequency of priapism but do not inhibit sexual activity. A promising new treatment is daily treatment with low-dose inhibitors of the enzyme phosphodiesterase type 5. These agents may reduce cellular nitric oxide action and decrease vasodilation, thus reducing erection duration. However, even patients with stuttering priapism may require emergency treatment for typical ischemic priapism in the setting of particularly severe symptoms or a markedly prolonged erection.

Surgical shunt procedures are used as a last resort in patients with low-flow priapism unresponsive to the aforementioned treatments, regardless of the precipitating cause of ischemic priapism. Treatment of nonischemic priapism requires less urgency. No risk of long-term damage is associated with the absence of immediate treatment and, although the condition is distressing, pain is not a prominent feature**.** *Conservative therapies*, such as rest, ice packs, and observation for several days, will help resolve the inciting arteriovenous fistulae in >60% of cases. If conservative management fails or is otherwise nonfeasible**,** *embolization is the next step***.** Embolization has >90% success rate in treating priapism, but still nearly 10% of patients may have erectile dysfunction after this procedure**.** *Surgical ligation of the cavernosal artery* or ligation of the fistula may be required if embolism fails. However, after ligation, close to half of patients experience erectile dysfunction. Alternative methods to treat nonischemic priapism include *injection of thrombin or methylene blue into the corpora cavernos*a in an effort to occlude the arteriovenous fistula, but these should be considered less favored alternatives to embolization.

ZIPPER INJURY AND PENILE ENTRAPMENT

Zipper injuries are more common in children than adults. Often the patient is uncircumcised and the foreskin gets caught and crushed when the zipper is closed. Lubricants such as mineral oil can be used to free the skin from the zipper, but this does not always work. Cutting the median bar of the zipper will separate the zipper, allowing the two sides of the zipper to fall apart. The median bar is the small piece of metal that connects the anterior and posterior plates of the zipper. A bone or wire cutter is needed to divide the median bar (**Figs. 2A** and **B**). If these tools are unavailable, another method is to grasp opposite sides of the zipper, one inferior and one superior to the site of zipper entrapment, and slowly separate the teeth by pulling in opposite directions. Local anesthesia is recommended before using this method.

If these methods fail to release the entrapped foreskin, emergent partial or complete circumcision to separate the prepuce from the zipper may be necessary. Glans edema mimicking paraphimosis can occur in circumcised or uncircumcised men in penile entrapment injuries. In these instances, external objects may constrict the mid to distal shaft, leading to the same pathophysiologic derangements seen with paraphimosis. Objects may either be placed intentionally for sexual stimulation or may occur sporadically, as in the case of a hair tourniquet in male infants. Hair tourniquets may be particularly difficult to diagnose, because the offending hair may be nearly invisible within an engorged and edematous coronal sulcus. An occult hair tourniquet should be considered, along with testicular torsion, in male infants who are crying inconsolably. In adolescent or adult men, rings or other constricting bands may be used for self-stimulation or to maintain an erection.

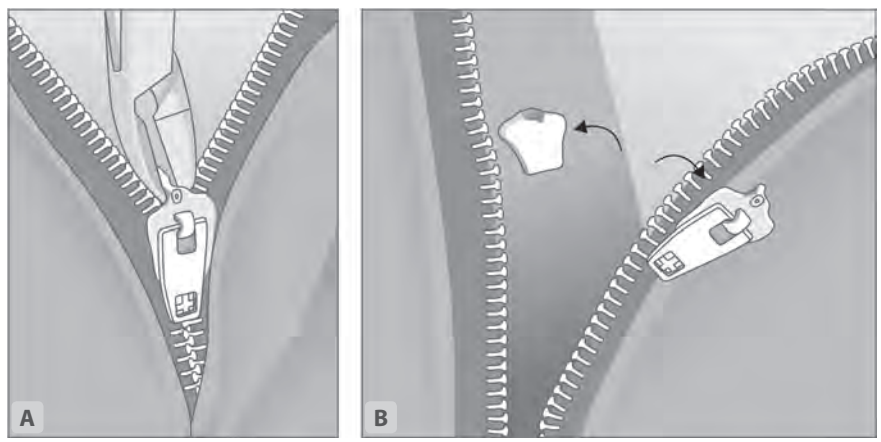
Depending on the object and degree of entrapment and distal edema, release may be challenging. Occasionally, constricting objects may be removed without the need for cutting or sawing. One method is the string method. Similar to that used to remove a ring from a finger, a flat string is passed under the ring so that it protrudes proximally. Then the distal end of the string is wound around the penis and when the proximal end of the string is pulled up and distally, with luck the ring will move distally, little by little, until it is removed. Glass saws may be helpful for removing glass bottles, but plastic bottles are not easily cut by a glass saw or scalpel. Rather, an oscillating cast saw is recommended for an entrapped plastic bottle.

Using a splint device, such as a wooden tongue depressor blade, between the bottle and the skin of the penis is recommended. Metal devices may be removed with ring cutters, but may require heavy equipment such as pneumatic saws used by fire department personnel to extricate victims from crushed automobiles. One challenge in using these machines is that the skin entrapped under the device must be protected from the blade.

In some cases, aspiration of blood from the entrapped corpora cavernosa may relieve enough edema so that a protective device can be placed before engaging the saw. Because a great deal of heat is often generated from these saws, continuous irrigation of the area with cold water or saline is also necessary to protect the penis from thermal injury. Time is critical when removing entrapped objects. With prolonged duration of entrapment, ischemia or gangrene of the distal penis may occur, in the most severe cases placing the penis at risk for possible amputation. This surgical cure is invasive and skin grafting is frequently necessary to close the wounds.

BALANITIS AND POSTHITIS

Balanitis is inflammation of the glans penis, and posthitis is inflammation of the penile foreskin. Often both the glans and foreskin are inflamed, *termed balanoposthitis*. Glans or prepuce



FIGS. 2A AND B: Zipper removal.

inflammation is often caused by infection. Uncircumcised men are at risk for developing infection because the tight foreskin, together with poor hygiene and smegma build-up, creates an environment conducive to the development of inflammation. Patients with this condition typically complain of a red, edematous glans or foreskin, often with discharge. Determining the causal agent may be challenging. *Candida albicans* is the causal agent in nearly one-third of balanitis cases. The typical findings of candidiasis are erythema and papules with "satellite" lesions. Burning and pruritus may also be present. Candida can be contracted from sexual activity with an infected partner. Diabetic patients or other immunosuppressed patients are at risk for candida balanitis or posthitis. Treatment with topical azole antifungal agents and effective hygiene typically is sufficient, but in severe cases a single oral dose of 150 mg of fluconazole may be necessary. Other common infectious causes include streptococcal and staphylococcal species, which typically require oral antimicrobial treatment. Sexually transmitted diseases, including chlamydia and syphilis, may also cause balanitis and posthitis. Therefore, cultures or other diagnostic testing for suspected causal agents may be necessary to help guide treatment. Balanoposthitis may be complicated by phimosis, cellulitis of the penile shaft, or abscess formation. Noninfectious causes of balanoposthitis occur less frequently overall, yet remain important considerations. Contact dermatitis may occur from condoms, spermicidal, or lubricating gels associated with condom use. Lichen planus is an inflammatory dermatosis that affects only the glans (balanitis), causing itchy red and whitish plaques. It is treated with high-potency topical steroids. Balanitis xerotica obliterans (BXO) is a rare condition of unknown origin that causes chronic inflammation of the glans, dry skin, and pruritus, and may be associated with endarteritis.

PEYRONIE'S DISEASE

Peyronie's disease was first reported in 1743. It is a connective tissue disorder in which plaques or scars form in the tunica albuginea, resulting in penile pain, induration, palpable plaques on the shaft that cause abnormal curvature of the erect penis, and ultimately erectile dysfunction. The characteristic scar formation can occur after major trauma and minor "microtrauma" during intercourse. In many cases, patients will not recall any distinct precipitating traumatic event. Patients with Peyronie's disease are thought to have a genetic predisposition for abnormal scar formation. Patients should be referred for nonurgent urologic surgery follow-up. Typical therapies range from tocopherol (vitamin E) pills to plaque injections with interferon alpha.

PENILE CALCIPHYLAXIS

Penile calciphylaxis is a rare disorder. Patients may present with severe penile pain from ischemia caused by calcification and fibrosis of the penile arteries. In its most extreme form, it may progress to gangrene, requiring penectomy. The underlying cause is often secondary hyperparathyroidism associated with end-stage renal disease. Affected patients may also have concurrent calciphylaxis of the limbs. Emergency urologic surgical consultation is needed for infection or necrosis requiring debridement.

PHIMOSIS

Phimosis is the condition in which a narrowed prepuce (foreskin of penis) cannot be retracted over the glans penis. It is derived from a Greek word *"phimos"* which means "muzzle". At birth almost 96% of male newborns have phimosis which resolves over time, so that normal retractable prepuce is seen in around 50% by the end of 1st year, 90% by 3 years, and in 99% by 14 years of age.

Etiology

Phimosis can be divided into physiological and pathological (true) phimosis.

Physiological (Primary) Phimosis

During neonatal development, the inner epithelial lining of prepucial skin is attached to the underneath glans. These naturally occurring adhesions and narrow prepuce inhibits retractability of prepuce over glans leading to physiological phimosis. As the child grows, epithelial debris get formed and accumulated under the prepuce causing its separation from glans (**Fig. 3**). This along with intermittent erections of penis leads to normal retractable foreskin, over the variable period of time ranging from birth to 18 years of age or may rarely be even more. However, around 2% individuals may not achieve this normal retractability even throughout their lives.

Pathological (Secondary) Phimosis

The pathological or true phimosis is due to scarring of distal prepucial skin (**Fig. 4**). The various reasons for such scarring could be poor hygiene leading to recurrent balanitis (inflammation of glans penis) or posthitis (inflammation of prepucial skin). Even overzealous attempts of forceful retraction of prepuce in physiological phimosis may lead to microtears, bleeding, inflammation, and healing with scarring.

The incidence of pathological phimosis is around 0.4 per 1,000 boys per year, much lesser compared to physiological. Another causative factor for pathological phimosis is BXO, a penile form of lichen sclerosus et atrophicus. BXO is a chronic inflammatory condition with unknown etiology affecting skin and mucous membrane, especially prepuce, glans penis,

FIG. 3: Phimosis in a child. ***(For color version, see plate 12)***

FIG. 4: Phimosis in an adult. ***(For color version, see plate 13)***

meatus, and distal urethra, accounting for the most common cause of secondary phimosis in children.

Clinical Presentation

It is important to differentiate between physiological and pathological phimosis as the treatments for both are different.

In physiological phimosis, the child is usually brought by anxious parents but the child himself may not be having any bothersome complaints, except for nonretractability of foreskin or ballooning of foreskin during voiding. The local symptoms, such as pain, swelling, and redness are absent. Urinary flow is good. This is contrary to pathological phimosis in which child may present with preputial pain and irritation, local infections leading to swelling and redness of skin, minor bleeding and sometimes dysuria, and recurrent episodes of urinary tract infections (UTIs). The parents may notice poor urinary stream, especially in cases with associated BXO. Few grading classifications according to the severity of phimosis have been proposed by various authors (**Box 2**).

BOX 2: Grading (classification) of phimosis based on severity.

Meuli et al. grading of phimosis

Grade 1: Fully retractable prepuce and stenotic ring in the shaft

Grade 2: Partially retractable prepuce with partial exposure of the glans

Grade 3: Partially retractable prepuce with exposure of only meatus

Grade 4: No retractability

Kikiros et al. grading of phimosis

Retractability of foreskin Score:

0. Full retractability, not tight behind glans, or easy
1. Full retraction of foreskin, tight behind the glans
2. Partial exposure of glans, prepuce (not congenital adhesions) limiting factor
3. Partial retraction, meatus just visible
4. Slight retraction (neither meatus nor glans can be visible)
5. Absolutely no retraction

Appearance of foreskin Score:

0. Normal
1. Crack in prepuce, "skin-splitting" on gentle retraction
2. Small white scar, partial circumferential
3. Balanitis xerotica obliterans or severe scarring ± bleeding

Evaluation

Phimosis is a fairly obvious clinical condition, requiring no specific laboratory tests or imaging modalities for diagnosis.

History

Though usual presenting complaint is ballooning of prepuce during voiding, a detailed history of all associated symptoms is vital in ruling out the likely complications.

History should also include episodes of recurrent fever, stream of micturition, and urinary problems.

Physical Examination

In physiological phimosis, the distal prepucial skin is healthy, pliant with typical pink mucosa seen pouting or flowering on gentle traction. However, in pathological phimosis, on gentle traction, there is abnormal scarring of prepuce and a cone-shaped structure is seen with a narrow white fibrotic ring at the tip. This clinical differentiation is very vital so as to avoid anxiety in parents and unnecessary surgical procedures.

Treatment

First and foremost thing in management of phimosis is to confirm whether, it is physiological or pathological. Management depends on age of child, type and severity of phimosis, and associated complications. Once it is confirmed that the phimosis is physiological, the most important thing is to reassure parents about the normalcy of the condition. Parents should be taught about the care of foreskin.

Treatment of phimosis can be divided into nonsurgical or conservative and surgical treatment. Though traditionally circumcision is considered as the standard treatment for phimosis, many topical ointments have been tried in recent years with a good success rate. In few recent trials, it was shown that only 8–14.4% of the total referrals had actual pathological phimosis requiring surgical intervention. Rest all could be managed conservatively and thus over-referrals could have been avoided.

Topical Preparations

Various topical preparations have been tried till date in form of steroids, estrogen, and nonsteroidal anti-inflammatory drugs (NSAIDs). Among these, steroids have been most widely used and have shown more promising outcomes.

Topical Steroids

Many studies in past few decades have shown a favorable success rate of topical steroid therapy, ranging from 70% to 95%, as shown in **Box 1**. The mechanism of action of topical steroids is believed to be local anti-inflammation and immunosuppression. They also reduce the dermal synthesis

of glycosaminoglycans, epidermal proliferation and stratum corneum thickness thereby causing skin thinning. *Most commonly used preparation is betamethasone 0.05% twice daily for a period of 4 weeks*. Other concentrations of betamethasone such as 0.1% and 0.06% have also been tried with almost similar success rates. Other steroids such as clobetasol propionate, triamcinolone, mometasone dipropionate, and fluticasone showed comparable results (**Table 1**).

Very few studies have mentioned the recurrence rates because of the short follow-ups in rest of the studies. The reported recurrence rate ranges from 2 to 14%, poor compliance being the most common reason. Almost all studies, who have reported the recurrence, have observed success after retreatment for few more months with same agent, and therefore reduction in need for circumcision.

Prepucial Stretching

The nonsurgical adhesiolysis by frequent manual retractions of prepuce has found to be a safe and effective treatment option for phimosis regardless of the age of the boy. Combination of topical steroids along with stretching adds to the improvement of overall outcome.

Surgical Treatment

Circumcision

Male circumcision is one of the oldest surgical procedures known to humans. It is also one of the most commonly performed surgical procedures worldwide to the extent that approximately 37–39% of men are circumcised worldwide.

Though sometimes treatment of phimosis is as per the parent's preference, the absolute indication of circumcision is secondary phimosis. However, circumcision may be indicated in some cases of primary phimosis such as recurrent balanoposthitis and recurrent UTIs, especially in patients with urinary tract abnormalities. The contraindications for circumcision are an acute local infection and congenital anomalies of the penis, like hypospadias, where the foreskin should be preserved as it may be helpful for a future reconstruction. Following techniques are used for circumcision.

- *Circumcision using devices*: Various devices are available nowadays for circumcision. *Gomco clamp* is a 4-piece device, designed with a structure which protects the glans, provides hemostasis, and does not require any additional suturing. In this method, glans is exposed by retracting the prepuce and adhesiolysis, followed by placement of a metal bell over the glans to protect it from damage. The prepucial skin is repositioned back over the bell and circumcision is done with a scalpel. The compression by an outside ring over the bell achieves the hemostasis. *Plastibell* is a device which works on a similar principle except that instead of an outer ring, a thread is tightly tied over a plastic bell covering the prepuce which achieves hemostasis. The skin sloughs after few days and Plastibell falls off. Another device named *Mogen clamp*, is applied across the stretched prepucial skin, after ensuring that the glans is free below the clamp. The hemostasis is achieved by the compression by the V-shaped clamp. The anesthesia for all these devices is usually regional, i.e., penile block. The complications are usually because of the technical factors and include injury to glans, insufficient or excess skin removal or asymmetric redundancy of skin and sometimes bleeding due to improper clamping.

TABLE 1: Role of various topical steroid in phimosis.

Author, year	*Number*	*Topical agent*	*Duration*	*Success rate*
Wright, 1994	139	0.05% betamethasone	1–2 months	80%
Golubovic, 1996	20	0.05% betamethasone	1 month	95%
Chu, Chen, and Diau, 1999	276	0.06% betamethasone	2 weeks	95%
Monsour, 1999	25	0.05% betamethasone	1 month	95%
Orsola, Caffaratti, and Garat, 2000	137	0.05% betamethasone	1–2 months	90%
Ashfield, 2003	228	0.1% betamethasone	6 weeks	87%
Yang, 2005	70	0.06% betamethasone valerate or clobetasone butyrate 0.05%	4–8 weeks	81.3% for betamethasone and 77.4% for clobetasone
Jorgensen and Svensson, 1993	54	0.05% clobetasol propionates	1–3 months	70%
Lindhagen, 1996	30	0.05% clobetasol propionate	1–2 months	89%
Pileggi and Vicente, 2007 Double-blind study	110 (56 mometasone, 54 placebo)	0.1% mometasone furoate versus placebo	8 weeks	88% with mometasone, 52% placebo
Esposito, 2008	240	Mometasone furoate 0.1% versus placebo	4 weeks	65.8% for mometasone and 16.6% for placebo
Letendre, 2009 randomized, double-blind, placebo controlled	43	0.1% triamcinolone versus placebo	2 months	76% with triamcinolone and 39% placebo
Zavras, 2009	1,185	0.05% fluticasone propionate	1–2 months	91.1%
Muller and Muller, 1993	30	0.1% estrogen	20 days	93%
Yanagiswa, 2000	15	Estrogen	2–8 weeks	87
Atila et al., 1997	32	Diclofenac sodium	1 month	75%

- *Free-hand circumcision*: This is done in operation theatre preferably under general anesthesia or penile block and includes excision of phimotic prepuce and suturing after hemostasis.
- *Sleeve technique*: In this technique, first a circumferential incision is marked on the outer prepucial skin, equidistant from corona. The inner prepuce is separated from glans by adhesiolysis using artery forceps. The prepucial inner mucosa is separated from the skin. The foreskin is excised preserving the mucosa, and remaining prepuce closed with absorbable sutures after achieving hemostasis.
- *Dorsal-ventral slit technique*: In this type, after initial adhesiolysis, two slits are taken, one on dorsal and one on ventral aspect and then these incisions are connected circumferentially, leaving the two free-edges which are then closed with absorbable sutures.
- *Preputioplasties*: Over the years many prepuce-preserving techniques have been described in literature: V-flap, Z-flap repair, triple incision plasty, limited dorsal slit, multiple Y-V plasty, and triple T. All have claimed their technique to be a better alternative to circumcision, especially for the patients who do not want their glans exposed. However, no comparative trial has been done to recommend their routine use in clinical practice. In short, the choice of surgical procedure depends upon surgeon's expertise and patient's/parent's preference.

Complications of circumcision: As complications can happen in any surgical procedure, circumcision is no exception. In one large systematic review of complications of circumcision, Weiss et al. found that the median frequency of any adverse event and any serious adverse event was 1.5% (range 0–16%) and 0% (range 0–2%), respectively. They also found that complications occurred more frequently in circumcision for older children than in neonates and infants.

- *Early complications*: By and large the complications of circumcision procedure are usually minor and treatable such as bleeding, surgical site infection or swelling, and inadequate skin removal. Other serious early complications include excessive bleeding, chordee, iatrogenic hypospadias, necrosis of glans, and amputation of glans. The excessive bleeding during or after circumcision, requiring blood transfusion, may occur in children with bleeding disorders like hemophilia. Therefore, it is very important to ask regarding any family history of such disorders before surgery.
- *Late complications*: These include chordee, epidermal inclusion cysts, excess redundant foreskin, prepucial adhesions or skin bridges, iatrogenic hypospadias recurrent phimosis, buried penis, suture sinus tracts, urethrocutaneous fistulae, and meatal stenosis. Most of these are treatable but require an additional surgical procedure, indicating the importance of proper operative technique.

A meta-analysis to assess sexual functions following adult male circumcision has concluded that the circumcision does not have any adverse effect on sexual function or penile sensitivity when compared with uncircumcised men.

Medical benefits of circumcision: Most of the studies in literature showed that uncircumcised males were more prone to sexually transmitted diseases such as syphilis, chancroid, herpes simplex, and human papillomavirus (HPV), whereas circumcised men were more prone to urethritis. Few randomized controlled trials (RCTs) done in African patients have shown protective effects of circumcision against human immunodeficiency virus (HIV) with almost 50% risk reduction.

There is no direct causal association of phimosis with penile carcinoma. However, indirect benefit by reduction in HPV infection, which is a causative factor for penile carcinoma, may be expected. Still routine neonatal circumcision to prevent penile carcinoma is not indicated.

The protective effect of circumcision against UTIs may be seen only in cases of recurrent UTIs and children with congenital urinary tract abnormalities such as high-grade vesicoureteral reflux.

Phimosis is the nonretractability of prepuce over the glans penis. Most of the newborns have phimosis due to natural adhesions between prepuce and the glans, and this is physiological and as the child grows he achieves normal retractability over a variable period of time. Secondary phimosis is a pathological condition, which must be differentiated clinically from primary phimosis. While primary phimosis can manage conservatively or by manual stretching and topical steroids, secondary phimosis definitely requires some form of treatment mostly surgical. There are various forms of treatment options available. The topical steroid applications along with repeated manual stretching of prepuce are quite safe and have a good success rate. The absolute indication for circumcision is pathological phimosis (BXO) or sometimes primary phimosis with recurrent balanoposthitis or UTIs. Various devices are now available for circumcision with almost equal success rates as conventional free-hand circumcision and with comparable complication rates. Complications associated with circumcision procedure are usually minor and treatable. Medical benefits offered by circumcision include protection against some sexually transmitted disease including HPV, HIV, and against recurrent UTIs, especially in cases of congenital urinary tract anomalies.

PARAPHIMOSIS

Paraphimosis is a urological emergency in which foreskin is left retracted due to its entrapment behind the glans penis. This leads to strangulation of glans and lymphovascular compromise of the prepuce leading to venous engorgement, inflammation, pain, and even necrosis, further impending the reduction of foreskin.

Etiology/Causes

The cause is most often iatrogenic. It occurs when the foreskin is retracted for urethral catheterization, penile examination, or during per urethral procedure like cystoscopy or meatal dilatation. Failure to reposition the retracted foreskin back over glans results in paraphimosis. Less commonly it may be due to trauma during sexual intercourse or self-inflicted injuries.

Pathophysiology of the Condition

When retracted foreskin remains trapped behind glans penis prolonged time, the blood and lymphatic flow to and from prepuce and glans is obstructed. This leads to vascular engorgement and subsequent edema of prepuce. Paraphimosis is a urological emergency which, if left untreated, may ultimately result in glans necrosis and rarely autoamputation.

Clinical Presentation

Though paraphimosis can occur in any age group, its incidence is lesser in young children (0.2%) compared to other penile lesions such as balanitis (5.9%) and phimosis (2.6%). Most common occurrence is in adolescent males with 1% incidence in all adult males above 16 years of age. The preceding event in adults is usually a Foley catheter insertion and in children, a forceful retraction of foreskin for examination or for cleaning. Whatever may be the reason, failure to return the retracted foreskin to its normal position over the glans remains the main culprit. Patient presents with a swelling in foreskin, usually with pain. The diagnosis is often confirmed on physical examination of prepuce and the glans, both of which are markedly edematous and congested. The proximal penile shaft usually remains unremarkable. The reduction of prepucial skin becomes difficult and painful due to the swollen prepuce and constricted band of edematous tissues behind the glans (**Fig. 5**).

Evaluation

History and Physical Examination

A detail history should be taken concerning foreskin retraction, urethral instrumentation, or presence of urinary symptoms. The external genitalia should be examined in detail with a focus on the color and consistency of the glans and prepuce, the severity of constriction around the penile corona and condition of proximal penile shaft. Though glans remains pink healthy in most of the cases, long standing cases may have dark red, dusky or even black glans indicating its ischemic necrosis. The viability of glans can also be confirmed by its palpation, as normal healthy glans is soft and pliable and becomes firm and inelastic after necrosis.

Treatment

The main aim of treatment of paraphimosis is reduction of preputial and glans edema and restoration of prepuce to its original position. There are many different methods of reduction of paraphimosis as described below.

Manual Reduction

Manual reduction method may be tried in mild, early, and uncomplicated cases. Because of the pain which gets further aggravated during manipulation, it may require some form of anesthesia such as topical lignocaine gel, oral narcotics, penile nerve block, or sedation. Manual reduction is done by giving circumferential compression over edematous prepuce and glans with gloved fingers in order to disperse the edema fluid. The reduction can simply be achieved by pulling the foreskin upwards towards the phallus, while maintaining the circumferential compression. Application of ice packs may also facilitate in reducing the edema; however, some surgeons discourage this method as it may further compromise arterial inflow to the already ischemic portion of the penis. Manual compression can also be achieved by tightly wrapping a compressive elastic dressing around edematous portion of the penis from the glans towards the base for 5–10 minutes.

FIG. 5: Paraphimosis in a child. ***(For color version, see plate 13)***

Pharmacological Therapy

Another way of reducing the preputial edema is application of mannitol (20%) soaked gauze around prepuce for a period of 30–45 minutes, with or without intermittent compression. This works on the principle of transfer of edema fluid from edematous prepuce down the osmotic gradient to hypertonic mannitol, reducing the edematous swelling. In another reported technique, Eutectic Mixture of Local Anesthetic (EMLA) cream containing 2.5% lidocaine and 2.5% prilocaine is applied to the glans in a glove covering for around 30 minutes and trapped foreskin can then be reduced with gentle traction. Injection of hyaluronidase (1 mL of 150 U/cc) also helps in reducing the edema. Hyaluronidase degrades the viscous hyaluronic acid and thereby increases the dispersion of edema fluid.

Minimally Invasive Therapy

This includes the most widely practiced method of multiple puncture technique, also known as Perth–Dundee technique. In this method, multiple (approximately 20) punctures with 26-gauge needle are made in edematous prepuce and the prepuce is then compressed to express out the edema fluid. As this is a painful method, it requires some form of anesthesia usually topical or penile block. Once the edema has subsided with the help of above described methods, paraphimosis can be reduced. For this, both the thumbs are placed on glans and rest all fingers are wrapped around the trapped prepuce. A gentle steady force is applied by thumb over glans along with countertraction achieved by constant pulling of prepuce outwards back over the glans.

Surgical Treatment

Surgical intervention is required when above described methods have failed to reduce the paraphimosis. This involves longitudinal dorsal slit cutting of prepuce at 12 O'clock till constricting band site and reduction of trapped prepuce back over the glans. The cut edges are over sewn with absorbable suture without approximating them. Circumcision is usually the last resort done reserved for recurrent episodes.

Paraphimosis is a urological emergency in which foreskin is left retracted due to its entrapment behind the glans penis causing inflammation, strangulation of glans. It usually occurs after failure of prompt repositioning of foreskin after its retraction. Urgent medical attention is necessary to avoid further damage which may even cause ischemic necrosis of glans in long-standing cases. Paraphimosis can occur in any age group. The diagnosis is clinical, no tests are required. The treatment options include manual reduction,

compression dressing, multiple puncture technique, dorsal slit and lastly circumcision. Patients should be taught regarding the reduction of foreskin every time it is retracted.

PENILE FRACTURE

Penile fracture is defined as disruption of the tunica albuginea with rupture of the corpus cavernosum secondary to trauma to penis in tumescent state. Penile fracture usually occurs during vigorous sexual intercourse or an aggressive manipulation of penis in an erect state. This is a urological malignancy and the rupture may extend to involve corpus spongiosum and urethra. The first case of penile fracture was reported by an Arab physician, Abu al-Qasim al-Zahrawi in Cordoba, more than 1,000 years ago.

Epidemiology

The incidence of penile fracture varies among different geographical areas, with higher incidence in Middle East and African regions compared to Western countries or Asian continent. The incidence of penile fracture is under reported as patients avoid to seek medical attention due to embarrassment. The reported incidence is around 1 in 175,000. The age distribution also varies in different geographical areas with mean age in Africans 26.4 years, in Asians 33.7 years, in Europeans 38.7 years, and in North Americans 37.6 years with a range of 12–82 years.

Etiology/Causes

Overall, the most common cause of penile fracture is the blunt trauma during a vigorous sexual intercourse, when the erect penis slips out of the vagina and hits the perineum or pubic bone, giving rise to a buckling injury. Again, causative factors differ according to the region. Trauma during sexual intercourse is more common cause in Western countries while in Middle East countries common causes include penile manipulations including kneading during masturbation, forceful bending of a tumescent penis during masturbation in order to achieve sudden detumescence known as "Taghaandan maneuver", or even tucking the erect penis into underwear. Taghaandan maneuver alone is responsible for >50% of cases in Middle East countries, while it accounts for only 8% of cases in Western population. Other reported causes are fall from bed during sleep on an erect penis, roll over injury during nocturnal tumescence, sudden change of position by female partner while an erect penis is still inside vagina causing its acute bend. "Woman on top" or reverse coitus is reported to be the riskiest position causing fracture penis.

Pathophysiology of the Condition

Tunica albuginea is a bilaminar structure covering both the corpora cavernosa. In flaccid state, the thickness of tunica albuginea is 2 mm, which decreases to 0.25–0.5 mm in tumescent state. It also has a high tensile strength which can resist intracavernous pressures up to 1,500 mm Hg. However, when erect penis is bent abnormally, there is sudden rise in intracavernosal pressure exceeding the tensile strength of the tunica albuginea. This leads to rupture of already thinned tunica, most commonly at ventrolateral aspect which is the thinnest part of tunica albuginea. The rupture of tunica albuginea is usually unilateral and transverse, involves overlying corpus cavernosum and may extend to corpus spongiosum and urethra. After penile fracture, penis becomes detumescent suddenly and a local hematoma develops over penile shaft confined by Buck's fascia. When Buck's fascia is disrupted, this hematoma may spread to the scrotum, perineum, and suprapubic region.

Clinical Presentation

Patient typically presents with a history of a cracking or popping sound in erect penis followed by immediate detumescence and development of pain and swelling in penis. Blood at tip of meatus, hematuria, and acute urinary retention give the hint of associated urethral rupture. Urethral injury incidence also varies region to region, with United States and Europe (20%) having higher incidence compared to Middle East and Asia (3%), may be related to the cause of trauma (intercourse related versus self-inflicted). Due to embarrassment, patients usually do not present to emergency room or present very late.

Evaluation

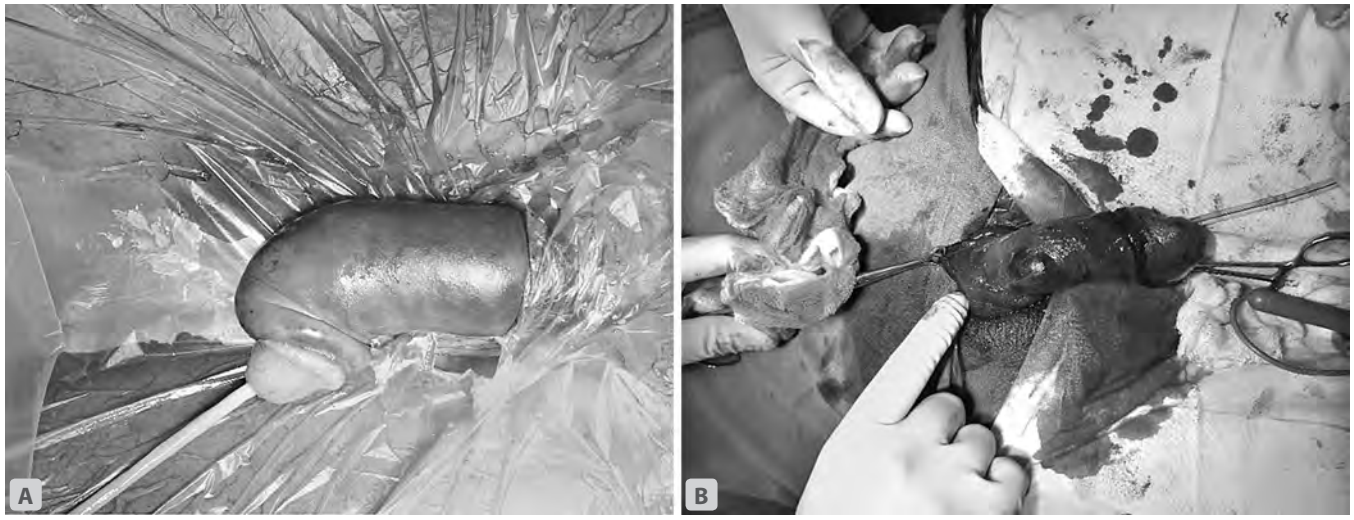
History and Physical Examination

Diagnosis of penile fracture is a clinical one with history and physical examination playing important role in establishing it. In history, one should ask regarding the time and type of trauma, presence of sudden detumescence, and presence of blood at tip of meatus, hematuria or any voiding disturbance.

On inspection, the most common finding is presence of penile swelling due to *penile hematoma*, bruising and deviation to one side, giving *an "eggplant" appearance, also* known as *"aubergine sign"* (**Figs. 6A** and **B**). The deviation of swollen penis is opposite to the side of tear, because of the mass effect of hematoma. This defect can sometimes be palpable with a blood clot over it and can be rolled under the fingers—known as *"rolling sign"*. A butterfly hematoma in perineum suggests rupture of Buck's fascia or associated urethral injury. Rest physical examination remains unremarkable. Patients late after trauma usually have present with erectile dysfunction, penile curvature, palpable plaques like Peyronie's disease and rarely urethrocutaneous or urethrocavernous fistula. Differential diagnoses include rupture of penile vessels (superficial or deep dorsal vein, dorsal or deep cavernous artery), lymphangitis of penis and Mondor's disease.

Investigations

Though the diagnosis of penile fracture is made clinically, few radiological investigations help in confirmation of diagnosis, to locate the exact site of tear and to diagnose-associated complications. Penile ultrasound is the preferred modality as it is readily available in emergency, cheap, noninvasive, and useful in locating exact site of tear and in ruling out fracture in suspicious cases. In case of clinical suspicion of urethral injury, retrograde urethrography can be done before surgery. However, because of possibility of inaccuracy and its time-consuming nature, on table flexible cystoscopy just before catheter placement is preferable. Magnetic resonance imaging and cavernosography are not routinely used because of the high expenses, limited availability, and time-consuming nature.



FIGS. 6A AND B: Examination of penile fracture. (A) Eggplant appearance of penile fracture; (B) Hematoma on ventrolateral aspect. ***(For color version, see plate 13)***

Treatment

Treatment can be conservative or surgical. Conservative approach may be advocated in cases of intact tunica on imaging but strong clinical suspicion. It includes cold fomentation, anti-inflammatory agents, fibrinolytics (trypsin and streptokinase), and antiandrogens (like stilboestrol, to prevent erections). However, conservative approach is not recommended because of the long-term complications such as corporeal fibrosis, delayed chordee with resultant shaft deformation (in up to 16% of cases), and plaque formation (in up to 50% of cases). Many studies and reviews of literature have shown that prompt surgical is associated with fewer complications and better long-term results in terms of erectile function compared to conservative treatment.

Surgical Approach/Surgical Repair

The most common and preferred approach is subcoronal circumferential incision with degloving of penis. Apart from being cosmetic, this allows surgeon for complete inspection of corpora and helps in identifying extra, small corporal, and urethral tears. Other reported incisions are longitudinal incision directly over the site of tear, inguinoscrotal and high scrotal midline raphe, though experiences with last two incisions are limited. The choice of incision is operator dependent.

Technique

Many surgical approaches have been described in literature. However, the surgical principles remain more or less universal, which includes identification and evacuation of hematoma and ligation of torn vessels, debridement of devitalized tissue, and repair of lacerations of the tunica albuginea (**Figs. 7A** and **B**). Though debridement of lacerated tissue is important, care must be taken to avoid excessive debridement of delicate and normal erectile tissue. Tunica tears are usually transverse and located ventrolateral where the tunica is thinnest, however laceration can occur at any site. Small or nonapparent tears can be localized by intracorporeal injection of normal saline and thereby inducing artificial penile erection (also known as Gittes test). This test also helps in confirming the integrity of repair.

Suture Material

Intermittent or continuous repair with absorbable sutures (2-0 or 3-0) is recommended by most of the surgeons worldwide. Though repair with nonabsorbable sutures provide equally good results, it may result in painful palpable knots. This problem can be solved by taking inverted knots.

Urethral Injury Repair

In cases of clinically suspected urethral injury, retrograde urethrography, ultrasonography, or preferably flexible urethroscopy should be done. However, in many cases (almost 50%) urethral injury can be clinically nonevident and be found intraoperatively. Partial urethral tears can be over sewn with fine absorbable sutures over a urethral catheter. Complete urethral disruption requires proper debridement, mobilization, and tension-free repair over a Foley catheter.

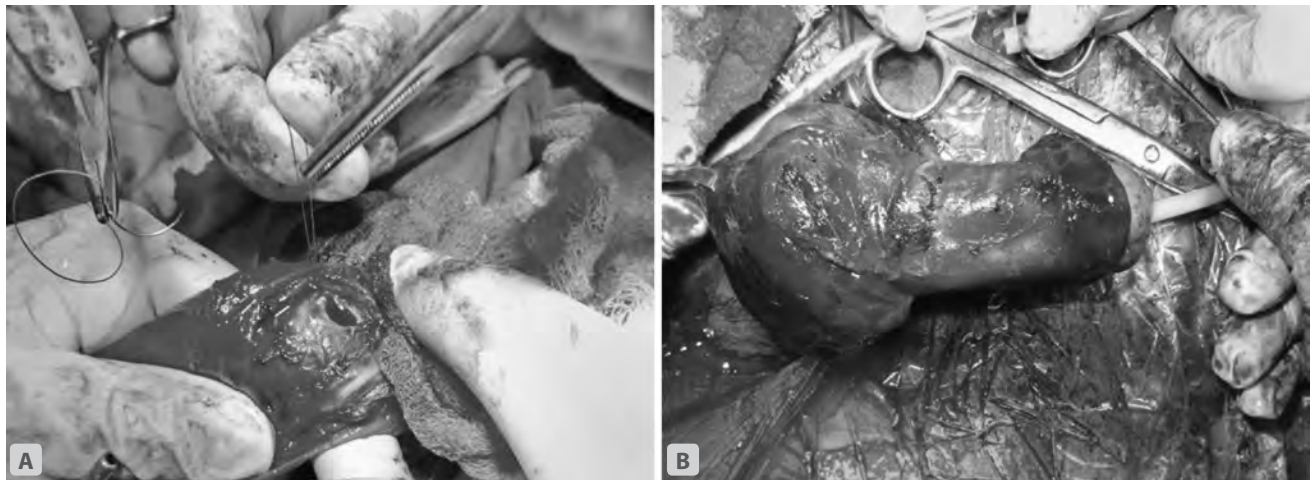
Timing of Surgical Repair

It has been shown in some of the reports and reviews from the literature that prompt repair is associated with good functional results compared to delayed repairs. However, timing of repair does not significantly affect rates of erectile dysfunction and penile plaque formation. Therefore, cases presenting even after few days should not be denied for surgical repair as they can have a good functional results in long-term. The dressing should be loose so that glans can be checked for early ischemic color changes. Patient should be instructed to avoid sexual activity for a period of 4–6 weeks to allow complete healing of the repair. A patient should be educated about the predisposing factors so to avoid recurrence. He should be instructed to avoid vigorous sexual intercourse, aggressive sudden penile manipulations, and unusual positions of intercourse like reverse coitus.

Complications

Long-term complication rates after a surgical repair are not very high. Reported complications include penile deviation due to fibrosis, skin necrosis, painful erections, and rarely erectile dysfunction.

Penile fracture is rupture of tunica albuginea due to trauma to penis in a tumescent state. Common causes vary geographically and include aggressive sexual intercourse,



FIGS. 7A AND B: Surgical correction of penile fracture. (A) Closure of tunica tear in process; (B) After completion of closure. ***(For color version, see plate 13)***

forceful penile manipulations, fall from bed, or roll over injury during nocturnal tumescence. Though the diagnosis is clinical imaging like ultrasound gives better idea on the number and site of tunica tear. Once diagnosis is confirmed, patient should be offered surgical repair at earliest and patients presenting even after few days should also be treated in same way. Surgical principles include evacuation of hematoma, identification and repair of tunica tear with running or interrupted absorbable sutures, and repair of associated urethral injury. Long-term results are better in surgical repair group compared to conservative. However, no significant difference in erectile function could be found in early versus delayed treatment. So all patients should be offered surgical management, irrespective of time between fracture of penis and presentation to hospital. Reported long-term complications include penile curvature, skin necrosis, painful erections, and rarely erectile dysfunction.

SUMMARY

As an organ of central importance to both the urologic and reproductive systems, penile emergencies have the potential to lead to significant morbidity for patients. Although there is generally considered to be a defined set of pathologies affecting the penis in the acute setting, recognition and prompt diagnosis of these conditions often can be challenging for clinicians. Because of the organ's anatomy and physiology, failure or even moderate delays in identifying these acute conditions may result in permanent dysfunction and morbidity. In the broadest sense, penile emergencies can fall into one of two major categories: Physiologic (relating to the venous outflow) or anatomic (relating to pathologies of the organ's complex tissue structure). Specific disease states include priapism, penile calciphylaxis, paraphimosis, phimosis, balanitis, posthitis, Peyronie's disease, and penile tourniquet syndrome.

Penile emergencies most commonly result from pathologic processes related to the unique anatomic structure and physiologic function of the organ. As the organ itself is essential for excretory and reproductive function, its pathologies can lead to devastating morbidity and in some cases mortality. Even with prompt diagnosis and treatment, penile emergencies can lead to permanent organ dysfunction. Prompt diagnosis, management, and urologic consultation are essential for having the best chance of minimizing sequela of these conditions.

114
CHAPTER

Acute Scrotal Emergencies

Devendra Richhariya

INTRODUCTION

Scrotal emergencies, however uncommon, can be life and fertility threatening. Testicular torsion, Fournier gangrene, and scrotal trauma are all considered emergent urologic conditions. These conditions need to be separated from the wide differential diagnoses presenting as acute scrotal pain to the emergency department. Diagnosis of testicular torsion is time sensitive. Testicular torsion has a >90% salvage rate if surgery is performed within the first 6 hours of symptom onset. After 6 hours, there is a time-dependent increase in the rate of testicular atrophy and orchiectomy. It is important to establish the diagnosis early and advocate for definitive management with urology colleagues.

ANATOMY

Knowledge of the relevant anatomy is important to understand the differential diagnosis and subsequent steps in the evaluation (**Fig. 1**). The testes are ovoid-shaped organs roughly 3–5 cm and vertically-oriented. The tunica albuginea covers them with continuous internal septations converging into a mediastinum tests which acts as the structural support for the organ. This, in turn, is enveloped by the tunica vaginalis. Epididymis is a curved structure roughly 6–7 cm in its longest dimension and posterolateral to the testis. The efferent ductules converge to form the ductus epididymis and eventually the vas deferens.

The vascular anatomy of the scrotal contents is also important to know. The testes receive a supply of blood from the testicular artery, deferential artery, and the cremasteric artery. Deferential artery and the cremasteric artery are branches of the inferior vesical and inferior epigastric artery, the testicular artery branches directly from the abdominal aorta. The testes are drained into the testicular vein via the pampiniform plexus. The testicular vein drains directly into the inferior vena cava on the right while it drains into the left renal vein on left. The vascular structures, vas deferens, and nerves are all encased within the spermatic cord, a conduit allowing passage from the peritoneum to the scrotum through the inguinal canal. The cremaster muscle is also found within the spermatic cord. Only small part of the testis and epididymis is surrounded by the tunica vaginalis and then attaches posteriorly to the scrotal wall. Here one should be aware about the congenital deformity known as the bell clapper deformity (incidence 12%) in which tunica vaginally surrounds the testis and part of the spermatic cord; the testicle is failed to fixed with the scrotal wall and able to twist freely and prone for the torsion (**Fig. 2**).

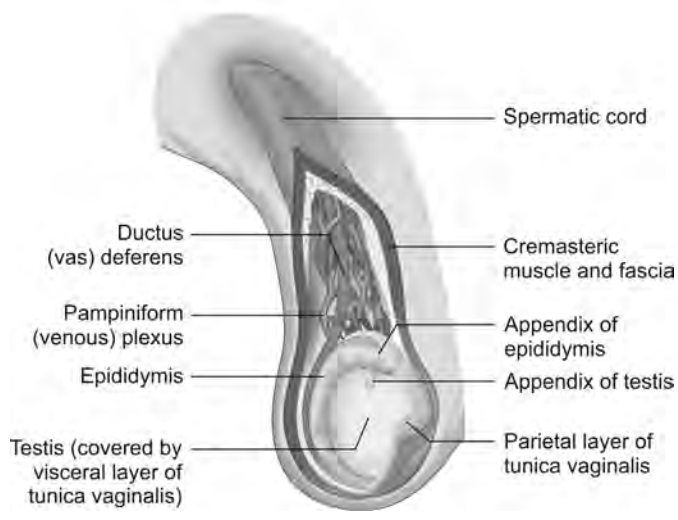

FIG. 1: Anatomy of scrotum.

ETIOLOGY OF ACUTE SCROTUM

An acute scrotum is defined as acute pain of the scrotum. Pain is typically accompanied by local signs, such as swelling or tenderness, and/or generalized symptoms, such as vomiting or fever. There is a large differential diagnosis for acute scrotal pain. True emergencies should be separated from urgencies. True urologic emergencies include testicular torsion, Fournier gangrene, and testicular trauma. Other abdominal emergencies to keep in mind that may present as scrotal pain include, but are not limited to, an incarcerated inguinal hernia, appendicitis, or referred pain from an abdominal aortic aneurysm. Torsion should be differentiated from appendage torsion and epididymitis, whereas Fournier gangrene should be ruled out in infectious presentations of scrotal pain, including scrotal cellulitis and scrotal abscesses. In the setting of trauma, it is important to identify penetrating trauma and

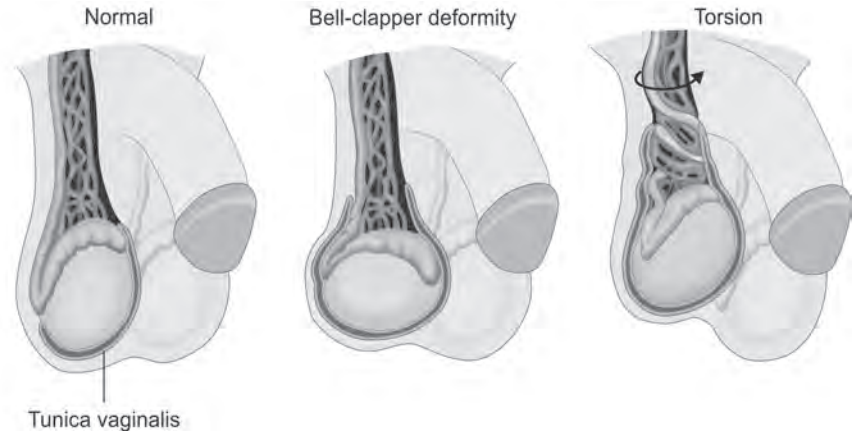

FIG. 2: Demonstration of normal testis, bell clapper deformity, and testicular torsion.

TABLE 1: Differential diagnoses for acute scrotal pain.	
Ischemic	Testicular torsion, torsion of the testicular appendage
Infectious	Epididymitis, epididymo-orchitis, orchitis, scrotal cellulitis, scrotal abscess, Fournier gangrene, Hansen disease, and filariasis
Traumatic	*Blunt*: Testicular contusion, testicular rupture, penetrating, testicular rupture, hematocele, and scrotal DE gloving
Inflammatory	Henoch–Schönlein purpura
Idiopathic	Idiopathic scrotal swelling
Oncologic	Testicular tumors
Other	Strangulated/incarcerated inguinal hernia, referred pain from abdominal pathology, for example, ruptured abdominal aortic aneurysm or nephrolithiasis

testicular rupture from simple testicular contusions. **Table 1** summarizes the list of the differential diagnoses for acute scrotal pain.

The presentation of an acute scrotum can be broken down into four subcategories: *The painful swollen testicle, the painless swollen testicle, the erythematous testicle, and the traumatic testicle.* Within each of these groups there is a diagnosis that cannot be missed. However, not all scrotal emergencies present with pain in the genital area. It is important to rule out scrotal emergencies in patients presenting with lower abdominal pain.

PAINFUL SCROTUM

Testicular Torsion

Testicular torsion occurs when the spermatic cord twists causing venous congestion, decreased arterial blood flow and eventually ischemia of the testicle. *There are two types of torsion: extravaginal and intravaginal*. Extravaginal torsion occurs in the perinatal period, it occurs with twisting of the entire tunica vaginalis. It may present as a vanishing testicle or painless swollen hemiscrotum. Intravaginal torsion is the twisting inside the tunica vaginalis, occasionally as the result of a *congenital bell clapper deformity***.** The deformity occurs when the testicle is not fully fused to the posterior scrotal wall. This results in the testicle being suspended horizontally, which predisposes it to torsion. This deformity is estimated to be present in approximately 12% of men. Testicular torsion can occur at any age, although it is most common at two peaks in life: During the first year of life and around puberty (12–18 years old). Testicular torsion generally presents as acute onset scrotal pain with associated nausea or vomiting. It can occur after minor trauma or during periods of testicular growth (i.e., puberty); however, it usually occurs in the absence of a preceding event. It is important to keep in mind that intermittent torsion may also precede complete torsion. Testicular torsion can often be hard to differentiate from appendage torsion and epididymitis. There are two features of the clinical history that have been shown to increase the likelihood of diagnosis. Presence of nausea and/or vomiting and <24 hours since the onset of pain have both been proven to be associated with testicular torsion more often than the latter diagnosis. One study demonstrated that, in patients with acute scrotal pain from testicular torsion, the presence of nausea and vomiting had a specificity of 93% and a sensitivity of 69%. Thus, in the setting of acute scrotal pain, systemic symptoms of nausea and vomiting make testicular torsion more likely.

In all cases of scrotal pain or lower abdominal pain in boys or men, a thorough genitourinary examination should be performed to assess for scrotal swelling, tenderness to palpation, location of tenderness, vascular swelling, discoloration, erythema, drainage, or warmth.

There are several *physical examination findings* that increase the likelihood of testicular torsion being the source of the painful scrotum. Multiple studies found that *abnormal cremasteric reflex and high position of the testicle* were more commonly found in patients with testicular torsion. The cremasteric reflex is defined as ipsilateral elevation of the testicle after stroking of the medial thigh. If absent, torsion may be more likely; however, if present, this by no means rules out torsion. The reflex can be absent in a significant percentage of normal men, as well as in those with upper and lower motor neuron disorders, spinal cord injuries, or nerve injuries after hernia repair. Absence of the cremasteric reflex has been shown to have a negative predictive value of 98%, meaning if the reflex is present, torsion is less likely. Another helpful physical examination finding *is anterior rotation of the epididymis*, which was found to have a 98% specificity in testicular torsion. Elevation of the testicle and transverse location of the testicle also had high negative predictive values of 95%.

When testicular torsion is suspected, a *wide-based gait* may be seen, because patients try to avoid leg contact with the tender scrotum. In perinatal torsion, it is possible that the contralateral side may also be torsed, without evidence or abnormal findings on clinical examination. Combination of history and physical examination can help narrow the diagnosis as well as differentiate between testicular torsion, torsion appendage, and epididymitis.

Appendage torsion: On examination, isolated superior pole tenderness has a strong correlation with torsion of the testicular appendage. Patients may also have the blue dot sign, which is visualization of the infarcted appendage through the scrotal skin appearing as a blue dot. This sign is pathognomonic for appendage torsion. **Table 2** presents comparison with testicular torsion and epididymitis.

Appendage Torsion

Appendage torsion, although not a scrotal emergency in itself, must be differentiated from testicular torsion. Appendage torsion is the twisting of a testicular or epididymal appendage, which is an embryologic remnant of the Müllerian ducts. Appendage torsion is usually seen in prepubertal boys 7–12 years old. Onset is acute to subacute. It is often difficult to differentiate appendage torsion from testicular torsion based on history because both groups may have acute onset testicular pain and swelling. However, patients with appendage torsion are less likely to have systemic symptoms, including nausea or vomiting (**Fig. 3**).

Epididymitis and Orchitis

Like appendage torsion, epididymitis and orchitis may present similarly to testicular torsion. Epididymitis and orchitis are inflammation of the structures within the scrotum. Epididymitis is inflammation of the epididymis, whereas orchitis involves the testicle. The most common cause of both is bacterial infection. The cause is generally broken down based on age group. In infants, epididymitis may be caused by sterile urine reflux secondary to a congenital anomaly. In children, a postviral infectious phenomenon is the most likely cause of the inflammation. Therefore, a careful history reviewing recent viral illness is important. In young boys under the age of 14 years, it is rare to have a bacterial cause. In young men under 35 years, the cause is most commonly sexually transmitted infection or complications from a sexually transmitted infection. In men over the age of 35 years, it is more commonly associated with benign prostatic hyperplasia. In the population of men who have sex with men, it is also important to consider *Escherichia coli* or fungal infections. Epididymitis may present with hemiscrotum pain and swelling, similar to testicular torsion or appendage torsion. It may also present with associated symptoms of abdominal pain, nausea, or vomiting. However, epididymitis, unlike testicular or appendage torsion, is more likely to present with dysuria and micturition complaints. Isolated orchitis is rare; it typically presents as a progression of epididymitis. When isolated, it is usually a result of a systemic viral infection (i.e., Coxsackievirus, Epstein–Barr virus, varicella, or echovirus). Mumps is the most common viral cause of orchitis. When the scrotum is involved, mumps presents as initial unilateral testicular involvement that later progresses to bilateral after 1–9 days. When the causative organism is bacterial, it is almost always epididymo-orchitis. Immunocompromised patients are also at risk of fungal infections.

On normal physical examination, the epididymis is found at the posterior-lateral aspect of the testicle. When palpated it feels soft and fleshy, similar to an earlobe. In epididymitis, the epididymis may be tender on palpation. Patients may not have testicular tenderness. The provider should also check for *Prehn sign*, which is relief of pain in the lateral recumbent position or with scrotal elevation. If orchitis is present, patients will have more testicular involvement, with increased testicular swelling and tenderness. Testicles should have a normal position in both disease processes (*see* **Table 2** for comparison with testicular torsion and appendage torsion).

Inguinal Hernia

In the differential diagnosis of painful scrotal swelling, it is important to consider an inguinal hernia. Inguinal hernias will not be elaborated further. It is mentioned here as a reminder

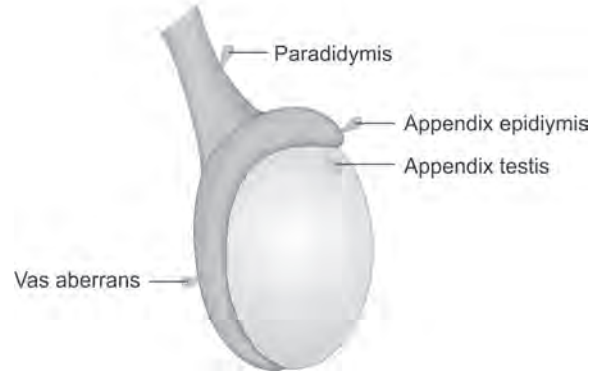

FIG. 3: Position of testicular appendage.

TABLE 2: Comparing testicular torsion, epididymitis, and appendage torsion.

History	*Testicular torsion*	*Epididymitis*	*Appendage torsion*
Age	Neonates and adolescents	Adolescents and young adults	Prepubertal
Pain onset	Acute	Gradual progressive	Acute to subacute
Associated symptoms	Nausea and vomiting	Dysuria	
Physical examination		Fever	
Cremasteric reflex	Absent	Present/absent	Present/absent
Testicles	Testicular swelling, progressive to diffuse hemiscrotal involvement, high riding, and transverse alignment	Epididymal swelling progressing to diffuse hemiscrotal involvement; normal position	Head of the affected testicle or epididymis; normal position

that the presentation of acute scrotal pain and swelling can be caused by pathologic conditions of the abdomen.

PAINLESS SWOLLEN SCROTUM

Hydrocele, Varicocele, and Spermatocele

Hydrocele is an accumulation of fluid around the testicle. It is the most common cause of painless scrotal swelling in children. The swelling is often more prominent while awake, standing, or crying. A varicocele is another cause of painless scrotal swelling. It most commonly occurs during puberty and on the left side due to a difference in venous drainage. A varicocele occurs when venous return from the scrotum is altered causing dilation of the spermatic cord veins, also known as the pampiniform plexus. Finally, a spermatocele can also cause painless testicular swelling. This occurs when a sperm-filled cyst arises in the epididymis.

On physical examination, hydrocele may be more prominent while awake, standing, or crying. It presents as posterior swelling behind the testicle. An otoscope can be used to shine light through the scrotal wall. A fluid-filled scrotum will allow light to shine through, whereas a thickened scrotal wall or enlarged testicle will not transilluminate. Varicoceles are often palpable on the posterior superior portion of the testes; often described as a "bag of worms". Finally, a spermatocele may feel like a painless cyst on the testicle. All painless masses should be differentiated from testicular malignancy.

Testicular Malignancy

Testicular malignancy is another cause of painless testicular swelling. However, this may be more easily distinguished from the above diagnoses on physical examination. It usually presents as an asymptomatic testicular mass. However, in rare cases, a mass may present with pain caused by acute bleeding within a tumor. Testicular malignancy generally presents as a firm nontender mass on examination.

ERYTHEMATOUS SCROTUM

Idiopathic Scrotal Edema

Idiopathic scrotal edema is a rare, self-limiting cause of an acute scrotum. It occurs between the ages of 3 and 9 years. It is defined as swelling of the scrotal skin without swelling of the deeper tissues. It is an important diagnosis to be aware of, because it needs to be differentiated from more malignant causes of scrotal edema and pain. Idiopathic scrotal edema generally presents as unilateral or bilateral scrotal swelling, erythema, and pain. It should be differentiated from scrotal abscess and deeper infections.

Scrotal Abscess and Fournier Gangrene

Scrotal infections can range from mild cellulitis to a surgical emergency, such as Fournier gangrene. Patients can develop superficial or deep infections. A scrotal abscess and cellulitis are examples of superficial infections. Scrotal abscesses are derived from simple hair follicles and only involve the scrotal wall. Deep infections involve deeper structures, such as the testes or epididymis. Fournier gangrene is a rapidly progressive polymicrobial necrotizing fasciitis of the perineal, perianal, or genital areas. Immunocompromised patients, particularly patients with a history of diabetes or alcohol abuse, are at higher risk for acquiring Fournier gangrene. The most important predictors of mortality are age >60 years or complications during treatment, such as need for mechanical ventilation or red blood cell transfusion.

Differentiating a scrotal abscess or cellulitis from Fournier gangrene may be difficult on first visualization. Patients may have overlying erythema or swelling. Crepitus and ecchymosis are common features in Fournier gangrene. Patients may also present with purulent discharge from the perineum or with fever. It is important to remember that fever may not always be present.

TRAUMATIC SCROTUM

Testicular Trauma

Isolated urologic trauma is relatively uncommon. It is more commonly found in patients with multiple traumatic injuries. Approximately 10% of all abdominal traumas also have a genitourinary injury. Traumatic injuries to the scrotum include blunt injuries, penetrating injuries, burns, bites, and scrotal avulsions. Blunt traumatic injuries may include scrotal hematoma, hematocele, testicular contusion, and complete testicular rupture. Scrotal hematocele occurs when the tunica vaginalis fills with blood, whereas disruption of the tunica albuginea is considered to be a ruptured testicle. Testicular rupture and penetrating injuries are true scrotal emergencies requiring surgical management. Testicular trauma commonly occurs playing sports or during motor vehicle accidents. Injury is more likely in motor vehicle accidents involving two-wheeled vehicles. Testicular dislocation is rare, but may occur with straddle injuries associated with motorcycle accidents. Half of all blunt testicular injuries occur while playing sports. Patients may present several days after blunt injury with symptoms similar to epididymitis. Traumatic epididymitis is a self-limiting inflammatory reaction after blunt trauma. Strangulation injuries, that is, entrapment in a zipper, are another source of testicular trauma. Zipper injuries more often occur in "impatient boys or intoxicated men". String, hair, or rubber bands can also cause strangulation injuries. In these cases, keeping child abuse on the differential is recommended. Scrotal trauma often presents with scrotal pain and swelling.

On examination patients may have scrotal discoloration or a tender, firm scrotal mass that fails to transilluminate. This could indicate a hematocele. An empty hemiscrotum in the setting of trauma is suggestive of testicular dislocation. In a patient with scrotal trauma, external signs may not correlate with internal injury. There should be high suspicion of testicular injury with any open wounds to the scrotum.

DIAGNOSIS

Aside from clinical diagnosis, ultrasonography is the diagnostic modality of choice for the presentation of acute scrotal pain. In general, ultrasonography is performed by a radiologist or ultrasonography technician; however, bedside ultrasonography by an emergency physician can also aid in diagnosis. Emergency physicians can accurately diagnose patients presenting with acute scrotal pain using bedside ultrasonography (**Box 1**). Ultrasonography is the diagnostic modality of choice when evaluating a painful scrotum. In

BOX 1: Bedside ultrasonography of the scrotum.

Positioning the patient: Use a sheet or towel under the scrotum to support the testicles. Have the patient hold the penis or position it superior laterally. Cover the penis for more privacy

Transducer: Use a linear high-frequency 6- to 15-MHz probe. Start the examination by asking where it hurts:

- First obtain a midline transverse view with both testicles, also known as the saddle view, with the indicator to the right of the patient. Look for decreased flow in the symptomatic testicle compared with the asymptomatic side:
  - Take transverse static color Doppler images of both testicles
  - Take a color Doppler clip to demonstrate flow
- Scan each testicle in the long axis (longitudinal plane) with the indicator to the head of the patient. The epididymis should be on the left of the screen and the testicle on the right
- Rotate the probe 90° with the indicator to the right of the patient for the transverse plane. Scan through the entire testicle. Make sure to scan both testicles
- Scan the spermatic cord in the longitudinal plane. Follow the cord from the testicle to the inguinal canal. Image the spermatic cord in the longitudinal and transverse planes; again, repeating on both sides. Look for the whirlpool or snail sign

TABLE 3: Testicular Workup for Ischemia and Suspected Torsion (TWIST) score.

History and physical presentation	*Points*
Testicular swelling	2
Hard testicle	2
Absent cremasteric reflex	1
Nausea or vomiting	1
High-riding testicle	1
High risk—7 points. 100% sensitive and specific for testicular torsion	

TABLE 4: Scrotal ultrasonography findings.

Scrotal conditions	*Ultrasonographic findings*
Testicular torsion	Absent or decreased flow in testicle, kink in spermatic cord (whirlpool, snail, or spiral sign)
Appendage torsion	Normal flow of the testicle with a hyperechoic area near the superior pole
Epididymitis	Increased or normal blood flow of testicle, sometimes a reactive hydrocele, enlarged epididymis with increased flow
Scrotal edema	Thickening of the scrotal wall, hypervascularity of the scrotum with normal appearance of the testicle and epididymis, i.e., Fountain sign
Fournier gangrene	Multiple echogenic foci (representing gas) with areas of dirty shadowing may be identified within the scrotal wall
Varicocele	Single vein diameter above 3 mm and/or >1 mm increase in diameter during the Valsalva maneuver or prominence of venous plexus
Hydrocele	Fluid collection separating the two layers of the tunica vaginalis
Testicular fracture	Hypoechoic, linear stripe without disruption of the tunica albuginea
Testicular rupture	Disruption of the homogeneous echogenic tunica albuginea

general, laboratory work and urinalysis are not helpful in the diagnosis of testicular torsion but may help with ruling in epididymitis. Ultrasonography findings consistent with testicular torsion include absent or diminished intratesticular blood flow in the symptomatic testicle when compared with the asymptomatic testicle, or evidence of spermatic cord torsion with a *"whirlpool or snail sign"*. Comparison of flow between both testicles is an important step in assessing for torsion. Imaging the spermatic cord to find a kink in the cord is more sensitive than color Doppler alone in adults and children.

More recently, researchers have been looking at a clinical scoring system to help diagnosis of testicular torsion. The Testicular Workup for Ischemia and Suspected Torsion (TWIST) score (**Table 3**) may help guide younger clinicians to the diagnosis of testicular torsion. In a validation study using the TWIST score among pediatric emergency physicians, a high TWIST score of 7 had a 100% specificity and 100% positive predictive value for testicular torsion.

Epididymitis and appendage torsion may be hard to differentiate on ultrasonography. Epididymitis generally appears with increased or normal color Doppler flow with an enlarged epididymis and sometimes a reactive hydrocele. Appendage torsion will appear to have normal flow, with an area of hyperechoic material near the superior portion of the testicle. Urinalysis may show pyuria in the setting of epididymitis.

The diagnosis of Fournier gangrene is primarily clinical. However, advanced imaging can be helpful if the diagnosis is not clear clinically. A computed tomography (CT) scan can play an important role in evaluating the extent of disease for surgical planning. CT findings may include fascial thickening, fluid collections, fat stranding, or subcutaneous emphysema. Ultrasonography may also be used in the early diagnosis of Fournier gangrene. On gray-scale ultrasonogram, the scrotal wall appears with multiple echogenic foci and areas of shadowing representing gas. Differentiating painless scrotal swelling is primarily clinical. However, ultrasonography can help confirm the diagnosis by identifying fluid-filled, vascular, or solid structures (**Table 4**).

TREATMENT

Painful Scrotum

As mentioned earlier in this chapter, testicular torsion is time sensitive. Manual detorsion can be attempted before surgical intervention but should not delay surgical intervention. *Trials of manual detorsion* have been found to decrease ischemia time. Even if the testicle is manually detorsed, surgery is still required. Surgical exploration is the definitive management for testicular torsion. Before performing manual detorsion, it must

be explained that the procedure is painful but, if successful, it will alleviate the pain. Analgesic medication, local analgesia injection (i.e., local lidocaine), or procedural sedation should be administered. Stand at the foot of the bed or to the right of the patient. Holding the testicle between the thumb and index finger, rotate it in an outward direction (like opening a book) from medial to lateral. The initial attempt should be with one and a half full rotations (540°). Relief of pain is a positive endpoint. You can also reassess with bedside ultrasonography. If the pain worsened with detorsion in the medial to lateral rotation, detorse in the lateral to medial direction, because a third of testicular torsions occur with medial-to-lateral rotation. After manual detorsion, patients still require emergent surgical intervention. The urologist will expose the scrotum in the operating room and examine the testicle for viability after detorsion of the spermatic cord. If viable, the testicle is sutured into the inner scrotal lining (also known as an orchiopexy). The noninvolved testicle is also sutured into the lining to prevent torsion. If the testicle is found to be nonviable, the patient will undergo unilateral orchiectomy.

Epididymitis treatment is based on age at presentation. For patients under the age of 14 years, treatment varies. If urine cultures are positive, some clinicians cover for urinary bacteria, whereas others conservatively manage without antibiotics. There should be follow-up with a pediatric urologist for evaluation of congenital genitourinary anomalies. For sexually active patients over the age of 14 years and younger than 35 years, antibiotics are the mainstay of therapy. The preferred treatment is ceftriaxone 250 mg intramuscularly plus doxycycline 100 mg daily for 10 days. If the patient practices anal penetration, use fluoroquinolone instead of doxycycline. The Centers for Disease Control and Prevention suggest levofloxacin 500 mg daily for 10 days or ofloxacin 300 mg twice daily for 10 days. For patients >35 years of age, single coverage with fluoroquinolone is appropriate. Adjuvants, including bed rest, ice, scrotal elevation, and nonsteroidal anti-inflammatory drugs (NSAIDs), can be helpful for symptom relief. Treatment of epididymo-orchitis is the same as described above. Isolated orchitis management is determined by the cause of the orchitis. If the patient seems to be suffering from toxicity, they may require admission; otherwise patients can have urologic follow-up in 5–7 days. Finally, management of appendage torsion solely consists of symptom relief. The same adjuvants used to treat epididymitis can be used with appendage torsion. The pain usually resides when the appendage degenerates in 1–2 weeks. It can recur depending on the number of appendages and their positions.

Painless Scrotal Swelling

After diagnosis of a hydrocele, varicocele, or spermatocele, the management is primarily with nonemergent urologic follow-up. With pediatric patients, the parents can be counseled that most hydroceles resolve by 18–24 months of age. With suspected testicular malignancy, the emergency clinician can start the workup with laboratory tests, including α-fetoprotein and β-human chorionic gonadotropin. These patients will need urgent urologic follow-up or even consultation while in the emergency department.

Erythematous Scrotum

Idiopathic scrotal edema is self-limiting. Episodes resolve in 1–4 days with symptom management: Scrotal elevation, rest, and NSAIDs. Scrotal abscesses can be treated similarly to abscesses on other areas of the body with drainage and antibiotic treatment. Depending on abscess location and clinical picture, surgical consultation may be necessary.

Fournier gangrene needs aggressive antibiotic therapy and surgical debridement. Like testicular torsion, Fournier gangrene is a true surgical emergency. Broad-spectrum antibiotics are recommended, but specific coverage for Fournier varies. Most articles, primarily case reviews and retrospective data, recommend broad-spectrum antibiotics, empirical coverage with piperacillin/tazobactam, and vancomycin. Ultimately, these patients need wide surgical debridement. Surgery is the definitive treatment. There is mixed evidence on hyperbaric oxygen as adjuvant therapy; most evidence comes from small retrospective studies or case reports, but they demonstrate some benefit or decreased mortality. All patients should be admitted to an intensive care unit because of the high mortality risk.

Traumatic Scrotum

Minor testicular trauma, such as contusions or zipper injuries, are managed conservatively with supportive care (ice, NSAIDs, scrotal support, and elevation), whereas major trauma is typically managed surgically (**Table 5**). If there is suspicion of testicular rupture recommendation is for scrotal exploration. Early exploration is associated with higher rates of testicular

TABLE 5: Scrotal trauma.

Condition	*Etiology/Presentation*	*Treatment*
Testicular dislocation	Significant blunt-force mechanism (dislocation to the abdomen or to subcutaneous tissues surrounding the external inguinal ring)	Surgical intervention
Testicular rupture	Disruption of the tunica albuginea	Surgical intervention
Testicular contusion	Intratesticular hematoma; intact tunica albuginea	*Typically, conservative*: Ice, rest, and elevation
Hematocele	Blood accumulation in the tunica vaginalis	Surgical drainage for large hematocele; conservative otherwise
Penetrating injury	Varies depending on cause	Typically, surgical exploration/intervention
Traumatic testicular torsion	Traumatically induced torsion has been reported	Surgical exploration/intervention

salvage. For penetrating injuries, surgical exploration is also recommended. More than half of all penetrating scrotal injuries have testicular involvement. For zipper injuries, there are several options for management. One technique is to use mineral oil. After local anesthesia, the clinician can use mineral oil on the zipper and surrounding skin to gently untangle the zipper from the skin. The clinician may also try using a wire cutter or bone-cutting pliers. Cut the diamond (or the median bar) of the zipper, which will cause the zipper to fall apart, freeing the skin.

SUMMARY

Although scrotal emergencies are rare within the emergency department, they can be life and fertility threatening. It is important to differentiate the surgical emergencies (testicular torsion, Fournier gangrene, and testicular trauma) from the less-urgent diagnoses of acute scrotal pain. Among the wide differential, it is imperative that the emergency physician identify the more concerning causes early to save lives and preserve fertility.

Renal Transplant Related Complications

115 CHAPTER

Vishal Saxena, Yogeshman Anand

INTRODUCTION

Organ transplantation is one of the most common modalities of treatment in patients with end-stage organ failure. With increasing success, more and more numbers of patients are coming in the emergency departments (EDs) for transplantation-related complications. Solid organ transplant patients regarded as a special population in the ED. In this chapter, brief description on common problem following the kidney transplant and principles for the management of patients with renal transplantation in the ED has been discussed. Every complaint from a transplant patient should be carefully evaluated. When major complaints are present, knowledge of the initial physiological condition of the allograft can help to rule in or rule out possible organ failure. Even minor changes in allograft functioning can indicate organ failure. The duration of time since the organ transplantation should always be considered when evaluating the patient's condition. Complications related to organ transplantation can be categorized into four groups: (1) Anatomical, (2) Infection, (3) Rejection, and (4) Drug toxicity. All these categories should be considered in the differential diagnosis. However, the exact etiology may not be known until admission to the hospital for further evaluation. Therefore, every complaint from a transplant patient should be carefully evaluated.

HYPERTENSION FOLLOWING KIDNEY TRANSPLANT

Hypertension (HTN) occurs in 60–80% of renal transplant recipients. It is associated with increased risk of graft failure, all-cause mortality, and cardiovascular disease (CVD). Risk factors are: Transplant renal artery stenosis (TRAS), calcineurin inhibitors (CNIs) and steroids, delayed and/or chronic allograft dysfunction, presence of native kidney, obesity, and diabetes mellitus (DM).

Transplant Renal Artery Stenosis

It is presents as worsening or refractory HTN and/or unexplained graft dysfunction, heart failure (HF), and flash pulmonary edema. Risk factors are operative trauma, atherosclerosis of transplant renal artery or iliac artery, cytomegalovirus (CMV) infection, and delayed graft function (DGF). Diagnosis includes Doppler ultrasound (US) which has 87–94% sensitivity and 86–100% specificity; spiral computed tomography (CT); magnetic resonance angiography (MRA); and arteriography [risk of acute kidney injury (AKI) due to contrast or thromboembolism]. Treatment includes conservative therapy with angiotensin-converting enzyme (ACE) inhibitor; percutaneous transluminal angioplasty (PTA) ± stenting (can restore perfusion in 70–90% but may recur in up to 10%); and surgery, if PTA unsuccessful or stenosis inaccessible to PTA (successful in 63–92% but recurrence rate up to 12% and high risk of complications, should be reserved for refractory HTN).

The kidney disease: Improving Global Outcomes (KDIGO) suggests a blood pressure target of <130/80 mm Hg irrespective of level of albuminuria (**Table 1**). Reduced dietary sodium chloride intake should the first step.

SURGICAL AND UROLOGIC COMPLICATION

Background

Occurs in approximately 6% of renal transplants, most occur within first 6 months after surgery. Ureteral stents reduce incidence of urine leaks and obstruction, but may increase cost of transplant and require cystoscopy for removal 3–6-week post-transplant.

Urinoma/Urine Leaks: 1–3% of Transplants

Most common site of leak is ureter—bladder anastomosis, though leaks from midureter and renal pelvis also seen. It presents as renal failure accompanied by enlarging fluid collection (usually adjacent to allograft and bladder), chemical peritonitis and ileus are frequent, occasionally leakage from wound. It may only manifest as DGF or immediately after ureteral stent removal.

Diagnosis

- Sample of fluid collection is sent for electrolytes and creatinine. If urine leak, then creatinine and potassium will be higher than serum.

TABLE 1: Choices of antihypertensive drugs for postrenal transplant.	
Diuretics	• Low dose thiazide diuretic (12.5–25 mg) is reasonable for patients with CrCl > 25–30 mL/min • *Advantages are*: Inexpensive, reduces edema, do not alter glucose or lipid levels, decreases risk of hyperkalemia, and potentiates the effect of ACE and ARBs
Beta blocker	• Especially attractive for patients with ischemic heart disease (IHD) • *Relative contraindication*: Peripheral vascular disease (PVD), reactive airway disease, and hypoglycemic reactions
ACE/ARBs	• Reduces proteinuria, stabilizes the deterioration in renal function in chronic allograft nephropathy (CAN), cardiovascular benefit, reduces insulin resistance, and useful in post-transplant erythrocytosis • Causes decrease in GFR which may interfere with dx of acute rejection (especially in first 6 months post-Tx); can exacerbate hyperkalemia especially in patients on CNIs; and can exacerbate anemia • Wait 3–6 months post-Tx before starting ACE inhibitor or ARB, if indicated • Despite beneficial effects on proteinuria and HTN, no long-term benefit on graft, patient survival has been shown in RCTs
Calcium channel blockers (CCBs)	• May ameliorate vasoconstriction induced by CNIs • *Non-DHP CCBs (diltiazem and verapamil)*: Potent inhibitors of CYP3A4, cause ↑ plasma levels of TAC, CsA, and sirolimus; effect occurs in 48–72 hours; close monitoring of CNI or mTOR inhibitor levels is required
Vasodilator and alpha blockers	Also effective, may cause reflex tachycardia. Excessive hair growth with minoxidil

(ACE: angiotensin converting enzyme; ARBs: angiotensin-receptor blockers; CsA: cyclosporine; CNIs: calcineurin inhibitors; CrCl: creatinine clearance; GFR: glomerular filtration rate; HTN: hypertension; mTOR: mammalian target of rapamycin; non-DHP CCBs: nondihydropyridine calcium channel blockers; RCTs: randomized controlled trials; TAC: tacrolimus)

- Nuclear medicine renal scan can also be diagnostic in cases where fluid is inaccessible.

Treatment

The majority of urinary leaks require surgical correction. Distal leaks with minimal extravasation and clinical stability may respond to Foley insertion for 5–7 days.

Lymphocele: 1–16% of Transplants

It occurs due to inadequate ligation of lymph vessels near iliac vessels or hilum which leads to lymph collection. It accumulates between the transplanted kidney and bladder. Small lymphoceles are frequent, but usually asymptomatic. Larger collections present few weeks to months after transplantation. A bulge near the surgical wound sometimes with extravasation of lymph and edema of lower limb ipsilateral to the graft may be seen. Rarely, compressive symptoms such as urinary urgency or hydronephrosis and allograft dysfunction may occur.

Diagnosis

Renal US shows the collection with associated compressive effects. Fluid sampling is done to rule out urinoma (serum creatinine/potassium are similar to serum).

Treatment

- Expectant treatment for small lymphoceles
- Drainage or laparoscopic/open surgery (marsupialization) for larger and recurrent collections

Ureteral Stricture: 3–6% of Transplants

It is usually due to ischemia because of inadequate distal blood flow in ureter, though fibrosis from local BK virus replication and rejection is also a possibility. Risk factors are donor age, DGF, and abnormal vasculature. It also presents as renal insufficiency with hydronephrosis on US despite decompressed bladder. Diagnosis is made by renal US or CT urogram. If the diagnosis is uncertain, antegrade pyelogram needs to be performed. Treatment is decompression of collecting system with nephrostomy to reverse renal insufficiency and perform pyelogram. Stent placement can temporize, dilatation with stents or balloons are frequently ineffective with success rate of 28–80%. Most patients need surgical reimplantation.

Allograft Pyelonephritis: 10–15% of Transplants in First Year

It results due to reflux from surgical bladder anastomosis. Risk factors are female sex, diabetes, urinary tract infections (UTIs) prior to transplant, immunosuppression (IS), ureteral stent AKI, fever, pain over allograft, frequently history of UTI symptoms preceding allograft pain. Occasionally it is asymptomatic and is found on biopsy done for graft dysfunction. Diagnosis is made clinically and confirmed with urine culture. CT anteroposterior (AP) can suggest diagnosis but not specific as perinephric stranding is common after all renal transplant surgeries. Treatment is intravenous (IV) antibiotics and treatment is continued for 2–3 weeks. Patients with two episodes in 6 months or three episodes in 1 year should be investigated further by urology. Such patients may benefit from suppressive antibacterials, such as methenamine 1 g BID plus vitamin C. Pyelonephritis may predispose to subsequent rejection and recurrent episodes can lead to allograft failure.

Asymptomatic Bacteriuria: 35–40% of Transplants

Urinary tract infections and episodes of pyelonephritis frequently preceded by periods of asymptomatic bacteriuria but most do not progress to symptomatic disease. Randomized trials of treating asymptomatic bacteriuria have not been associated with reduction in UTIs, hospitalizations, or pyelonephritis.

INFECTION AFTER KIDNEY TRANSPLANTATION

Infectious complications occur in more than two-thirds of patients in the 1st year with UTIs and viral infections being the most common causes (**Table 2**). Infections are the second leading cause of death in transplant recipients. Risk factors for infection after transplant are donor-derived infections, prior and recent recipient exposures, prior and current IS regimens, and recent treatment for rejection.

CYTOMEGALOVIRUS INFECTION

Risk of CMV disease is related to donor/recipient serologic match: High-risk: D+/R–; intermediate risk: D+/R+, and D–/R+; low-risk: D–/R–. It is associated with increased risk of acute/chronic rejection, graft failure, Epstein–Barr virus (EBV)-associated post-transplant lymphoproliferative disorder (PTLD) and other opportunistic infections.

It presents as:

- *CMV syndrome*: Fevers, malaise, weight loss, diarrhea, arthralgias, leukopenia, thrombocytopenia, and transaminitis
- *Tissue-invasive disease*: Gastrointestinal (GI) [most common tissue-invasive disease in kidney transplant recipient (KTR); colitis > gastritis; CMV viral load may be negative; if clinical suspicion is high, need biopsy with staining for CMV], pneumonitis, nephritis, hepatitis, and retinitis

Prophylaxis

Valganciclovir (900 mg QD, adjusted for CrCl) significantly reduces risk of CMV post-transplant. Duration is minimum 6 months if high risk; 3 months if intermediate risk, consider 3 months if low risk.

Treatment

PO valganciclovir (900 mg BID, adjusted for CrCl) and IV ganciclovir (5 mg/kg q12, adjusted for CrCl) equivalent; consider IV if tissue-invasive disease or significant GI symptoms. Treat until viral load undetectable × 2 weeks, then start secondary prophylaxis. Consider dose reduction of antimetabolite during/after treatment of CMV.

TABLE 2: Timeline of common infections after kidney transplantation (KT).

<1 month	*1–12 months*	*>12 months*
• Wound infection • UTI • Dialysis access infection • *Clostridium difficile* colitis • Multidrug-resistant organisms: MRSA, VRE, and ESBL • Donor-derived infections (uncommon)	• BK polyomavirus • Herpes viruses: CMV, EBV, HSV, and VZV • PJP • *Cryptococcus*	• Community-acquired pneumonia • UTI • Fungal infections • Late reactivation of herpes viruses

(CMV: cytomegalovirus; EBV: Epstein–Barr virus; ESBL: extended spectrum beta-lactamase; HSV: herpes simplex virus; MRSA: methicillin-resistant *Staphylococcus aureus;* PJP: *Pneumocystis jirovecii* pneumonia; UTI: urinary tract infection; VRE: vancomycin-resistant enterococci; VZV: varicella-zoster virus)

Resistant Cytomegalovirus Infection

It occurs in 1–2% of KTRs. Risk factors for resistant CMV include D+/R– and longer duration of antiviral exposure.

Treatment

Cidofovir and foscarnet; mortality rate up to 11% in resistant CMV.

BK POLYOMAVIRUS INFECTION

Ubiquitous polyomavirus establishes latency in genito-urinary (GU) tract and can reactivate in setting of IS. BK viruria occurs in approximately 30%, BK viremia in 15–20%, and BK nephropathy in 1–10%. BK viruria can cause hemorrhagic cystitis [more common after hematopoietic stem cell transplantation (HSCT)] or irritative voiding symptoms. Only sign of BK viremia/nephropathy typically is increasing creatinine. Viral replication in urine and blood is most common in 1st year post-transplant. Risk factors are degree of IS (most important), old age, male gender, diabetes, Caucasian, ureteral stent, and donor/recipient serologic mismatch. Kidney biopsy shows intranuclear viral inclusions, interstitial infiltrates, and lymphocytic tubulitis (may be difficult to distinguish from acute rejection); immune staining is positive for SV40. Screening is done by BK virus polymerase chain reaction (PCR) in blood. It is done at minimum of 3 months interval in first 2 years, then annually through till 5th year. Screening should be resumed after treatment for rejection. Decrease in IS particularly antimetabolites, e.g., mycophenolate mofetil (MMF) and azathioprine (AZA) decreases risk of nephropathy and graft loss.

FUNGAL INFECTIONS POST-TRANSPLANT

Fungal infections in KTRs can prove fatal. *Aspergillus* and mucormycosis historically have been associated with high morbidity and mortality risk. The mainstay of treatment is marked reduction in IS. Survival has improved slightly when this is combined with newer antifungal agents. Given regional variations in endemic fungal prevalence, patient residence, and travel history need to be considered in the evaluation of a patient. Lifelong prophylactic fluconazole therapy is used by some transplantation centers to prevent coccidioidomycosis infections for patients residing in endemic areas. The presentation of coccidioidomycosis (valley fever) can be respiratory symptoms, joint infections, or disseminated disease with a characteristic rash.

ALLOGRAFT REJECTION

Acute renal allograft rejection is a major cause of allograft dysfunction. There are two principal histologic forms of acute rejection:

1. Acute T cell-mediated (cellular) rejection (TCMR), which is characterized by lymphocytic infiltration of the tubules, interstitium, and, in some cases, the arterial intima.

2. Active (acute) antibody-mediated rejection (ABMR), the diagnosis of which requires morphologic evidence of acute tissue injury, evidence of circulating donor-specific alloantibodies, and evidence of antibody-endothelial cell interaction (such as C4d deposition in the allograft).

Antibody-mediated rejection and acute TCMR may coexist at the same time in the allograft. Subclinical rejection is defined as the presence of histologic evidence of acute rejection on biopsy without an elevation in the serum creatinine concentration. Subclinical rejection is detected by a protocol, or surveillance, biopsy, which is obtained at a protocol-driven, prespecified time after transplantation or on detection of de novo donor-specific antibodies (DSAs) rather than for an indication such as allograft dysfunction. Most of the reports of subclinical rejection involve TCMR. However, there are reports of allografts with histologic manifestations of ABMR in the absence of functional deterioration of kidney function.

Calcineurin Inhibitor Nephrotoxicity

The CNIs, tacrolimus and cyclosporine, are used as part of a maintenance IS regimen in >90% of KTRs. While these agents are used to prevent acute rejection, they are associated with nephrotoxicity and are a common cause of acute and chronic allograft dysfunction. CNI nephrotoxicity can manifest as either acute azotemia, which typically occurs within the first 3 months post-transplant and is largely reversible after reducing the dose, or as chronic progressive renal disease, which generally occurs after 3 months post-transplant and is usually irreversible. Other renal effects of the CNIs include tubular dysfunction and, rarely, a thrombotic microangiopathy that can lead to acute graft loss.

Thrombotic Microangiopathy

Thrombotic microangiopathy in the KTR may be the result of recurrent disease [e.g., in patients with a prior history of thrombotic thrombocytopenic purpura or complement-mediated hemolytic uremic syndrome (HUS)], CNI nephrotoxicity, active (acute) ABMR, or a hypercoagulable disorder (such as antiphospholipid syndrome). In addition to acute allograft dysfunction, common clinical features include microangiopathic hemolytic anemia, thrombocytopenia, and increased lactate dehydrogenase levels.

Recurrent Primary Disease

In patients whose primary renal disease was glomerulonephritis, disease recurrence must be considered as a possible cause of allograft dysfunction. Recurrence rates vary depending upon the specific glomerular disease. Glomerular diseases that commonly recur post-transplant include primary focal segmental glomerulosclerosis (FSGS), primary membranous nephropathy, membranoproliferative glomerulonephritis, complement-mediated HUS, and C3 glomerulopathy. Late recurrence (i.e., >1 year post-transplant) may be seen in many diseases, including FSGS, membranoproliferative glomerulonephritis, immunoglobulin A (IgA) nephropathy, and diabetic nephropathy. Biopsy of the renal allograft is required for diagnosis.

NEW-ONSET DIABETES AFTER TRANSPLANT

Tacrolimus, more than cyclosporine, is toxic to pancreatic islet cells. New-onset diabetes after transplantation (NODAT) affects up to 40% of transplant recipients, though the accuracy of this statistic is limited by controversy about the definition of NODAT. Risk factors for the development of NODAT are obesity, African American and Hispanic ethnicities, family history of diabetes, and hepatitis C virus (HCV) infection. Those with known diabetes before the development of ESRD are likely to require more intensive therapy.

Electrolyte Abnormalities

Electrolyte abnormalities are common post-transplantation. Hyperkalemia can be associated with CNIs, sulfamethoxazole, ACE inhibitors, and angiotensin-receptor blockers (ARBs) and with reduced glomerular filtration rate (GFR). CNIs can cause hyperkalemia with hyperchloremic metabolic acidosis due to downregulation of specific tubular transport proteins. Hypomagnesemia (magnesium, 1.2–1.7 mg/dL) is seen in most transplant recipients as a result of renal magnesium wasting due to tacrolimus. In addition, proton pump inhibitors may also contribute to hypomagnesemia. Oral magnesium replacement should target a level > 1.5 mg/dL because levels > 2.2 mg/dL are rarely achieved and usually result in magnesium-induced diarrhea.

POST-TRANSPLANT MALIGNANCY

The most common post-transplantation malignancy is nonmelanotic skin cancer. Squamous cell skin cancer risk is 100-fold increased among transplant recipients, especially in Latinos and whites as compared to the general population. All transplant recipients should wear sunscreen and be screened annually by a dermatologist. Though squamous cell skin cancers do not typically metastasize, if untreated, metastasis can occur. Recurrent skin cancers should prompt consideration of conversion to a mammalian target of rapamycin (mTOR) inhibitor, which has better efficacy in control of epithelial cell-derived skin cancers.

Post-transplant lymphoproliferative disorder is seen in 0.8% of adult and 2.6% of pediatric recipients. The majority of PTLD cases are driven by an EBV infection. The higher prevalence in children is due to a lack of acquired immunity to EBV. EBV infection or reactivation results in clonal expansion of B lymphocytes, resulting in lymphoma. PTLD often presents with infiltration of the internal organs, central nervous system, or intrathoracic or intra-abdominal lymph nodes. Palpable lymphadenopathy is uncommon. Presenting symptoms include low-grade fevers, shortness of breath, headaches, or abdominal discomfort. Physicians should have a low threshold for CT in patients presenting with these symptoms. Initial treatment is reduction in IS, followed by chemotherapy with R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone). Renal cell cancers are seen more frequently in the transplantation population, likely related to malignant degeneration of cysts in patients with underlying polycystic or acquired cystic disease. There are no accepted

guidelines for screening transplant recipients for renal cell cancer. However, hematuria in a transplant recipient warrants urologic evaluation that includes ultrasonography or CT of both the native and transplanted kidney.

SUMMARY

Emergency department physician must be aware about the solid organ transplant-related complication because organ transplant nowadays is a common modality of treatment for end-organ damage. When dealing with the clinical findings of solid organ transplant patients, ED professionals should remember that symptoms may be vague and nonspecific. Furthermore, signs and symptoms related to infectious complications vary with the source of infection, pathogenic organism, and level of immunosuppression. It is important to continue appropriate immunosuppression while managing transplantation-related complications. Transplant patients require extensive laboratory and radiological evaluations to rule out an infectious etiology, evaluate the allograft function, and determine drug toxicity. With an increased awareness regarding transplantation, ED physician can offer accurate and effective management.

116
CHAPTER

Headache

Devendra Richhariya

INTRODUCTION

Headache is one of the most prevalent patients' complaints, whether as chief or ancillary, in emergency departments (ED), consist of millions of ED yearly visits. Despite of uncertainty and major knowledge gaps, it was estimated that percentage of the adult population with an active headache disorder is almost 50% in general, with minor difference in various societies. It is a functionally disabling disorder leading to considerable years living with disability (YLDS), and has been experienced at least once by almost everyone. Therefore, it has taken into consideration by World Health Organization (WHO) as a public-health priority, in 2000. Although most of the cases are benign in nature, but needs some special attention regarding various aspects including primary pain management, diagnostic approach, disposition, and outpatient follow-up.

Headache is one of the common presentations in ED. About 2–5% of patients in various ED are due to headache, apart from these most of the patients with headache do not visit ED also. Important aspect of management of headache in emergency is identification of life-threatening causes of headache such as subarachnoid hemorrhage (SAH) and meningitis and early initiation of the treatment in these life-threatening causes. It is frequent scenario that patient with acute headache immediately sent to nearest computed tomography (CT) scan center by general physician in view of attendant anxiety and in hope that this will identify some cause. But this will delay in receiving the appropriate treatment while taking care full history alone differentiate the fatal (need further investigation and immediate intervention) from nonfatal causes (need only reassurance and discharge) in other word approach should be to classify the patient into two groups: Primary headache such as migraine, tension or cluster and secondary headache such as SAH, CVA, meningitis, temporal arteritis, carotid dissection, and sinus thrombosis. Educating the patient about probable causes and various treatment options are really helpful in headache management in ED. The main objectives for emergency physician while evaluating acute headache patients:

- Identify causes of secondary headache
- Rule out life-threatening causes
- Pain management
- Investigate and manage appropriately
- Follow-up

ETIOLOGY

When it comes to etiology, most acceptable categorization for headache is primary versus secondary causes, based on presence or absence of a pathologic structure justifying the symptoms (**Table 1**). The first recorded classification system was published by "Aretaeus", the ancient Greek physician, active during 1st century CE. Today, the 3rd edition of the International Classification of Headache Disorders is available that has been released by classification committee of International Headache Society (IHS) in 2018 (was published in 2013 in a beta version ahead of the final version) showed in **Box 1**.

PATHOPHYSIOLOGY

The brain parenchyma has no pain receptors, so is not sensitive to pain itself. But, some other components, adjunct to it such as meninges, blood vessels, skin, etc. have nociceptors that could stimulated from traction or by irritation. It usually defines the

TABLE 1: Categories of headache.

Primary headache	*Secondary headache*
• Tension • Cluster • Migraine • Febrile headache • Dental headache • Trigeminal neuralgias • Postlumber puncture headache • Others such as exertional, sex headache, and cough headache	• Subarachnoid hemorrhage • Stroke • Traumatic/nontraumatic EDH, SDH, and intracranial hemorrhage • Carotid or intracerebral arteries dissection • Head trauma • Brain infection • Intracranial space occupying lesion • Metabolic or toxic causes

(EDH: epidural hematoma; SDH: subdural hematoma)

BOX 1: The International Classification of Headache Disorders 3rd Edition.

Part one: The primary headaches

- Migraine
- Tension-type headache (TTH)
- Trigeminal autonomic cephalalgias (TACs)
- Other primary headache disorders

Part two: The secondary headaches

- Headache attributed to trauma or injury to the head and/or neck
- Headache attributed to cranial or cervical vascular disorder
- Headache attributed to nonvascular intracranial disorder
- Headache attributed to a substance or its withdrawal
- Headache attributed to infection
- Headache attributed to disorder of homoeostasis
- Headache or facial pain attributed to disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cervical structure
- Headache attributed to psychiatric disorder

Part three: Painful cranial neuropathies, other facial pains, and other headaches

- Painful lesions of the cranial nerves and other facial pain
- Other headache disorders

pathophysiology of secondary type's headache. But, unlike secondary causes, the pathophysiology of primary headache disorders is not well understood and proposed theories were changed during the time. For example, it was long assumed that some vascular involvement is explaining the migraine pathophysiology. This vascular theory, which was settled and progressed in the 20th century, is no longer accepted. It seems that the literatures are yet nonconclusive in this era and more studies are still required to understanding the pathophysiology of primary headache disorders.

CLINICAL PRESENTATION

Headache is the sensation of pain anywhere in the region of the head or neck. Depend on the type, it could present with various manifestations. The presentation process is so important for the in-charge physicians. Some may present with new onset rapid progressive headache raise the attention to critically important underlying cause; on the other hand, some present with chronic pain not responded to their regular treatment. The details were discussed in the following sections.

Concerning features-red flags: Although most of headaches are benign, but there are still some life-threatening causes. Red flags are highly important points that careful attention to them by rapid reviewing in dealing with each patient, help the physician to differentiate the serious cause require further emergent investigations. Overall, complaining of first or worst headache, progressively worsening headache, headache triggered by exertion or started while engaged in sexual intercourse or after a recent traumatic event, presence of focal neurological findings or papilledema on physical examination, and any alteration in mental status warrant further work up in ED. To remember of the red flags for recognizing a secondary type headache, the American Headache Society recommends using of "*SSNOOP*" mnemonic abbreviated for the items below:

- ***S***ystemic symptoms (fever or weight loss)
- ***S***ystemic disease [human immunodeficiency virus (HIV) infection and malignancy]
- ***N***eurologic symptoms or signs
- ***O***nset sudden (thunderclap headache)
- ***O***nset after age of 40 years
- ***P***revious headache history (first, worst, or different headache)

EVALUATION

As obviate from the mentioned points in previous section, all the red flags were assessed through a detailed history taking and focused physical examination.

For a confident history taking, patient should ask for 10 important points about the pain including location, pattern and onset, activity at the onset (during marked exertion or coitus), characteristics (throbbing, steady, or tension), exacerbating or alleviating factors, history of trauma, risk factors (HIV or another immunocompromised state), prior history of headache, intensity, and associated symptoms (blurred vision, fever, nausea, vomiting, or syncope).

Physical examination also including of general appearance assessment, checking the vital signs, head and neck evaluation (acute red eye, poorly reactive or nonreactive pupils, or 3rd nerve palsy), and precise neurological examination (even the least change in mental status, any focal neurologic deficit or alteration in cerebellar tests). Ophthalmoscopy is also necessary for demonstrating or ruling out the possible loss of venous spontaneous pulsation or presence of papilledema.

Interpretation of Finding

It is expected that the primary evaluations reveal some findings that their interpretation leads to suggesting appropriate differential diagnosis which will be the basis for the next steps of patient evaluation process and proper decision-making in fact. Those life-threatening diagnoses which need treatment interactions right after confirming the diagnosis or even before are called as critical diagnosis **Table 2**. SAH, carbon monoxide (CO) poisoning, temporal arthritis, meningitis or encephalitis are among the most important critical diagnosis of a patient presenting with headache. Space occupying lesions including brain abscess and hemorrhagic events, cerebral vein thrombosis (CVT), glaucoma, hypertensive crisis, and mountain sickness are also considered as emergent diagnosis.

INVESTIGATIONS

Considering the suggested differential diagnosis, the patient may undergo some paraclinical procedures including laboratory and/or imaging. Complete blood count (CBC), and a coagulation profile may all required laboratory tests. Cerebrospinal fluid (CSF) analysis in those with impression of meningitis/encephalitis following lumbar puncture (LP) and erythrocyte sedimentation rate (ESR) in those suspected as giant cell arteritis are also required. Requesting for common biochemical profile is usually unnecessary. Most of the patients, who are suspected for secondary causes almost always need

TABLE 2: Interpretation of findings—most likely cause of secondary headache.

Presenting symptoms in emergency	*Most likely cause of headache*
Severe, sudden onset headache, altered mental status, history of hypertension, smoking, SAH, cerebral aneurysm, arteriovenous malformation/trauma, and coagulopathy	Subarachnoid hemorrhage/ intracerebral hemorrhage/subdural hematoma
Fever, neck stiffness, altered behavior, seizures, photophobia, history of ear infection, brain surgery, trauma, and immunocompromised status	CNS infections/ meningitis
Jaw pain, changes in vision polymyalgia, gradual onset, and severe throbbing pain	Temporal arteritis
Dizziness, fatigue, weakness, nausea, vomiting, confusion, syncope, headache in winters, and dull frontotemporal pain	Carbon monoxide poisoning
Sudden, moderately, severe, pain around eye unilateral vision change, and redness	Acute glaucoma
Neck pain, vertigo, history of trauma, stroke symptoms, Horner syndrome, and upper extremities weakness	Cervical artery dissection
Associated with nausea, vomiting, seizures, ocular nerve palsies, chemosis, proptosis, papilledema, pregnancy, postpartum, hypercoagulable, and oral contraceptive use	Venous sinus thrombosis
Chronic progressive headaches, papilledema, and history of malignancy	Intracerebral tumor/ space occupying lesion/increased ICP/ idiopathic intracranial hypertension
Headache associated with vertigo, vomiting, ataxia, and dysmetria,	Cerebellar infarction

(CNS: central nervous system; SAH: subarachnoid hemorrhage; ICP: intracranial pressure)

to perform a nonenhanced head CT scan as soon as possible. Almost all the hemorrhagic causes are diagnosed by this imaging. It also may revealed some findings pointing to other intracranial lesions such as brain abscess or tumors, that may require contrast enhanced magnetic resonance imaging (MRI) in next step. Advanced imaging techniques including magnetic resonance angiography (MRA) and magnetic resonance venography (MRV) are also may necessitate in suspicion of vascular disorders including intracranial aneurism and cerebral venous thrombosis (CVT) respectively.

TREATMENT

Along with diagnostic approach, pain management is always necessary in all patients; since benign primary disorders are the most frequent diagnosis that is the only intervention in most cases as well. There are frequent guidelines for

TABLE 3: Parenteral pain control medications in ED.

Agent	*Dosage*
Acetaminophen	• <50 kg: 12.5 mg/kg IV q4h OR 15 mg/kg IV q6h; not to exceed 750 mg/dose or 3.75 g/day infuse IV over at least 15 min • ≥50 kg: 650 mg IV q4h OR 1,000 mg IV q6h; not to exceed 4 g/day infuse IV over at least 15 min
Ketorolac	• IV: 30 mg as single dose or 30 mg q6h; not to exceed 120 mg/day • IM: 60 mg as single dose or 30 mg q6h; not to exceed 120 mg/day
Ibuprofen	400–800 mg IV infused over 30 min q6h PRN; not to exceed 4,200 mg/day
Morphine	• SC/IM (opioid-naïve patients): 5–10 mg q4h PRN; dose range, 5–20 mg • IV (opioid-naïve patients): 2.5–5 mg q3–4h PRN, infused over 4–5 min; dose range, 4–10 mg

(ED: emergency department; IV: intravenous; IM: intramuscularly; SC: subcutaneously)

management of acute headaches that generally recommended several different agents. Intravenous (IV) acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and opioids are common first choice. Corticosteroids, magnesium sulfate, caffeine, ergotamine, and sumatriptan may also be required. Serotonin antagonist (granisetron), intranasal lidocaine, and high-flow oxygen were also studied in this regard but have reported conflicting results. There is an interest about using IV ketamine as a treatment option for acute pain but does not provide significant relief. Despite of huge number of randomized clinical trials (RCTs), there is not an agreement on a single approved guideline. Overall, it is likely that investigators have tried to reduce using opioids and replace them by nonopioid agents that assumed have less side-effects, but opioids administration remains still prevalent in the ED. **Table 3** shows the dosage of some more frequent agents used as parenteral pain control medications in ED. All secondary type headaches are required specific intervention depend on the exact diagnosis, whether surgical or nonsurgical. Surgical interventions are usually conducted in cases of intracranial hemorrhagic insults, brain mass, and abscess. Nonsurgical treatments are also including antibiotic therapy in meningitis, antiviral in encephalitis, corticosteroid in temporal arteritis, oxygen therapy in CO poisoning, topical treatment to lower intraocular pressure (IOP) in glaucoma, and anticoagulation in CVT (even hemorrhagic ones).

Tension Headache

Most common type of headache presentation in ED. Tight or compression type sensation usually bilateral nonpulsatile type associated with stress and occurs daily not aggravated by exertion. Compliant of feeling constant pressure or weight on shoulders neck and head. Headache start gradually but increase in severity at the end of the day. Once the secondary headache is excluded tension headache can be treated with NSAID, chlorpromazine, metoclopramide, and sumatriptan.

Treatment of tension headache: Reassurance, anxiety and depression assessment, minor tranquilizers, tricyclic antidepressant, treatment with diazepam, chlordiazepoxide, and aspirin is helpful. Alprazolam: Antianxiety and antidepressant action. If severe depression suicidal ideation, or refractory to treatment then psychiatrist consultation.

Cluster Headache

As compared to migraine and tension headache cluster headache is uncommon. Cluster headache usually unilateral, short duration and associated with parasympathetic autonomic features such as lacrimation, rhinorrhea, warm, and redness of face. Headache is so severe that it awakens the patient from sleep. Objective of treatment in ED is control the pain and abort the cluster headache. Start oxygen inhalation by face mask at the rate of 7–10 L/min for 15 minutes. Subcutaneous sumatriptan 6 mg helpful in aborting the cluster headache attack. Subcutaneous sumatriptan is fast acting. Antiemetics should also be given to cluster headache patient. As recurrence is common after discharge from ED so adequate maintenance therapy should be prescribed to the patient.

Treatment of cluster headache: Subcutaneous injection of sumatriptan 6 mg abort cluster headache within 15-minutes, inhalation of 100% oxygen, ergotamine 1 mg at bed time total weekly dose not >14 mg, lithium 600–900 mg in chronic form, and prophylactic drugs are prednisolone, lithium, methyleserzide, ergotamine, and verapamil.

Migraine

Migraine is common headache disorder after tension headache. Migraine is typically unilateral recurrent throbbing associated with nausea, photophobia, and phonophobia either associated with aura or without aura. Medications used to treat in ED are summarized in **Table 4**.

SUMMARY

In dealing with a patient complaining of headache, ruling out the critical and emergent diagnosis in ED is far more important than ruling in an exact benign diagnosis. Therefore, the physician should make his/her effort in this regard. Pain management should consider for all types of headache whether primary or secondary. Further investigation in ED should also be considered for those suspected for secondary types based on history and physical examination findings. If secondary cause of headache is identified after detailed examination and neuroimaging, patient should be admitted and manage appropriately (**Flowchart 1**). If workup is normal patient should be discharged with follow-up with neurologist.

TABLE 4: Drug therapy for migraine in ED.

	Abortive medication for migraine		
Preventive medications for migraine	***Analgesics***	***NSAIDs***	***Antiemetics***
Propranolol: 40–120 mg BD	Aspirin 500–650 mg	Ibuprofen 200–300 mg	Metoclopramide 5–10 mg
Metoprolol: 100–200 mg/day	Paracetamol 500 mg	Diclofenac 50–100 mg	Chlorpromazine 10–25 mg
Amitriptyline: 25–75 mg HS	Propoxyphene 65 mg	Naproxen 500–700 mg	Promethazine 50–100 mg
Valproate: 400–600 mg BD	Codeine 60 mg	Flurbiprofen 50–100 mg	Diphenhydramine 50 mg
Flunarizine: 5–15 mg/day	***Ergot derivatives*** *are low-cost medication and with vasoconstriction effect. Main adverse effects are nausea, vomiting angina, cramps, numbness, and tingling. Contraindicated in hepatic, renal failure, coronary artery disease, peripheral vascular disease, pregnancy, and hypertension*		
Serotonin antagonists Pizotifen: 0.3–3 mg/day Methyleserzide: 1–6 mg/day	***Triptans*** efficacy and safety are established by well-designed trials triptans are 5HT 1B/1D receptor antagonist. Adverse effects are skin reaction, dizziness, hypertension, and chest discomfort Contraindicated in angina and coronary artery disease. Sumatriptan, naratriptan, rizatriptan, and zolmitriptan are in use. ***Parenteral sumatriptan***: 6 mg of subcutaneous sumatriptan is highly effective in acute attack

117
CHAPTER

Acute Dizziness and Vertigo

Ramyajit Lahiri, Subhra Choudhury

INTRODUCTION

Dizziness is a common presentation in an emergency department (ED) with varying underlying pathology. The diagnosis is complex. Studies suggest 3.5% patients presents with complaints of dizziness in ED. This is really a challenge for emergency medicine department to determine the exact cause of this dizziness and then provide treatment. Those found to have life-threatening causes arranging a proper disposition for them. Very little Indian literature is available stating the prevalence of this symptom in the Indian population. A study done by Raman et al. on prevalence and etiology of vertigo in adult rural population. There they have done survey on 10,000 adult patients between ages of 20 and 79 years. This study highlighted that 0.71% population having vertigo. Among multifarious causes cardiovascular cause is 0.32%, and neurologic dizziness account for 0.14%. Metabolic disease resulted in dizziness to 0.09% and 0.08% results of otologic disease. Miscellaneous disease 0.08%. To properly determine the exact cause in busy ED is tough. Many life-threatening diseases presents with dizziness. This results in multiple testing, imaging, and longer duration of ED stay. As per a study done in the United States of America (USA) on 2013, the approximate expense was 4 billion for patients presenting in ED. The 12% of that cost was on computed tomography (CT) scan of brain.

Dizziness is a nonspecific term used by patients to denote a variety of symptoms including vertigo, light-headedness, unsteadiness of gait, and disorientation. While dizziness and vertigo are often used interchangeably, they differ phenomenologically. While dizziness can be a manifestation of different causes, vertigo is necessarily a disorder of the vestibular system, or its central connections in the brainstem or rarely the temporal lobe resulting in an illusion of movement occurring horizontally and rarely vertically or obliquely.

DEFINITION

Dizziness is an impairment in spatial perception and stability and can range from fleeting faintness to a severe balance disorder that makes normal functioning impossible.

Accordingly, dizziness can be classified into four groups:

1. Vertigo
2. Disequilibrium without vertigo
3. Presyncope or near faint
4. Psychological dizziness (associated with panic attacks and anxiety disorders)

Vertigo is a symptom where a person feels as if they or the objects around them are moving when they are not. Often, they describe it like a spinning or swaying movement. It is an illusory sensation of movement in space.

Disequilibrium refers to imbalance or unsteadiness in the absence of vertigo. It can occur secondary to dysfunction in vestibular, somatosensory, visual systems, frontal lobes, cerebellum, and basal ganglia.

Presyncope is the sensation of light-headedness, which occurs just before fainting and is due to a transient impairment in cerebral circulation. The distinguishing feature from vertigo is the lack of an illusion of motion. It is often accompanied by pallor and weakness.

Psychological dizziness includes a combination of floating, swimming or rocking sensation, with giddiness which are usually accompanying features of stress, anxiety or fatigue, and an occasionally accompany labyrinthine disorders.

ETIOLOGY

It is commonly taught in old textbooks to diagnose a dizzy patient based on asking the patients "what actually they mean by dizzy". Current approach gives more emphasis on history and clinical examination. This helps in making more specific diagnosis. Multiple diseases can represent with dizziness. Many of them are benign but few are life-threatening. The main goal for emergency physician is to identify correctly the life-threatening causes. A 2008 study on 9,472 patients by National Hospital Ambulatory Medical Care Survey (NHAMCS) shows 50% of patients are having medical condition which includes cardiovascular pathology. Approximately 11% patients having neurological problems and 33% having otovestibular cause. In this prospective study they classified cardiovascular, cerebrovascular, infection, toxin, and metabolic causes as dangerous (**Table 1**). If timely treatment is not given, they can produce devastating results. They found 15% of the study population is having this dangerous disease where age >50 years are

more prone (21% compared to 9.35% in <50 years) with $p < 0.001$. Aortic dissection, carbon monoxide toxicity, and pulmonary embolus are all treatable causes which can presents as giddiness but rarely.

One institutional prospective study shows 30% has dangerous disease compared to 43% having peripheral vestibular disease. One retrospective study with 475 cohort done in Germany ED where a neurologist saw dizzy patients coming to ED. He diagnosed 73% as benign disease and only 23% as dangerous disease. This was blinded by a follow-up with another neurologist (not aware of previous diagnosis) showed almost 44% diagnosis got changed. Among that 6 patients initially diagnosed as benign found to have stroke in follow-up. This can actually results in catastrophe. Multiple studies have done to determine the cause of dizziness in patients presenting in ED. One study highlighted that subtle neurological abnormality with abnormal gait points toward cerebrovascular cause.

TABLE 1: Causes of vertigo.

Peripheral	*Central*	*Systemic/Vertigo mimics*
• BPPV • Labyrinthitis • Meniere's disease • Vestibular neuritis • Perilymph fistula • Acute otitis media • Schwannoma	• Stroke/TIA • Epilepsy • Migraine • Brain tumors • Multiple sclerosis • Familial ataxia syndrome • Postconcussion syndrome • Meningitis/ Encephalitis	• Ototoxic drugs • Anemia • Hypoglycemia • Dyselectrolytemia • Cardiac arrhythmias • Aortic dissection • Carbon monoxide poisoning • Adrenal insufficiency • Pulmonary embolism • Anxiety and panic attacks • Hyperventilation syndrome • Thiamine deficiency

(BPPV: benign paroxysmal positional vertigo; TIA: transient ischemic attack)

PHYSIOLOGY

The brainstem control centers integrate the information received from the specialized sensory receptors of the inner ear along with signals from vision and proprioception to determine the three-dimensional orientation of a person. The linear and angular acceleration receptors are present in the otolithic macula and the semicircular canals (SSCs) respectively. Electrical activities from these receptors travel along the vestibular nerve to reach the vestibular nuclei in the brainstem, where it forms vestibule-ocular reflex, vestibule-spinal tracts, and its connections with the cerebellum and emetic centers. Disruption of these pathways leads to the patient experiencing a disturbance in orientation.

Peripheral Vestibular System

The peripheral vestibular system consists of the paired vestibular sensory end organs of the SSCs and the otolithic organs (**Fig. 1**). These are present within the fluid filled bony channels of the otic capsule and are responsible for perception of both the sense of position and motion. The vestibular nerve is the afferent connection to the brainstem nuclei for the peripheral vestibular system. Within the ampulla of the SSCs are the end organs of cristae, which contain specialized hair cells that transduce mechanical shearing forces into neural impulses. The hair cells or the cilia extend into a gelatinous matrix better known as the cupula, which acts like a hinged gate between the vestibule and the canal itself.

The otolithic organs of the utricle and saccule are found within the vestibule, and are responsible for the perception of linear acceleration. Here also, the end organs consist of a flattened, hair cell rich macular area whose cilia project into a similar gelatinous matrix. The matrix here is however different, and contains a blanket of calcium carbonate crystals, better known as otoliths, with a mean thickness of around 50 μm.

Central Vestibular System

The main brainstem nuclei that receive afferents through vestibular nerve are the superior (Bechterew's nucleus), lateral (Deiter's nucleus), medial (Schwalbe's nucleus), and descending (spinal vestibular nucleus) nuclei (**Fig. 2**). The superior vestibular nucleus is apparently the major relay station

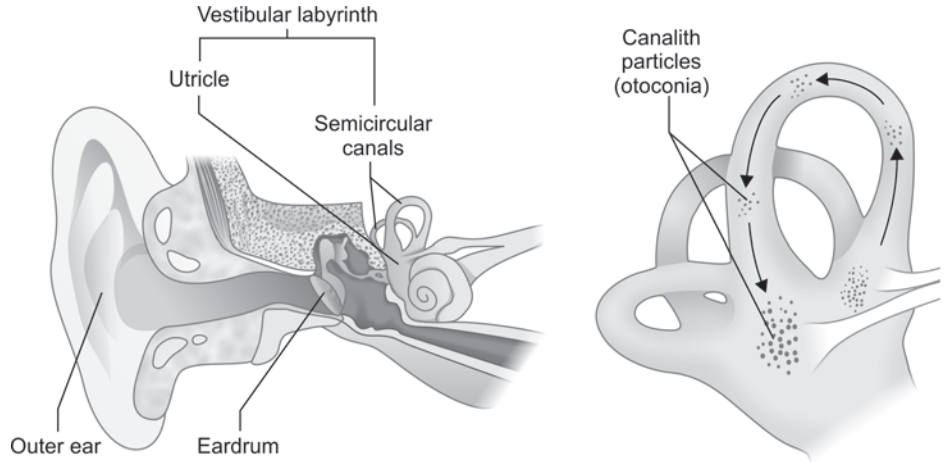

FIG. 1: Peripheral vestibular system.

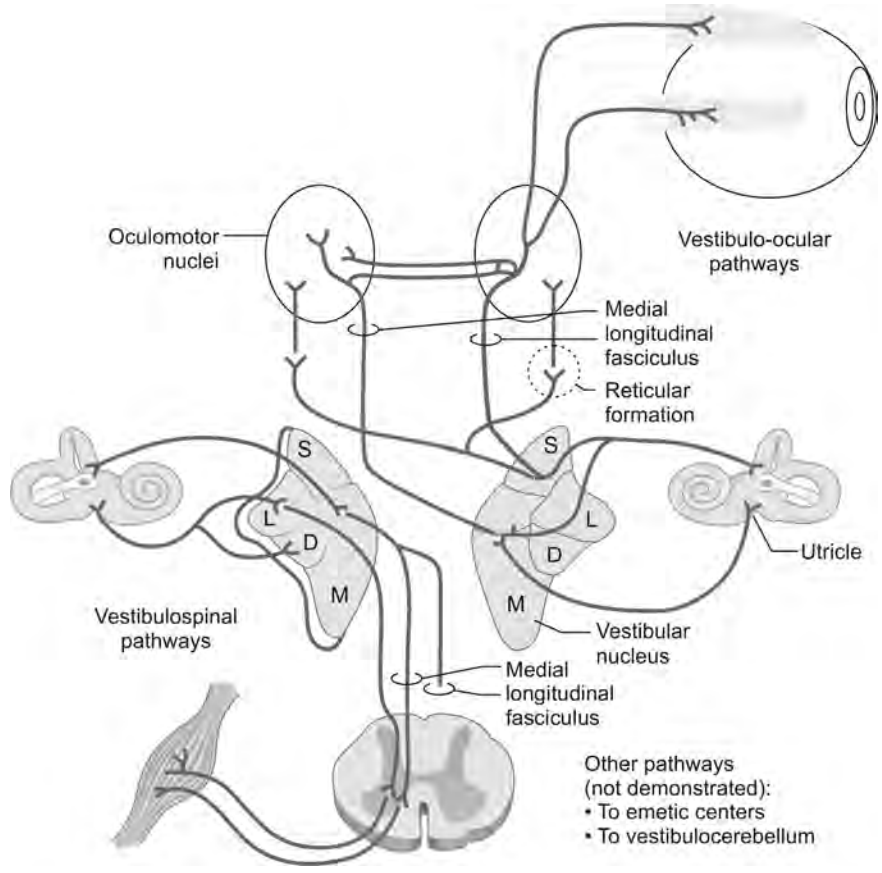

FIG. 2: Central vestibular system.

for conjugate vestibulo-ocular reflex (VOR) mediated by the SCCs. The lateral vestibular nucleus appears to be important for the control of ipsilateral vestibulospinal reflexes. The medial vestibular nucleus, because of it connections with the medial longitudinal fasciculus, appears to be responsible for coordinating eye, head, and neck movements. The descending vestibular nucleus apparently has an integrative function with respect to signals from the vestibular nuclei, the cerebellum, and an amorphous area in the reticular formation postulated to be a region of neural integration. The vestibular nerve in part also directly projects to the phylogenetically oldest parts of the cerebellum—the flocculus, nodulus, ventral uvula, and the ventral paraflocculus, thereby, facilitating smooth pursuits and VOR.

PATHOPHYSIOLOGY

Acute benign paroxysmal positional vertigo (BPPV) patients occasionally complain of persistent symptoms that may be due to repeated triggering symptoms with small, inadvertent head movements or anticipatory anxiety about moving. The main pathophysiology lies in the otolith debris degeneration within the utricle, and the migration of the debris into the SSCs—predominately the posterior canal that causes the manifestation of symptoms.

Meniere's disease is characterized by symptom triad of episodic vertigo and tinnitus with fluctuation in hearing, followed by a symptom-free period. Controversy exists regarding pathophysiology of Meniere's disease. The underlying mechanism is believed to be distortion of the membranous labyrinth resulting from over accumulation of endolymph mainly due to malabsorption, or due to endolymphatic hydrops. Many patients usually have endolymphatic hydrops, the reverse is not always true.

Few reversible causes include noise, toxins such as salicylates, viral infections, and immune mediated mechanism. Most of these does not show morphological changes unless they become permanent.

Vestibular neuritis is believed to be an inflammatory disorder selectively affecting the vestibular portion of the 8th cranial nerve. The cause is presumed to be of viral origin [e.g., the reactivation of latent herpes simplex virus (HSV) infection], although other causes of vascular etiology and immunologic in origin have been proposed. The typical presentation of vestibular neuritis is usually with the acute onset of vertigo, nausea, vomiting, and balance problems.

Labyrinthitis is an inflammatory response within the membranous inner ear structures, response to infection. It is generally a short-lived minor illness that has the potential to cause temporary or permanent hearing loss. Other symptoms include nausea and vomiting, pain in the affected ear, vertigo, and fever.

Posterior circulation stroke is another reason for acute onset vertigo along with nystagmus, gait disturbance or imbalance, and other neurological deficits. The main reason is compromised blood flow to brainstem or cerebellar vermis leading to the dizziness.

While epilepsy is commonly accompanied by dizziness or vertigo, vertigo is only rarely caused by epilepsy (Bladin et al. 1998). This arises primarily because vertigo is much more commonly caused by ear conditions.

Epileptic vertigo is thought to be cause by abnormal stimulation of parts of the cortex that represent the vestibular system—parietal, temporal, and frontal cortex. Specific areas include the superior lip of the intraparietal sulcus, the posterior superior temporal lobe, the posteromedial parietal lobe (Wiest et al., 2004), the temporal parietal border regions (Penfield, 1954; Blanke et al., 2000; Kahane et al., 2003), V5 (Laff et al., 2003), and frontal cortex—left middle frontal gyrus (Kluge et al., 2000).

CONCERNING CLINICAL FEATURES

Red flags: Persistent vertigo, progressively worsening symptoms, vertical nystagmus, associated severe headache, diplopia, dysarthria, dysphasia, ataxia, cerebellar signs, cranial nerve palsies, papilledema, fever, vomiting, and skew deviation.

EVALUATION-HISTORY AND PHYSICAL EXAMINATION

A useful strategy may be is to ask the patient to describe their symptoms without using the word "dizzy." As described earlier the first step would be to determine whether the symptom refers to a true vertigo, disequilibrium or unsteadiness, presyncope or light-headedness or psychogenic dizziness.

Rotatory or true vertigo: If the patient describes his dizziness as a clear spinning or rotator sensation, which is precipitated or worsened by head movements or changes in posture, it can be reasonably ascertained to be a true vertigo. It is inconsequential whether the sensation is of oneself spinning or the surroundings spinning. The patient may also complain of a feeling of being pushed backward or being tilted to one side. The sensation of spinning is also aggravated by turning the head or neck, e.g., looking up or down or turning to one side while lying in bed. Most of these symptoms are likely to be due to a disorder of the vestibular lesion, either peripheral or one of its central connections.

Disequilibrium or imbalance or unsteadiness: This is a feeling of loss of balance, or being unsteady on one's feet. It is typically noticed when a person walks or attempts to walk, and is aggravated by walking on uneven ground or in the dark. There is no spinning sensation, just a feeling that the person will fall or lose balance. Various causes include, bilateral vestibular failure, cerebellar disorders, Parkinsonian disorders, myelopathies, and neuropathies. A diagnosis of the cause of balance disorder can be made by enquiring carefully into certain specific issues, such as worsening of unsteadiness on closing eyes or walking into a dark room, or on keeping feet on different steps or a slowness of activities or a shooting pain down the back on flexing the neck. Also, evidence of oscillopsia when walking (bilateral vestibulopathy), oscillopsia when looking to either side (typical of downbeat nystagmus), slurred speech, slowness of activities, and numbness over the extremities, can also give a clue to the underlying condition that has resulted in imbalance.

Presyncope/Light-headedness/Faintness: A syncope will result in loss of consciousness. However, if a patient has a milder form, namely a presyncope, he usually experiences dizziness. This is an effect of compromised cerebral circulation usually secondary to cardiovascular causes. Typical symptoms include a sensation of feeling faint as if he may pass out, a curtain like darkness falling in front of the eyes or voices and sounds coming from a distance and usually occurs when the patient suddenly stands after he has been sitting or squatting for a long time. On occasions similar symptoms can be noticed on excessive emotional stress, cough, and micturition known as vasovagal syncope. In such situations, it is prudent to record the blood pressure in both, supine and standing posture, to rule out orthostatic drop in blood pressure.

Psychogenic dizziness: As described earlier, it may be due to psychogenic factors, such as stress, depression or anxiety. The symptoms usually are nonspecific, such as tingling or numbness or an inability to think clearly. However, on occasions there may be a tendency on the part of the physician to miss the above three categories and state a diagnosis of psychogenic dizziness. One must remember this is a diagnosis of exclusion and other causes must be adequately ruled out, before calling dizziness "psychogenic."

For the sake of brevity, we will restrict ourselves to the history that pertains to true vertigo. Once a diagnosis of rotator or true vertigo has been made it is imperative to distinguish between peripheral and central causes (**Table 2**) and also to narrow down the differential diagnosis based on the duration of the episode of vertigo. **Table 3**. History also be asked about whether acute onset of vertigo (**Table 4**) or recurrent vertigo (**Table 5**) and further causes can be narrowed down.

Accompanying central symptoms: Central symptoms if present, such as diplopia, dysarthria, dysphonia, dysphagia, dysesthesia, and limb ataxia or weakness would unequivocally point to a central disorder. Significant headache could herald the presence of a central cause like vestibular migraine or sometimes even more sinister cause like dissection of the vertebral artery.

TABLE 2: Distinguishing features of between peripheral and central causes.

Feature	*Peripheral*	*Central*
Nystagmus	Commonly combined (horizontal and torsional), Inhibited by fixation of eyes on to object, does not change direction with gaze to other side	Purely vertical, horizontal or torsional, and not inhibited by fixation of eyes on object, may change direction with gaze toward fast phase of nystagmus
Imbalance	Mild-to-moderate, generally able to walk	Severe, not able to walk or stand sometimes
Nausea and vomiting	Commonly severe	Varies
Hearing loss and tinnitus	Common	Rare
Neurological (no auditory)	Rare	Common
Latency followed by provocative maneuver	Up to few seconds	Up to 5 seconds

TABLE 3: Typical duration of symptoms for different causes of vertigo.	
Duration	***Suggested diagnosis***
A few seconds	*Peripheral cause*: Unilateral loss of vestibular function, vestibular neuronitis—late stage, and Meniere's disease—late stage
Seconds to minutes	BPPV and perilymphatic fistula
Minutes to hours	Posterior circulation TIA and perilymphatic fistula
Hours	Meniere's disease, perilymphatic fistula, migraine, and acoustic neuroma
Days	Acute vestibular neuronitis, stroke, migraine, and multiple sclerosis
Weeks	*Psychogenic*: Persist for weeks without improvement

(BPPV: benign paroxysmal positional vertigo; TIA: transient ischemic attack)

TABLE 4: Common causes of acute onset and prolonged vertigo.			
	Clinical history	***Examination***	***Management***
Vestibular neuritis	Acute or subacute onset of rotatory vertigo	Peripheral vestibular spontaneous nystagmus and pathological head impulse test	• Brief course of high dose steroids • Vestibular rehabilitation
Labyrinthine concussion	Onset after blow to head, hearing loss and tinnitus, symptoms of brain concussion	Hearing loss, possible blood or cerebrospinal fluid in ear canal	Vestibular rehabilitation
Lateral medullary infarction	Vascular risk factors, sudden onset, facial numbness and weakness, diplopia, dysphagia, and lateropulsion	Ipsilateral Horner's syndrome, facial numbness, lack of coordination, decreased gag reflex, and contralateral numbness in limbs	• Thrombolysis • General management of stroke • Control of vascular risk factors • Gait and balance training
Cerebellar infarction	Cardiac disease, vascular risk factors, sudden onset profound imbalance, and possible lack of limb coordination	Central ocular motor disturbance, gait and/or limb ataxia	• Thrombolysis • Secondary prophylaxis of stroke • Control of vascular risk factors • Gait and balance training

TABLE 5: Common causes of recurrent vertigo.			
	Clinical history (in addition to nausea, vertigo, and vomiting)	***Examination (between attacks)***	***Management (in addition to treatment of symptoms)***
Meniere's disease	Fluctuating hearing loss, ear fullness, roaring tinnitus, and possible sudden falling spells (otolithic crises)	Hearing loss (unilateral in most cases) and impaired vestibular function	• Betahistine in a high dosage and long-term treatment • Rarely transtympanic gentamicin or steroids
Autoimmune inner-ear disease	Fluctuating and slowly progressive hearing loss, may be systemic symptoms of autoimmune disease	Hearing loss (bilateral in many cases), interstitial keratitis, arthritis, and rash	High dose steroids
Perilymph fistula	"Popping" sound, hearing loss, or tinnitus after head trauma, barotrauma, cough, sneeze, straining, etc.	Possible positive fistula sign (nystagmus induced by pressure change in external ear canal)	• Avoidance of straining • Explore ear if symptoms persist
Vestibular migraine	Headache, other aura, numbness, motion sensitivity, dysphagia, and lateropulsion	Minor ocular motor dysfunction	• Beta blocker • Topiramate • Valproic acid

Triggers, aggravating, and relieving factors: It is important to take cognizance of what triggers an attack, what worsens it, and what relieves it. Dizziness precipitated by positional changes, looking up or down, or turning sideways in bed is usually due to BPPV. Loud noise or pressure changes may suggest superior canal dehiscence or labyrinthine fistula or sometimes even Meniere's disease. Recent viral infection may precede viral neuritis and a history of anxiety may suggest hyperventilation as a cause for vertigo.

Drug history: Certain drugs such as aminoglycoside antibiotics, diuretics, antidepressants, alcohol, and antipsychotics can all cause vertigo and a careful history should be taken to rule out an iatrogenic cause.

Clinical Examination

- Check for nystagmus
- Check skew deviation
- Head impulse test (HIT)
- Cranial nerve examination
- Cerebellar function testing
- Gait
- Some special tests

HiNTS examination: The HiNTs examination is a screening tool for distinguishing a central cause of vertigo from an acute peripheral vestibulopathy (APV), such as BPPV or vestibular neuritis and is particularly useful in an ED setting.

Nystagmus: The clinical examination for giddiness starts with, checking for nystagmus in each eye separately. By covering the nontesting eye, or shining a pen light on the testing eyes intermittently nullify visual fixation. Absence of nystagmus in a patient with no visual fixation essentially rules out a vestibular cause for the dizziness. Note, if it is present in primary gaze (i.e., looking straight ahead) and or in lateral gaze. What direction is the fast component? If the nystagmus is worse looking in one direction, with the fast component present in that same direction on contralateral gaze, it is unidirectional and reassuring for peripheral vertigo. If, for example, a patient has right-beating (fast direction to the right) nystagmus with rightward gaze and leftward gaze, this is unidirectional right-beating nystagmus. The most common peripheral nystagmus, BPPV, in the posterior SSC consists of a unidirectional horizontal nystagmus with a torsional component. Bidirectional nystagmus, i.e., fast component to the right with rightward gaze and to the left with leftward gaze, is concerning for a central process, as is vertical nystagmus or pure torsional nystagmus.

Skew deviation: Once nystagmus is tested look for skew deviation. Skew deviation (a vertical misalignment of the eyes due to imbalance in the gravity sensing pathways) is not sensitive (30%) but is specific (98%) for a brainstem lesion. To test this the patient has to look directly at the examiner's nose, while the physician alternately covers the right and left eye, alternately back and forth, approximately every 2 seconds. In patients with skew deviation, each time the covered eye is uncovered, there is a slight vertical correction (1 side corrects upward and the other corrects downward). The amplitude of correction is small—1–2 mm, therefore, it is key for the examiner to focus on one eye, rather than following the both eye. A normal response is no vertical correction, and an abnormal response should be considered a stroke in patients with an acute vestibular syndrome (AVS). This can be best appreciated by slow motion video recording with smart phone.

Head impulse test: If nystagmus is truly absent, then this is unlikely to be a vestibular process therefore, HIT is probably not useful and may yield false information.

For testing HIT, ask the patient to sit facing the examiner at the same level. Ensure that the patient does not have any neck issues such as vertebrobasilar insufficiency and neck range of motion is adequate. Ask the patient to keep their eyes focused on a distant target or the tip of the nose of the examiner during the testing procedure and avoid premature eye closure. Now move the head quickly and unpredictably to 10–15° to one side and then rapidly bring back to neutral position, care needs to be ensured to avoid cervical spine injury during the testing. In a normal person, the eyes remain on the target after the examiners movement of the head to one side. In an abnormal response, the eyes are dragged off the target by the turning of the head, called corrective saccade. The corrective saccade indicates a deficient VOR on the same side of the head turn and indicating a peripheral vestibular lesion on the same side. *In other words, the HIT is positive (consistent with peripheral vertigo) if there is a significant lag with corrective saccades*. If you can see the correction, it is abnormal. Compare this to the contralateral side; a difference in the speed of correction should be noted. The horizontal HIT is consistent with peripheral vertigo if it is positive in one direction only. *If there is a lag in corrective saccades in both directions, it may be concerning for central vertigo*. This test can also be performed in the vertical plane. *A lag in corrective saccades in the vertical plane is always suspicious for a central etiology for vertigo*.

Use of video nystagmography can help in the interpretation and accuracy of this test. This test is reported to have a higher specificity (82–100%) than sensitivity (34–39%) In one report, flexing the head forward by 30° during the test increased sensitivity to as high as 71–84%. The absence of a corrective saccade in AVS is consistent with a stroke, and that's why HIT is only useful in patients with the AVS and nystagmus. Occasionally, patients with posterior circulation stroke have a falsely positive (abnormal) HIT, usually from a lateral brainstem infarct involving the location where the vestibular nerve enters the brainstem. These strokes are uncommon and involve the anterior inferior cerebellar artery (AICA) stroke territory or an infarction directly involving the inner ear (labyrinthine stroke) itself. In both situations, hearing is usually acutely lost.

Interpretation of HiNTS Examination

If the HiNTs examination is entirely consistent with peripheral vertigo (positive HIT, unidirectional and horizontal nystagmus, negative test of skew), then, it is 100% sensitive and 96% specific for a peripheral cause of vertigo. However, it must be kept in mind that *all* findings must be present for the HiNTs examination to be invoked. If, for example, the patient has horizontal rightward nystagmus with right gaze and no skew, but has no findings on impulse test, you cannot invoke the HiNTs examination to clear the patient.

Next comes the examination of the cranial nerves and cerebellar function, which targets cranial nerve findings that localize the pathology to the brainstem. This key examination includes testing for pupillary function, facial motor and sensory symmetry, and dysarthria. Specifically, lateral medullary stroke (Wallenberg syndrome), an important cause of the AVS, merits special attention. These patients complain of dysarthria, dysphagia, or hoarseness due to lower cranial neuropathy and may have Horner syndrome with subtle ptosis and anisocoria that may only be evident in dim light (so that the normal larger pupil fully dilates, making the difference in pupil size more apparent). A common physical examination finding is ipsilateral hemifacial with decreased pain and temperature sensation with contralateral hemianesthesia. Routine testing of only light touch can miss this finding.

Cerebellar testing in addition to noting the presence of a scanning speech, also comprises ascertaining the presence of nystagmus (discussed above), along with evaluation of limb/appendicular ataxia, brought out by Finger-Nose or Finger-Finger—nose test and, the heel shin test. If abnormal and unilateral usually indicates an acute and possibly vascular

lesion of the ipsilateral cerebellar hemisphere. Also, truncal, stance, and gait ataxia should be looked into to rule out cerebellar vermian lesions as described below.

While testing for gait ideally, the patient should walk unassisted, but for patients who are too symptomatic to walk, test for truncal ataxia by asking the patient to sit upright in the stretcher without holding onto the side rails. Patient who cannot walk or sit up unassisted is unsafe for discharge. Additionally, an AVS patient who is unable to walk is more likely to have a stroke opposed to vestibular neuritis. Imaging is not infallible in patients with AVS. CT is a poor choice of investigation for posterior circulation stroke. Magnetic resonance imaging (MRI), even with diffusion-weighted imaging (DWI), misses 10–20% of strokes in spontaneous AVS during the first 24–48 hours. In small brainstem strokes, MRI (with DWI) can still miss 50% of the cases when tested within 48 hours. Importantly, 50% of those small strokes were not due to small vessel disease but due to vertebral artery atherosclerosis or dissection. Therefore, in patients with the AVS, the physical examination leads to a correct diagnosis as frequently than imaging.

Dix-Hallpike Test

If BPPV is suspected, it can be safely diagnosed by clinical examination—the Dix-Hallpike test (**Fig. 3**).

The patient is made to sit up straight with the head turned 45° on the side of the ear to be tested. The clinician then lies the patient down quickly with their head hanging past the end of the bed and extending their neck 20°, maintaining the initial rotation of the head. The clinician then watches the patient's eyes for torsional and up-beating nystagmus, which should start after a brief delay and persist for no >1 minute.

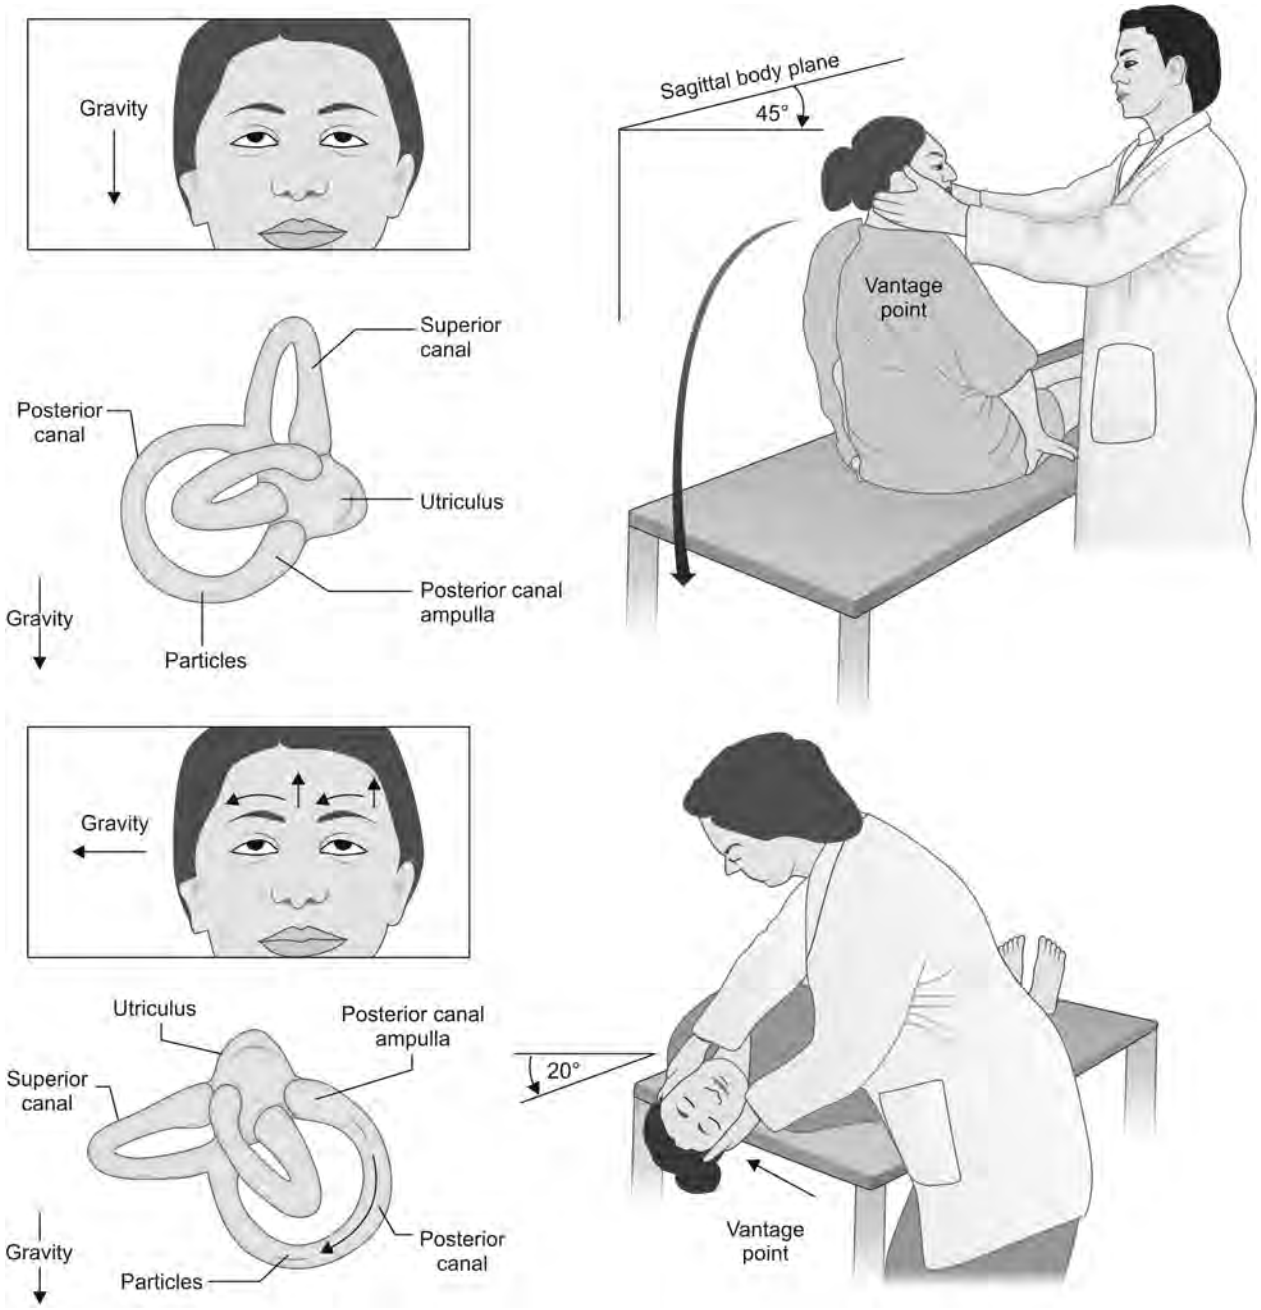

FIG. 3: Dix-Hallpike test.

This would indicate a positive test. If the test is negative but clinical suspicion remains high, the patient should be given a chance to recover for at least 1 minute, and then testing of the other ear can be undertaken. Lateral canal pathology may not be detected by this method, and a supine roll test may be done if this is suspected. Nausea and vomiting are common side-effects and can be avoided by administering prior antiemetics. A down beating nystagmus, nystagmus in different directions on multiple testing, presence of headache, diplopia, and abnormal cranial nerve or cerebellar functions are mostly suggestive of a central pathology. *If Dix-Hallpike test is inconclusive and there is still high degree of clinical suspicion of BPPV, supine roll test can be done.*

Supine Roll Test (Pagnini-McClure Maneuver)

It is done for horizontal canal BPPV. The ideal head position is with the horizontal SSCs in a plane perpendicular to the floor (parallel to gravity). This can be accomplished by tucking the chin 30° forward (either by elevating the back of the head manually, or by placing a supporting pillow under the head) or by inclining the examining table 30° (reverse Trendelenburg position, i.e., with head above feet) (**Fig. 4**). In patients with horizontal canal BPPV, a brisk horizontal nystagmus will develop within a few seconds after turning the head to one or both sides. If the positioning is correct and the BPPV is restricted to the horizontal canal, the nystagmus vector should be purely horizontal. The direction of the nystagmus will differ depending on the location of the pathological otoliths in the horizontal canal (long arm vs. short arm) and the side being tested. Note, that the nystagmus may occur while testing one or both sides, even if the disease is unilateral.

Unterberger's test: Vestibulospinal reflexes can be assessed while standing with eyes closed or on one's toes, and during tandem walking with eyes open and eyes closed as well as during the stepping tests (Unterberger's) eyes close, marching in place for 30 seconds, in which case an imbalance is reflected in excessive turning.

OTHER TEST

Video nystagmography: Any standard procedure for testing for vestibular function should comprise testing for pathological nystagmus, VOR, saccades, and smooth pursuit. A video camera, is used to directly record eye movements, which then interfaces with a digital computer. Saccadic and smooth pursuit eye movements can be digitally and quantitatively evaluated. Ocular pursuit is assessed by asking the patient to follow a moving laser target smoothly. The laser target is moved in sinusoidal pattern. The advantages of video nystagmography, is that it is inexpensive, and does not interfere with vision and does not require head restraint.

Caloric testing: It uses a nonphysiological stimulus to induce endolymphatic flow in the horizontal SCC. The chief advantage of this test is to stimulate each ear individually. This produces a horizontal nystagmus, by creating a temperature gradient from one side of the canal to the other. Each ear is irrigated with water which is 7° lower and 7° higher than body temperature, i.e., 30°C and 44°C respectively. The patient lies in a supine position with head tilted upward to 30°, bringing the horizontal SCC into a vertical plane. Recordings are made with the patient's eyes open behind Frenzel's goggles or in total darkness.

Posturography: The easiest method to record human postural sway uses a so-called force plate, which records the position of a subject's center of mass when upright. With such a device the platform on which the subject stands can be moved simultaneously with the visual surround. A constant angle between the foot and lower leg is maintained by coupling the platform to the sway of the subject, thereby, reducing a major source of somatosensory input to the postural control system. If the subject closes his eyes, or if the movement of the visual enclosure is coupled to body sway, the subject is also deprived of visual information, about postural sway. With this method the influence of the labyrinth on the upright posture through the vestibulospinal system can be studied in an isolated manner.

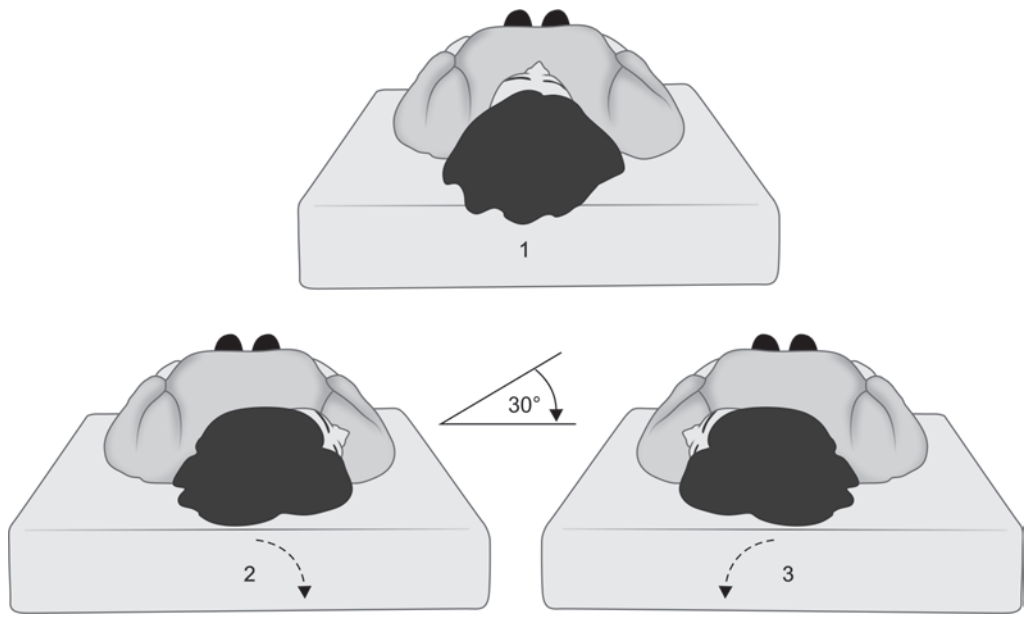

FIG. 4: Supine roll test (Pagnini-McClure maneuver).

It can be used to:

- Differentiate between vestibular, visual, and somatosensory impairments to postural control.
- Differentiate between peripheral sensory and central nervous system (CNS) postural control abnormalities.
- To isolate sensory and motor components of postural instability associated with neurological diseases.
- To document age related changes in balance function, and to differentiate between organic balance problems and a physiologic postural sway.

INVESTIGATIONS

- *Arterial blood gas (ABG):* To look for metabolic, as well as electrolyte abnormalities bedside.
- *Electrocardiogram (ECG):* To rule out cardiac arrhythmia and myocardiac ischemia/infarction.
- *Two-dimensional (2D) echocardiography*: To look for cardiac contractility, wall motion abnormality, and to guide fluid in hypotensive patients.
- *Diffusion weighted (DW) MRI brain:* To rule out stroke.
- *Focused assessment with sonography for trauma (FAST) and extended (eFAST):*
- Complete blood count, C-reactive protein, Liver function test, Blood culture, cerebrospinal fluid studies, 24 holter monitoring

MANAGEMENT

The management begins with supportive care. If stroke is suspected then a neuroimaging study could help in establishing the diagnosis. But as discussed earlier there is certain percentage of chance MRI might miss. While performing MRI patients should be closely observed. If stroke is confirmed to be the cause and the patient presents within 3 hours of onset, thrombolytic treatment can be considered depending upon National institutes of health stroke scale (NIHSS).

A short course of corticosteroids should be considered for patients with vestibular neuritis. After the initial severe symptomatic time period, it is important that patients resume activities because this helps the brain to compensate for the asymmetry of vestibular signals. A formal vestibular therapy program has been shown in a randomized trial to improve outcomes in patients with vestibular neuritis.

Recurrent Positional Dizziness

In case of recurrent positional dizziness, positional testing and particle repositioning improves symptoms. When the patient with posterior canal BPPV is placed in the head-hanging position (Dix-Hallpike test) with the head turned toward the affected side, a burst of upbeat and torsional nystagmus is seen. To reposition the debris Epley maneuver can be done bedside. Success of the maneuver can be confirmed by retesting. If nystagmus continues to be triggered by the Dix-Hallpike test, the Epley maneuver can be repeated.

When the particles are in the horizontal canal, the nystagmus triggered by head movement is a horizontal nystagmus rather than the vertical-torsional nystagmus seen with BPPV of the posterior canal. The nystagmus of horizontal canal BPPV typically lasts longer than posterior canal BPPV. Horizontal canal BPPV can be more difficult to treat than posterior canal BPPV. The repositioning strategy to have the patient roll toward the unaffected side (360°) in 90° increments. Another approach is simply to instruct the patient to lie on the unaffected side for hours, which can be done at home rather than in the ED. *BPPV of the anterior canal* is quite rare. *This cause will also respond to the Epley maneuver. If lateral canal BPPV is diagnosed, it can be managed by Lempert roll maneuver or Gufoni maneuver.*

Epley Maneuver

To begin with, the patient is made to sit up straight with the head turned 45° on the side of the affected ear. Then the patient is made to lie down flat maintaining the position of the head for about 30 seconds. Then the head is suddenly turned by 90° so that the patient is now looking 45° toward the side of the healthy ear. Maintain this position for about 30 seconds, and then roll over to the side of the healthy ear before sitting up (**Fig. 5**).

Gufoni Maneuver

Geotropic type: The patient is taken from the sitting position to the straight side-lying position on the unaffected side for about 30 seconds. Then the patient's head is quickly turned toward the ground at about 45–60° and held in position for 1–2 minutes. After that the patient then sits up again with the head held toward the shoulder on the unaffected side until fully upright and then may be straightened.

Apogeotropic type: The patient is taken from the sitting position to the straight side-lying position on the affected side for about 30 seconds. From this point there are *two variations* of this maneuver that can be done, based on the possibility that debris can be on either the utricular or the canal side of the cupula (or just lodged in the anterior arm of the lateral SSC) (**Figs. 6A** and **B**).

In one variation, the patient's head is then quickly turned toward the ground 45–60° and held in position for 1–2 minutes, which would free the debris from the utricular side of the cupula. The patient then sits up again with the head held toward the shoulder on the unaffected side until fully upright and then may be straightened. In the other variation, the patient's head is turned nose up, 45–60° and held in that position for 1–2 minutes, which would free the debris from the canal side of the cupula (or from being lodged in the anterior arm of the lateral SSC).

Lempert Roll Maneuver

Start from the supine position or from lying on the involved side. Now roll his or her head (or full body) to the unaffected side, and keep rolling in the same direction until his or her head is completely nose down or prone. Some recommend ending the maneuver here and returning to sit (270° roll) as anatomically the debris is repositioned. However, as originally published, complete the final roll (full 360°), and return to sitting position. Hold each position for 15–30 seconds or until nystagmus stops (**Fig. 7**).

Symptomatic Treatment

Patients who present with severe nausea and vomiting typically require intravenous fluids during the ED stay. When drug therapy is necessary to reduce symptoms in the acute setting, generally two different categories of drugs are used: Vestibular suppressants and antiemetics medicines. They

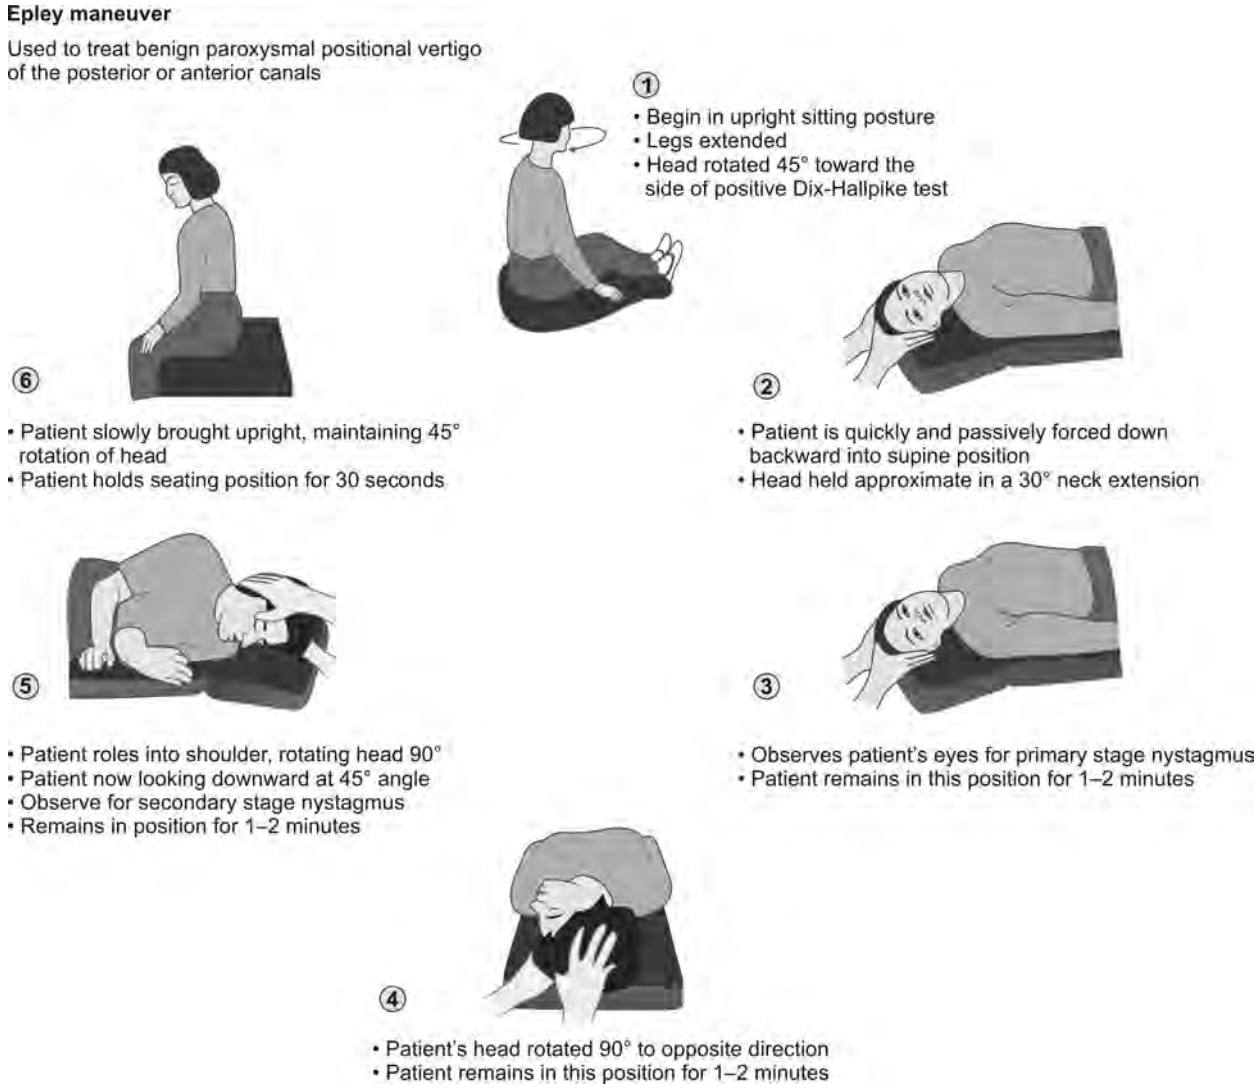
help to symptomatically reduce dizziness in acute attacks, but are generally not effective as prophylactic agents. When taken on a daily basis, the medicines are more likely to result in side-effects or reduce the brain's ability to compensate (as with vestibular neuritis). The major classes of vestibular suppressants include antihistamines, benzodiazepines, and anticholinergics. Most of the vestibular suppressants have anticholinergics or antihistamine qualities, giving them antiemetic properties in addition to the effects on vertigo. A major side-effect of both medicine categories is drowsiness, although this effect probably contributes to the therapeutic effect as well.

Pharmacological Treatment

Benign paroxysmal positional vertigo should not be routinely treated with vestibular suppressant medications such as antihistamines and/or benzodiazepines as there is no evidence in the literature to suggest that any of these vestibular suppressant medications are effective as a definitive, *primary treatment for BPPV or effective as a substitute for repositioning maneuvers*. Benzodiazepines have anxiolytic, sedative, muscle-relaxant, and anticonvulsant properties derived from potentiating the inhibitory effect of the gamma-amino butyric acid system. In prolonged dizziness, these medications can reduce the subjective sensation of spinning but also can interfere with central compensation in peripheral vestibular conditions.

Antihistamines, however, appear to have a suppressive effect on the central emetic center to relieve the nausea and vomiting associated with motion sickness. Other medications that are often used for motion sickness include promethazine, which is a phenothiazine with antihistamine properties, and ondansetron, which is a serotonin-5HT3 antagonist. Last, anticholinergic medications, such as scopolamine, block acetylcholine, and a widespread CNS transmitter, can help with motion sickness by reducing neural mismatching.

Conversely, vestibular suppressant medications have the potential for significant harm as they may produce drowsiness, cognitive deficits, and interference with driving or operating machinery. Benzodiazepines significantly increase the risk for falls. The risk of falls increases in patients taking multiple medications. Benzodiazepines and antihistamines interfere with central compensation for a vestibular injury. The use of vestibular suppressants may obscure the findings on the Dix-Hallpike maneuvers. In addition, there is evidence of additional potential harm from the antihistamine class of medications on gastrointestinal motility, urinary retention, vision, and dry mouth in the elderly.



Epley maneuver
Used to treat benign paroxysmal positional vertigo of the posterior or anterior canals
1
• Begin in upright sitting posture
• Legs extended
• Head rotated 45° toward the side of positive Dix-Hallpike test
2
• Patient is quickly and passively forced down backward into supine position
• Head held approximate in a 30° neck extension
3
• Observes patient's eyes for primary stage nystagmus
• Patient remains in this position for 1–2 minutes
4
• Patient's head rotated 90° to opposite direction
• Patient remains in this position for 1–2 minutes
5
• Patient roles into shoulder, rotating head 90°
• Patient now looking downward at 45° angle
• Observe for secondary stage nystagmus
• Remains in position for 1–2 minutes
6
• Patient slowly brought upright, maintaining 45° rotation of head
• Patient holds seating position for 30 seconds

FIG. 5: *Continued*

Continued

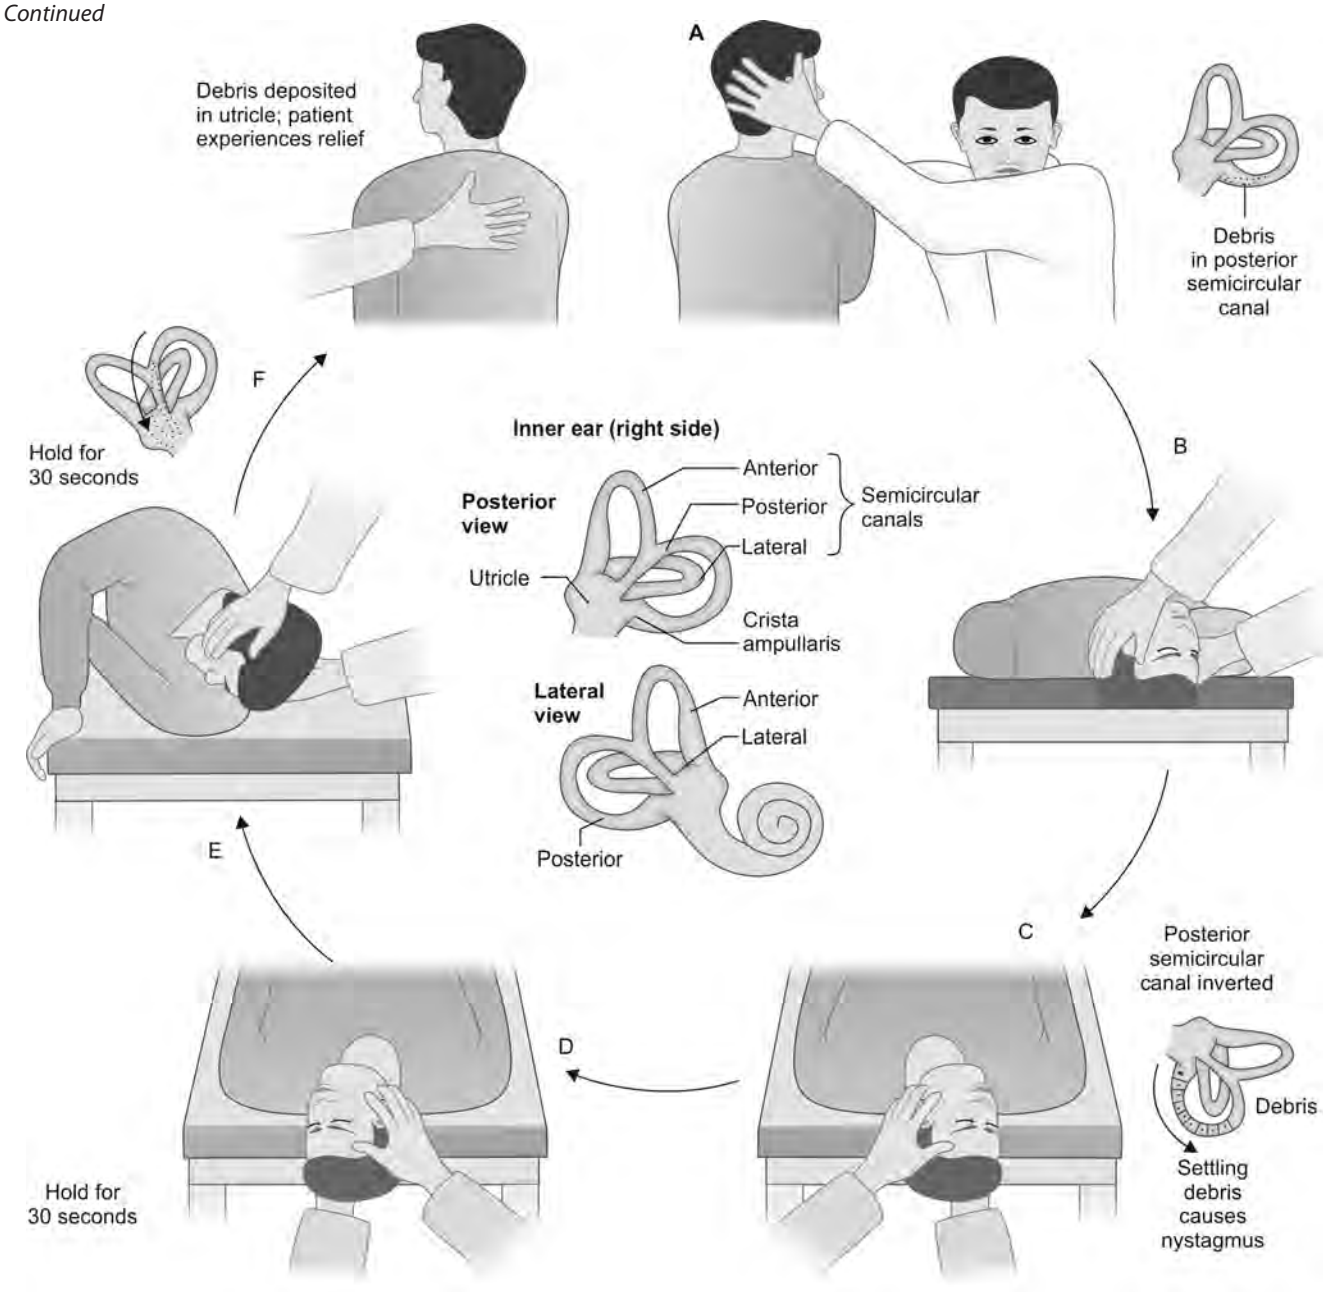


FIG. 5: Epley maneuver.

Particle repositioning maneuvers should be done for BPPV. In patients with severe symptoms, drugs should be prescribed for short durations. Patients should be counseled regarding the disease process, reassured, and encouraged to go back to regular work as soon as possible so as the central compensation can take place. For the central and systemic causes of dizziness and vertigo, treatment should be aimed at the specific cause. Patients should be adequately followed up for assessing response to therapy or treatment failure.

SUMMARY

Dizziness, vertigo, and unsteadiness are common complaints caused by numerous diseases. Therefore, diagnosis can be difficult, leading to overutilization of resources and misdiagnosis. Dizziness can be a problematic presentation in the emergency department, both from a diagnostic and a management point of view. Dizziness is one of the most common reasons for presentation in emergency department for an evaluation. Symptoms can be vague, inconsistent, or unreliable and overlapping among the many potential causes. Accurate and efficient, history, and physical examination more likely to result in a specific diagnosis. The ability of emergency physician to identify the key features of the most common benign peripheral vestibular disorders as well as red flags allows to sort through the most common types of dizziness presentations in the emergency department. Approach to patient with acute dizziness vertigo is summarized in **Flowchart 1**.

118 CHAPTER

Altered Mental Status: Delirium

Devendra Richhariya

INTRODUCTION

Synonym: Acute confusion state, acute brain failure, acute organic reaction, and acute encephalopathy.

Altered mental status is common and challenging presentation for emergency physician. Altered mental status can present in all age (pediatric to geriatric) group but more in elderly age group and in about 5–12% of total emergency patient. Altered mental status is considered as disorder of arousal (basic alert and wakefulness) with disturbance in consciousness (awareness, memory, attention, thought perception, and psychomotor behavior). Altered mental status is a nonspecific term used to describe spectrum of brain dysfunction such as delirium, dementia, and psychiatric disorder. Altered mental status clinically present as abnormal behavior, confusion, agitation, hyper alertness, obtundation, stupor and coma. Early differentiation in all three entity and management in emergency department is important. This is very important task of emergency physician to identify acute or chronic changes of mental status.

Delirium is acute onset fluctuation of symptoms, changes in attention, cognitions, and awareness (**Fig. 1**). Delirium associated with highest morbidity and mortality if missed in emergency department. Dementia is chronic deterioration of cognition with or without behavioral disturbances. If chronic changes and impairment of dementia are not identified it adversely affect the outcome because patient unable to follow the discharge instruction and their histories are also unreliable. Hallucination and delusion may be the common features in altered mental status and psychiatric disorder. This chapter discuss the risk factors etiology approach to managing the altered mental status.

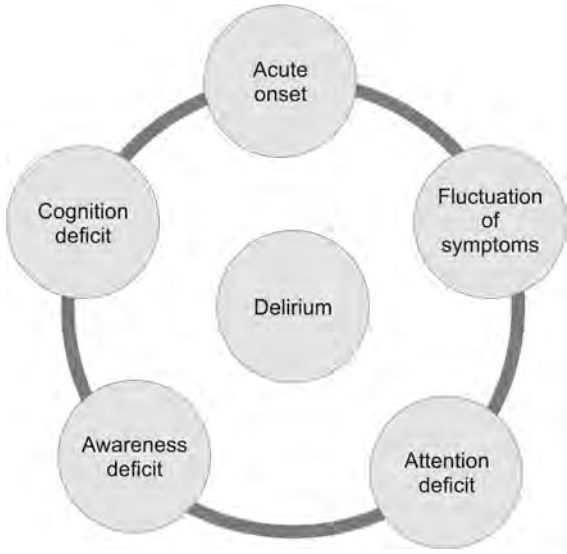

FIG. 1: Clinical components of delirium.

DEFINITION

Delirium is defined as acute onset fluctuating changes in cognition, attention, and awareness, changes are rapid in onset within hours or day and usually reversible. Patient of delirium typically present as inattention, disorganized thinking, perception disturbance, and altered conscious level (somnolent or agitated). Elderly group are increased risk (**Box 1**) of mortality if delirium is missed in emergency department.

BOX 1: Risk factors for acute confusional state.

- Elderly male
- Multiple comorbidities
- Advance form of comorbidities
- Previous episode of delirium
- Advance dementia
- Chronic kidney disease
- End-stage liver disease
- Postoperative status such as recent hip fracture
- Conditions like burn hypoalbuminemia dehydration
- Malnutrition infection AIDS
- Multiple medications and dependence such as benzodiazepine
- Alcohol abuse or withdrawal
- Socially neglected stressful people
- Visual or hearing problem
- Poor mobility terminally ill
- Prolong intensive care unit admission

(AIDS: acquired immunodeficiency syndrome)

About 70–80% of delirium are missed in emergency department due to time pressure or not recognized due to subtle nature and if admitted also be missed in hospital setting. It is very crucial to avoid missed diagnosis in understanding about subtype of delirium in hyperactive, mixed, and hypoactive form.

SUBTYPE OF DELIRIUM

In its *hypoactive form* patient present with lethargic condition while in *hyperactive form* patient will be agitated, restless, anxious, and in *mixed* variety fluctuation of symptoms occurs. Morbidity and mortality are high, if this condition remain untreated or missed in emergency department either due to its subclinical nature of the disease or due to work load and also raises serious issue related to quality of the care. Patient with hypoactive symptoms like lethargy and elderly people are prone for "missed diagnosis" in emergency department. Patients with delirium are vulnerable and may not cooperate with the staff so emergency physician should focus on maintaining airway, breathing, circulation vitals, and normal blood sugar level.

RECOGNIZING THE DELIRUM

In view of high morbidity and mortality in missed cases of delirium and varied and fluctuation clinical presentation it is important to understand the disease course and various assessment as well as diagnostic tools for delirium.

Clinical Presentation

Delirium is acute or subacute onset with fluctuation of symptoms and start with irritability and disturbance in sleep cycle (day time sleep), bizarre behavior, hyperalertness, and confusion. Most of the time family members are the first one who notice the confusion. Other clinical features are clouding of consciousness, reduced level of alertness and arousal, deficit in attention and awareness and concentration, disorientation for time and place, short-term memory deficit, hallucination, illusion, agitation, asterixis, unsteady gait, and tremors.

There are several tools available for assessment of confusion in emergency department. AVPU simplest scale which stands for alertness response to verbal and painful stimuli and unresponsiveness. There is no assessment of "response to painful stimuli" so limited usefulness of this scale. *Richmond agitation sedation scale (RASS) and Glasgow coma scale (GCS)* described 40 years ago and are most familiar among physicians.

Confusion assessment methods: First described by Inouye and colleagues in 1990 based on the *diagnostic and statistical manual of mental disorders revised 3rd edition* (DSMIIIR) criteria, helpful for nonpsychiatric trained physician to diagnose delirium quickly and accurately. Confusion assessment methods (CAM) consists of four components: (1) acute onset mental status changes fluctuating course; (2) Inattention; (3) disorganized thinking and; (4) altered level of consciousness. First two components are mandatory and either of two from rest of two necessary for diagnosis of delirium.

Differentiating Delirium from Psychiatric Illness

Another important concern is to differentiate delirium from psychiatric illnesses as most of the causes of delirium are reversible if identify and treated urgently. One should not be confused with the presence of history of psychiatric illness because many medical conditions exacerbate the underlying psychiatric illness and make the situation more complex and here effective management depends on the high index of suspicion. Some differentiating points of delirium from dementia and psychiatric illness are shown in **Table 1**.

PATHOPHYSIOLOGY OF DELIRIUM

Pathophysiological mechanism of the delirium is complex and related to various neuronal connectivity and trigger factors. Various triggers such as stroke, major surgery, and medications substance abuse or withdrawal can activates/inhibits various neuronal transmitters in response and give rise to various symptoms (**Fig. 2**).

ETIOLOGY

Very important for the emergency physician to identify the systemic and life-threatening cause of acute confusional state and manage urgently. Emergency physician should be able to identify life-threatening causes such as hypoxia, hypoglycemia stroke, hypertensive encephalopathy, Wernicke

TABLE 1: Differentiating delirium from dementia and psychiatric illness.

Features	*Delirium*	*Dementia*	*Psychiatric illness*
Onset and course	Acute (hours-to-days) fluctuating	Insidious (months-to-years) progressive	Acute or insidious progressive/chronic
Vitals	Abnormal	Normal	Normal
Attention	Abnormal	Normal (except in severe dementia)	Normal
Cognition	Abnormal	Abnormal	May be abnormal
Orientation	Abnormal	Often abnormal	May be abnormal
Reversibility	In most of cases	Irreversible	Usually not
Hallucination	Visual ± auditory	Absent	Auditory
Delusion	Transient	Absent	Continuous
Movements	Asterixis tremor may present	Absent	Absent

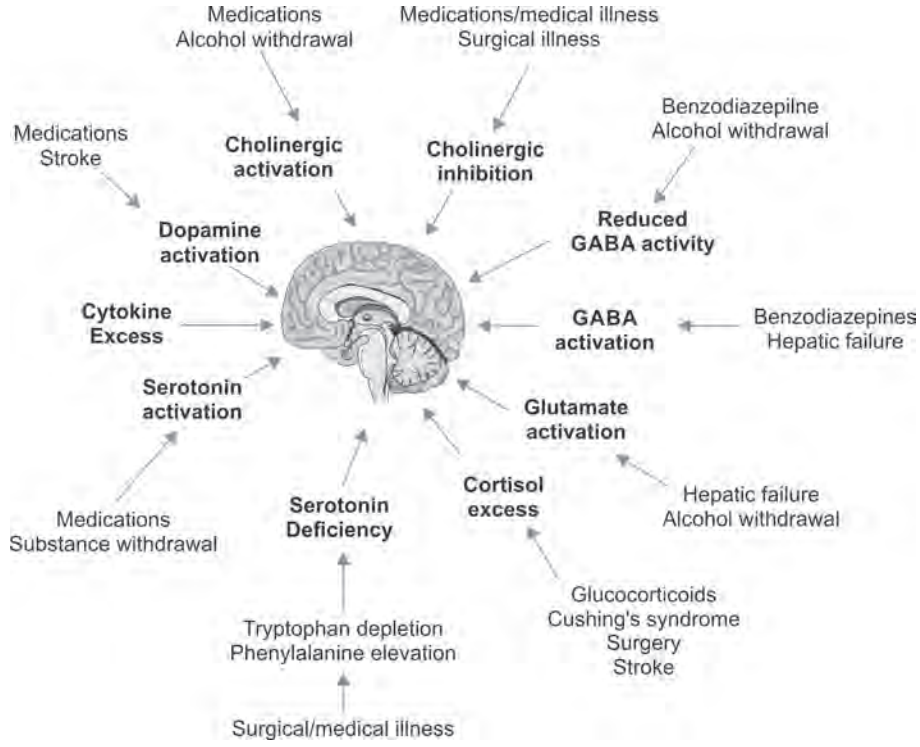

FIG. 2: Pathophysiology of delirium.
(GABA: gamma-aminobutyric acid)

encephalopathy, meningitis/encephalitis, status epilepticus, and poisoning and treat them on priority basis. Other systemic causes should also be ruled out (**Table 2**).

TABLE 2: Etiology of delirium.

Systemic	Infections including urinary tract infection, malaria, pneumonia, sepsis, inadequate pain management, trauma (head injury) dehydration, hypothermia, and hyperthermia
Metabolic	Hypoxia, hyponatremia, hypoglycemia, hyperglycemia, renal, hepatic, thyroid dysfunction, thiamine B_{12}, and nicotine deficiency
Central nervous system	*Stroke*: Ischemic/hemorrhagic, subarachnoid hemorrhage, subdural/ epidural hematoma, meningitis, encephalitis, seizure, and postictal state migraine space occupying lesion brain tumor brain abscess
Cardiac system	Acute myocardial infarction, heart failure, and cardiogenic shock
Medications	Benzodiazepine, morphine, steroid, antiepileptics, antiparkinsonism, and anticholinergics
Toxic substance	Alcohol intoxication or withdrawal, substance misuse or withdrawal, and carbon monoxide poisoning
Others	Postoperative state urinary retention, bladder catheterization and physical retrain

EVALUATION

Immediate Steps

Put the patient on monitoring device so that vital signs are recorded immediately and airway, breathing, and circulation can be assessed and ringer lactate can be started if poisoning is suspected for circulatory support. Abnormal vital signs in nonagitated patient is a dangerous sign and indicates systemic illness. Use the point of care testing to identify the life-threatening cause immediately such as random blood sugar, blood gases, and electrocardiogram (ECG).

History

Taking history in these patients are difficult as patients are often confused and disoriented. In most of the patients' history alone gives the diagnostic clues so emergency physician should obtain the information through previous medical records, family members, and friends. History of fever, headache, suicidal tendency fall or trauma, alcohol use or any substance abuse should be recorded.

Elderly are more vulnerable for acute confusional state/ delirium so emphasis should be given on their medication chart and recent changes done in medication doses. Important drugs that causes acute confusional state/delirium need screening are benzodiazepines, opiates, antidepressants, muscle relaxants, anticholinergics, and sympathomimetics. Anticholinergic group of medication, narcotic, and benzodiazepines are the drugs which commonly precipitate delirium especially in elderly group of population. Promethazine, diphenhydramine, hydroxyzine, lomotil, meclizine, amitriptyline, and doxepin are the drugs with anticholinergic properties and generally prescribed to elderly.

Generally, elderly population with comorbidities are on multiple drugs regimens so while evaluating the delirium in emergency department it is mandatory to check the medication

list regarding recent addition of any culprit medication or dose modification. Emergency physician should take help of **Table 3** to identify the medications/substances.

Physical Examination

Head, eyes, ears, nose, and throat examination, neck examination for stiffness, cardiovascular and respiratory examination for any murmurs or abnormal lung sounds, abdominal and genitourinary examination, and neurological examination: GCS score and asterixis can be seen in hepatic encephalopathy.

Laboratory and Radiology Tests

Appropriate laboratory and radiological tests should be carried out to confirm the suspected conditions. Complete hemogram, kidney function test, liver function test, thyroid function test, and arterial blood gases interpretation are the basic investigations. Electrocardiograph and cardiac enzyme should be performed urgently if any cardiac event is suspected. Chest X-ray will be helpful in identifying the lung pathology.

Computed tomography (CT) head is not indicated in all cases of acute confusional states but more helpful in elderly group of patients, and or on anticoagulation history of trauma immunocompromised patient noncontract CT head is usually sufficient. Lumbar puncture and cerebrospinal fluid (CSF) examination should be considered in patient with fever and confusion. Urine drug screen should be used cautiously due to false positive and negative results. Recommended laboratory and radiology tests are summarized in **Table 4**.

MANAGEMENT

Management of Agitation

Physical or chemical restrains of patient are required whenever there is possibility of "self-harm" and agitated behavior dangerous to hospital staff. Close observation of patient is required to record changes in tone, speech, irritability, clinched jaw, and fist for intervention at the right time. Physician must record the GCS before applying any measures for agitation control. Medications used for chemical restrain are haloperidol (antipsychotic agent)/lorazepam. Few characteristic features of commonly used haloperidol and lorazepam are described in **Table 5**.

Drug Therapy

Haloperidol is commonly used first line medication for delirium. *Haloperidol* given in 2–5 mg intramuscular. *Olanzapine*: 2.5–5 mg orally once a day. *Risperidone* 0.5 mg orally twice daily. *Quetiapine* 12.5–25 mg orally twice daily,

TABLE 4: Laboratory and radiological tests for evaluation of acute confusional state.

Laboratory and radiology investigations	*Clue about causes of acute confusional state/delirium*
Complete hemogram	Acute anemia, (hemorrhage), leukopenia, leukocytosis, (infection), thrombocytosis, and thrombocytopenia
Kidney functions and electrolytes	• Hyponatremia, hypoglycemia, and hyperglycemia, • Acute kidney injury and uremia
Liver functions test and ammonia levels lipase	Jaundice, hepatic failure, hepatic encephalopathy, and pancreatitis
Thyroid function test	Myxedema or thyroid storm
Arterial blood gases	Hypoxia, hypercarbia, and metabolic acidosis
ECG	Myocardial infarction, arrhythmias, and drug toxicity
Cardiac enzyme	Myocardial infarction
Chest X-ray	Pneumonia, pulmonary edema, and heart failure
CT abdomen	Appendicitis, pancreatitis, and obstructive uropathy
Noncontrast CT head	Stoke, mass, and lesion
Lumber puncture and CSF examination	Meningitis and encephalitis

(CT: computed tomography; CSF: cerebrospinal fluid; ECG: electrocardiogram)

TABLE 3: Medication/toxidrome and their systemic effects.

Drugs	*Effects*	*Clinical features*
Alcohol benzodiazepines	CNS depression	Decrease motor activity hypotension
Alcohol benzodiazepines withdrawal	Agitation, excitation, and hallucination	Sweating, tachycardia, and mydriasis
Opiates	Sedation	Hyperventilation and miosis
Opiates withdrawal	Anxiety	Nausea, vomiting, and tachycardia
Cholinergic	CNS depression	• Salivation, lacrimation, urination, bradycardia, and miosis are muscarinic effects • Hypertension, tachycardia, and fasciculations are nicotinic effects
Anticholinergics	Agitation and coma	Tachycardia, flushed and dry skin, dry mucus membranes, hyperthermia, decreased bowel sounds, urinary retention, and mydriasis
Sympathomimetics	Agitation, seizures, and coma	Hypertension, tachycardia, hyperthermia, diaphoresis, hyperpnea, and mydriasis

(CNS: central nervous system)

TABLE 5: Characteristic features of haloperidol and lorazepam.

	Haloperidol	***Lorazepam***
Qualities	High-potency antipsychotic, less sedative, and less chances of exacerbation of delirium	Short-acting
Dose	Mild/moderate cases 0.5–2 mg orally twice/thrice daily. Severe cases 2–5 mg IM every 8 hours	0.5–2 mg orally/IM/IV every 2–4 hours
Precautions	Monitor for extrapyramidal symptoms, hypotension, rise in temperature, and CNS depression	Can cause hypoxic cardiac arrest use cautiously in elderly severely ill and patient with low pulmonary reserve myasthenia gravis
Contraindication	Severe depression, comatose, hypersensitivity, and Parkinson's disease	Hypotension, sleep apnea, severe respiratory insufficiency, and CNS depression
Interaction	Raises tricyclic antidepressant, concentration, and hypotensive action of antihypertensive drugs	Raises toxicity when used with alcohol phenothiazine barbiturates

(CNS: central nervous system; IM: intramuscular; IV: intravenous)

is used for hypoactive form of delirium. *Benzodiazepine*: Lorazepam 2 mg intravenous is also used commonly alone or with haloperidol and diazepam is the drug of choice when delirium is suspected due to alcohol withdrawal.

Specific Treatment

Interpret the history, physical examination, laboratory and radiological investigations, and appropriate drug therapy should be started. Withdraw or reduce the drug causing confusion or delirium. Correct electrolyte abnormalities. Antibiotic to treat the infection. Adequate pain management to reduce the agitation.

Supportive Management

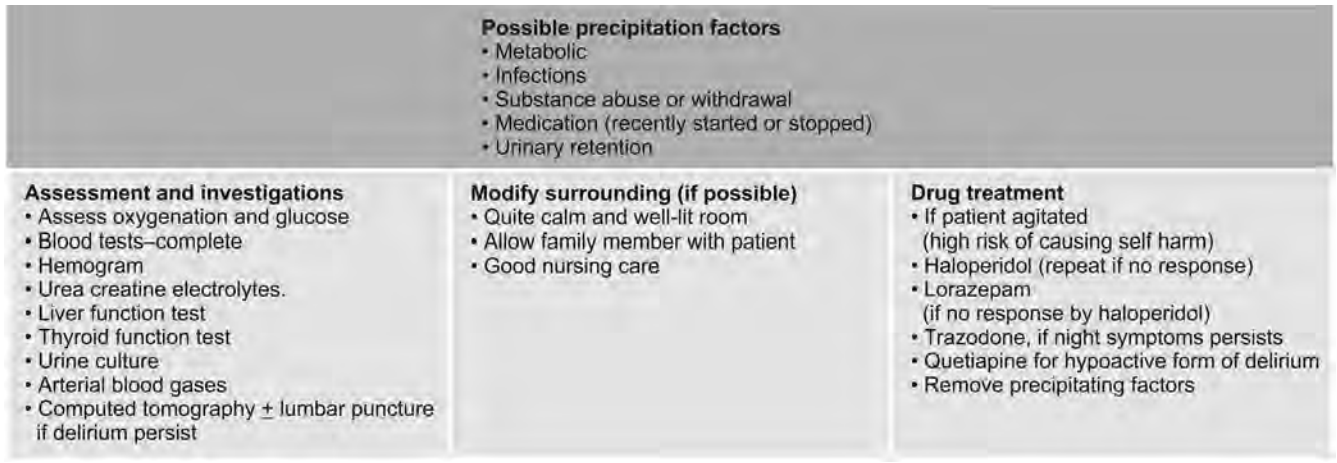
Team of doctor, nurse, social worker, and managers are required to give supportive care. These measures reduce the need of antipsychotics and benzodiazepines drugs. Important measures should be initiated are: Avoid long stay of patient in emergency department. Monitoring device that may irritate the patient should be avoided, vitals can be checked intermittently, and intravenous fluid can also be given intermittently as bolus instead of continuous infusion. False alarm of monitoring devices can also irritate and disorient the patient. Urinary catheters also increase agitation and risk of infection and increase length of hospitalization, there is always risk of traumatic self-removal of catheters. Physical restrain also increases agitation and delirium, use only for brief period if necessary. Arrange adequate lighting of surroundings and presence of family members and close friends. Placing white board/clock/calendar in room displaying date and time for orientation. Increase mobilization by avoiding physical restrain. Minimize sleep disruption provide calm environment. Handle gently. Avoid frequent ward transfers and multispecialty complexity. Provide glasses and hearing aids if necessary. Avoid sedation if possible, they increase confusion and risk of falls.

DISPOSITION

According to various studies acute confusional states/delirium is marker of severity of illness and multiple comorbidities, and also associated with in hospital and long-term mortality. Acute confusional state adversely affects the patient quality-of-life. These patients are more to develop hospital acquired infections, pressure, sore, malnutrition, fractures, and repeated hospitalization. Most of the patients of delirium need hospitalization once they are identified in emergency department. A very few patients can be discharged if closed supervision and monitoring can be arranged at home but frequent hospitalization are reported in these patients.

SUMMARY

Delirium is common in emergency department especially in elderly with comorbid conditions. This nonspecific type of presentation actual has serious underlying pathology. If there is missed diagnosis or delay in management, leads to poor outcome and high in hospital mortality. Confusion assessment method is best tool for emergency department for assessment of delirium. Delirium is acute change in mental status, fluctuation in attention, awareness, and cognition. Physical examination, trauma evaluation, and stroke scale evaluation. Diagnostic evaluation to confirm diagnosis. Treat the underlying cause. Apply supportive and nonpharmacological measures. Haloperidol for hyperactive delirium to control the agitation and quetiapine for hypoactive form of delirium. In view of high morbidity, mortality, and poor outcome, patient should be admitted and managed aggressively. Evaluation and management of delirium is summarized in **Figure 3**.



Possible precipitation factors
• Metabolic
• Infections
• Substance abuse or withdrawal
• Medication (recently started or stopped)
• Urinary retention
Assessment and investigations
• Assess oxygenation and glucose
• Blood tests–complete
• Hemogram
• Urea creatine electrolytes.
• Liver function test
• Thyroid function test
• Urine culture
• Arterial blood gases
• Computed tomography ± lumbar puncture if delirium persist
Modify surrounding (if possible)
• Quite calm and well-lit room
• Allow family member with patient
• Good nursing care
Drug treatment
• If patient agitated (high risk of causing self harm)
• Haloperidol (repeat if no response)
• Lorazepam (if no response by haloperidol)
• Trazodone, if night symptoms persists
• Quetiapine for hypoactive form of delirium
• Remove precipitating factors

FIG. 3: Summary evaluation and management: delirium.

119
CHAPTER

Acute Ischemic Stroke

Chandril Chugh

INTRODUCTION

Stroke is considered as one of the leading causes of morbidity and mortality in the world. As per the World Health Organization (WHO), stroke is defined as rapidly progressing neurological deficits that is vascular in origin. Stroke is classified broadly into three categories; ischemic stroke, hemorrhagic stroke, and subarachnoid hemorrhage. Ischemic stroke occurs due to blockage of blood vessel which limits the blood supply to the brain whereas hemorrhagic stroke occurs due to rupture of blood vessel leading spillage of blood in the intracranial cavity. Hemorrhagic stroke could be classified as intracerebral hemorrhage or subarachnoid hemorrhage depending on the site of blood spillage. Approximately 60–80% of all strokes are ischemic. Assessment and management of patients who have suffered a stroke includes testing to determine the precise etiology of the event so as to prevent recurrence and management of risk factors. Immediate intervention should be applied for minimizing brain injury, treating medical complications, and moving toward uncovering the pathophysiologic basis of the patient's symptoms.

EPIDEMIOLOGY AND RISK FACTORS

According to the WHO, 5 million die and another 5 million are left permanently disabled out of 15 million people who suffer stroke worldwide each year. Worldwide, 68% of all strokes are ischemic and 32% are hemorrhagic. Numbers from the United States of America (USA) differ a little with 87% of all strokes being ischemic, 10% hemorrhagic and about 3% being subarachnoid hemorrhage. Data regarding prevalence of stroke in India is lacking; however, it can extrapolate from the data available from the west. In 2001, crude prevalence rate of stroke in India was 147/100,000 and the annual incidence rate was 36/100,000 as per study done by Banerjee et al.

Men are at higher risk for stroke than women; one-third of strokes occur in persons younger than 65 years, although stroke often is considered a disease of elderly persons. Risk of stroke increases with age, especially in patients older than 64 years, in whom 75% of all strokes occur. Risk factors of stroke are categorized into modifiable and nonmodifiable group (**Box 1**). Patients with cardiovascular disease more prone for embolic ischemic strokes which may arise directly from the heart or the aorta. List of conditions that carry a high-risk for embolic strokes are shown in **Box 2**.

ISCHEMIC STROKE CLASSIFICATION

According to the multicenter trial of acute stroke treatment (TOAST) there are three kinds of ischemic stroke:

1. Large vessel stroke
2. Small vessel stroke or lacunar stroke
3. Cardioembolic stroke

Large artery strokes could be due to thrombotic or embolic occlusion of the major arteries of the brain such as the internal carotid artery (ICA), middle cerebral artery, anterior cerebral

BOX 1: Nonmodifiable and modifiable risk factors.

Nonmodifiable risk factors include:

- Age
- Race
- Sex
- Ethnicity
- History of migraine headaches
- Fibromuscular dysplasia
- *Heredity*: Family history of stroke or transient ischemic attacks (TIAs)

Modifiable risk factors include:

- Hypertension
- Diabetes mellitus
- Cardiac disease
- High cholesterol
- Previous stroke
- Carotid stenosis
- Hyperhomocysteinemia
- *Lifestyle issues*: Excessive alcohol intake, tobacco use, illicit drug use, and physical inactivity
- Obesity
- Oral contraceptive use/postmenopausal hormone use

BOX 2: Risk factors for embolic strokes.

Arrhythmias:
- Atrial fibrillation and paroxysmal atrial fibrillation
- Sick sinus syndrome
- Sustained atrial flutter

Valvular heart disease:
- Rheumatic mitral or aortic valve disease
- Bioprosthetic and mechanical heart valves
- Fibrous nonbacterial endocarditis (i.e., Libman–Sacks endocarditis), antiphospholipid syndrome, and cancer (marantic endocarditis), and systemic lupus erythematosus
- Infective endocarditis

Thrombus and structural lesion:
- Papillary fibroelastoma
- Left atrial myxoma
- Atrial or ventricular thrombus

Structural heart disease:
- Recent myocardial infarction (within 1 month)
- Chronic myocardial infarction together with ejection fraction <28%
- Congestive heart failure with ejection fraction <30%
- Dilated cardiomyopathy

Surgical:
- Coronary artery bypass graft (CABG) surgery

Conditions which have been associated with embolic stroke but lack definitive evidence are mitral annular calcification, patent foramen ovale, left atrial smoke on echocardiogram, atrial septal aneurysm, left ventricular aneurysm, and aortic arch atheroma. Genetic diseases, storage diseases, and traumatic vascular diseases are well known causes of stroke which are beyond the scope of this chapter.

artery or the vertebrobasilar system. Lacunar strokes are more often due to involvement of smaller or perforating blood vessels supplying the deeper structures of the brain.

CLINICAL PRESENTATION

Clinical signs of stroke depend upon the part of the brain involved. American heart association/American stroke association (AHA/ASA) have popularized the FAST algorithm to diagnose stroke in the *prehospital setting*. FAST acronym stands for **F**acial droop, **A**rm weakness, **S**lurred speech, and **T**ime of onset. Another easy way to remember to signs of stroke is the BEFAST method. This method also takes into account the symptoms of the posterior circulation.

BEFAST: **B**alance (loss of balance/dizziness), **E**yes (disturbance of vision in one or both eyes), **F**ace (facial droop), **A**rm (weakness), and **S**peech (slurred) **T**est.

All the symptoms *need not be* present to diagnose stroke. Any of the above-mentioned symptoms can be present and is helpful in diagnosing ischemic as well as hemorrhagic stroke.

For complete assessment of a stroke patient, it is recommended to use the National institutes of health (NIH) stroke scale. According to the latest stroke metrics a patient with acute stroke should be examined by a trained physician or a neurologist within 10 minutes of arrival to the emergency room. Common stroke syndrome and their symptoms are shown in **Table 1**. Common stroke mimics are shown in **Table 2**.

TABLE 1: Common stroke syndrome and their symptoms.

Anterior cerebral artery	• Contralateral motor deficits • Contralateral sensory deficits • Gait apraxia
Middle cerebral artery	• Aphasia (expressive and receptive) • Contralateral motor deficits • Contralateral sensory deficits • Homonymous hemianopia • Neglect
Posterior cerebral artery	• Alexia (inability to read) • Choreoathetosis • Cranial nerve III palsy • Motor deficits • Sensory deficits • Visual disturbances
Vertebrobasilar artery	Ataxia, cranial nerve palsies, coma, dizziness with nausea and vomiting Dysarthria, dysphagia, motor deficits with contralateral sensory deficits
Posterior inferior cerebellar artery (Lateral medullary (Wallenberg's) syndrome)	Ataxia—ipsilateral, contralateral limb with ipsilateral face pain, cranial nerve IX and X palsy, dysmetria, ipsilateral Horner syndrome, nystagmus, and vertigo
Anterior inferior cerebellar artery	Cranial nerves V and VII palsy, ipsilateral Horner syndrome, motor deficit of the face, nystagmus, and vertigo
The five classic lacunar syndromes result from occlusion of a single penetrating artery, which may be caused by small vessel vasculopathy, cardioembolism, or large artery atherosclerosis	• Pure motor—weakness of opposite side of face arm and leg • Pure sensory—sensory loss of opposite side of face arm leg • Sensorimotor—weakness and sensory loss of opposite side of face arm leg • Ataxic hemiparesis—contralateral ataxia out of proportion to mild weakness • Clumsy hand dysarthria—weak face and clumsy ipsilateral hand, dysarthria, and dysphagia

RADIOLOGICAL INVESTIGATIONS IN ACUTE STROKE

Computed tomography (CT): Urgent CT brain under stroke protocol with angiography of head and neck vessels. The most important early imaging test is noncontract CT of the brain. This helps with one of the first branch points of therapy, which is distinguishing hemorrhagic stroke from ischemic stroke. Some hospitals use emergent magnetic resonance imaging (MRI) to evaluate patients with possible stroke, but this is much less common. Rapidly obtaining a noncontract CT of the head should be a priority in working-up the patient with suspected CVA. Head CT is the first and most important test when evaluating for thrombolysis and helps in differentiating

hemorrhage, subdural hematoma, and tumor. On CT, most ischemic strokes eventually become visible as hypodensities of the brain parenchyma, but CT is largely normal for at least 6 hours. The earliest CT signs are loss of the cortical ribbon and gyral edema (**Figs. 1A** and **B**).

Magnetic resonance imaging: On MRI, strokes will appear hyperintense on T2-weighted sequences. Cytotoxic edema and accompanied ischemic cell death can be detected by diffusion-weighted imaging (DWI) and can appear very shortly after onset of ischemia. True diffusion positivity of DWI will appear dark may be delayed up to 48–72 hours, particularly in the brain stem, and typically lasts 10–14 days.

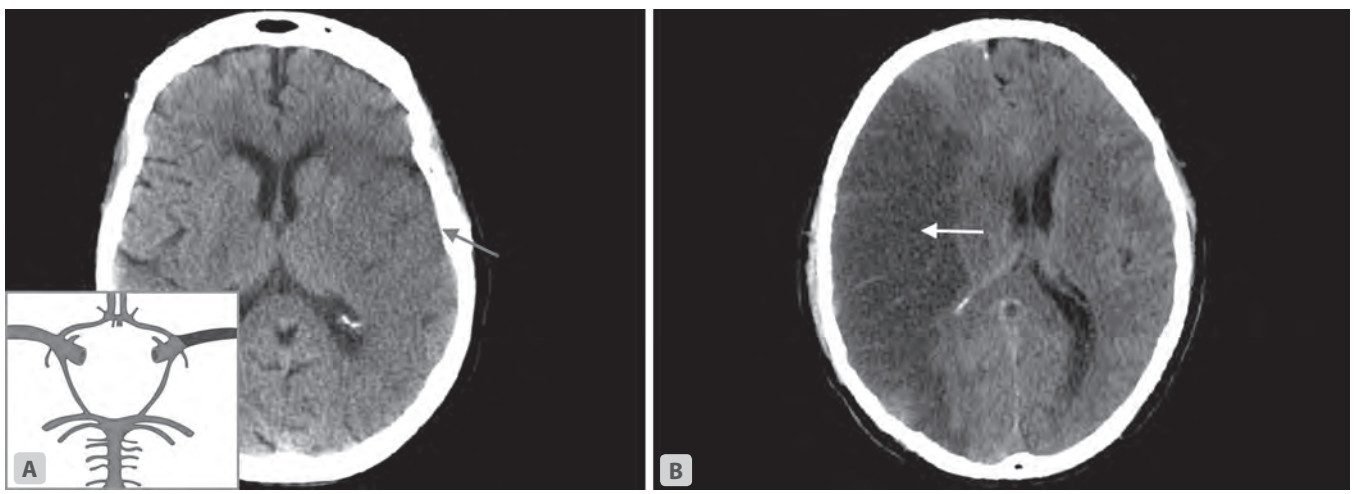
TABLE 2: Stroke mimics.

Toxic-metabolic	• Hypoglycemia or hyperglycemia • Hyponatremia or hypernatremia • Ingestion or overdose • Drug toxicity • Intoxication (alcohol and illicit drugs) • Hepatic encephalopathy
Intracranial hemorrhage	Intracerebral hemorrhage, subarachnoid hemorrhage, and subdural hematoma
Infectious	• Sepsis • Encephalitis • Meningitis
Structural lesions	• Brain mass or tumor • Spinal cord lesion
Others	• Demyelinating disease (i.e., multiple sclerosis), seizure or Todd paralysis • Migraine • Idiopathic intracranial hypertension • Reversible cerebral vasoconstrictive syndrome • Central nervous system vasculitis • Vestibular dysfunction • Hypertensive encephalopathy • Peripheral neuropathy • Dementia • Conversion disorder

Perfusion imaging: Vascular occlusion of the brain causes three-compartment changes in the brain parenchyma and divided into three categories: (1) The infarct core, which represents nonviable brain tissue, which cannot be salvaged; (2) The penumbra, which represents tissue that has reduced blood flow, but the potential for survival if blood flow is restored; and (3) The outer zone, which survives regardless of treatment. Recent endovascular therapy trials utilized perfusion imaging techniques to identify patients with a mismatch between the volume of hypoperfused tissue and the volume of nonsalvageable infarct core.

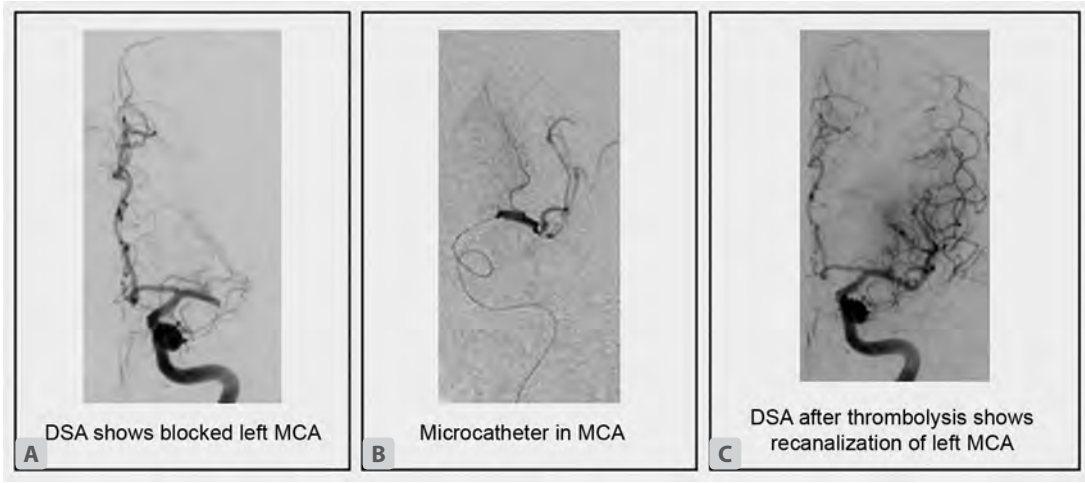
Computed tomography or MRI, both uses the same basic concepts for perfusion imaging. With the help of perfusion imaging we can measure the time for blood to reach brain tissue time to peak of the residual function (Tmax) and mean transit time (MTT) and the amount of blood flowing through the brain vasculature, including capillary and venular flow [cerebral blood volume (CBV) and cerebral blood flow (CBF)]. Tmax is the time it takes the contrast to reach maximum enhancement in the selected region of interest. Time between the arterial inflow and the venous outflow reflected by MTT. CBV is the volume of blood available per unit of brain tissue. CT perfusion uses iodinated contrast whereas magnetic resonance perfusion uses gadolinium to achieve these measurements. The acquisition and processing of perfusion images take time and expose patients to additional iodinated contrast and radiation.

Digital subtraction angiography (DSA): This is the most accurate investigation in diagnosing most of the diseases of blood vessel. A small tube (catheter) is guided from the leg blood vessel into the blood vessel we wish to study followed by dye (contrast) injections to obtain the images (**Figs. 2A** to **C**). CT/MR angiography is also an option in some cases.



(CT: computed tomography; MCA: middle cerebral artery)

FIGS. 1A AND B: (A) CT showing early sign of middle cerebral artery with loss of definition of gyri and grey white boundary; (B) CT scan of brain showing MCA infarct.



(MCA: middle cerebral artery)

FIGS. 2A TO C: Digital subtraction angiography in diagnosis of stroke.

MANAGEMENT OF ACUTE STROKE

Time is most important factor in the management of acute ischemic stroke. Patient with ischemic stroke loses 1,900,000 brain cells every minute, about 14,000,000,000 nerve connections are destroyed every minute, and 12 km (7.5 miles) of nerve fibers are lost every minute. The brain ages 3.6 years for every hour it is deprived of blood supply. Ischemic stroke therapies are cantered on restoring the blood flow in blocked vessels. *There are two modalities of treatment available for treatment of acute ischemic stroke. Intravenous thrombolysis and mechanical thrombectomy*. The only medication currently approved by the Food and Drug Administration (FDA) for acute ischemic stroke is intravenous tissue plasminogen activator (IV tPA), administered within 3–4.5 hours of onset of symptom. Only alteplase is approved for acute stroke thrombolysis.

Concept of thrombolysis: When the blood flow to the brain stops suddenly, brain cells start dying immediately, but few cell in "penumbra" area can survive for few hours with low oxygen or low energy state. If blood flow is restored in this area within window period then these cells can be salvaged and become functional (**Fig. 3**). Favorable outcomes are achieved in 30–50% of cases. Major risk of treatment is symptomatic brain hemorrhage.

Once the clinical diagnosis of an acute stroke is made the following steps need to be followed:

- Ensure that the patient is medically stable.
- Evaluate for reversible causes of neurological symptoms.
- Determine the nature of stroke (ischemic vs. hemorrhagic)
- Treatment of stroke
- Determine the causes of stroke (beyond the scope of this chapter).

Ensure the Patient is Medically Stable: Never Forget the Airway, Breathing, and Circulation

In the treatment of acute stroke time is of the essence. Medical stability of the patient should be established as soon as possible so that stroke management can proceed. Like in every medical emergency airway, breathing, and circulation need to be assessed. Hypoxia should be avoided and corrected

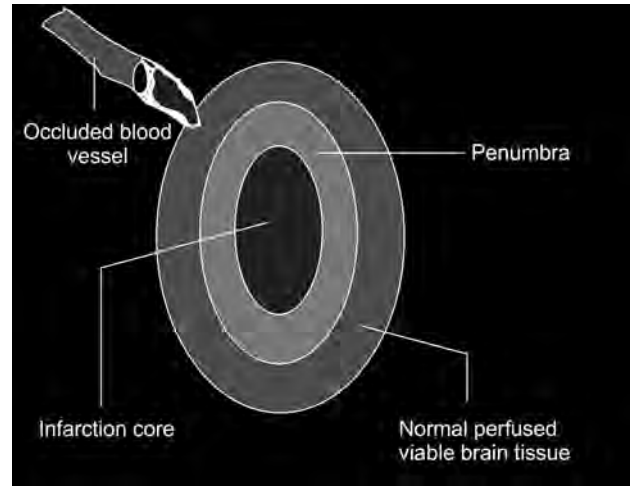


FIG. 3: Concept of thrombolysis (preservation of penumbra).

immediately and if the airway is not protected or the patient needs ventilator support intubation should be considered. Respiratory distress is prominent in large strokes, intracranial hemorrhage, and strokes affecting posterior circulation present with loss of consciousness and bulbar dysfunction.

Evaluation of Reversible Causes of Neurological Symptoms

As per the stroke guidelines of finger-stick glucose it is an essential test before thrombolysis is started. Following basic tests can be considered in special patient groups but the start of thrombolytic therapy if indicated should not be delayed unless the patient has a history of bleeding disorder, is taking anticoagulants or has history of thrombocytopenia. After completion of acute management of stroke other laboratory tests such as liver function, kidney function, etc. can be done.

- Electrocardiogram (this should not delay the noncontract brain CT)
- Complete blood count (CBC) including platelets
- Troponin
- Prothrombin time (PT) and international normalized ratio (INR)

- Activated partial thromboplastin time (aPTT)
- Ecarin clotting time (ECT), thrombin time, or appropriate direct factor Xa activity assay (if the patient is taking new oral anticoagulants)

Determine the Nature of Stroke (Ischemic vs. Hemorrhagic)

First test needed to start stroke treatment is a plain head CT. Head CT without contrast is sufficient to rule out hemorrhage and start stroke treatment. As per the guidelines, systems should be established so that brain imaging studies should be performed within 20 minutes of arrival in the emergency department (ED) in patients who may be candidates for intravenous alteplase and/or mechanical thrombectomy (door to imaging time). Further studies can be conducted depending on the time of onset of symptoms which will further aid in management.

- *If the patient presents within first 6 hours of symptoms onset:* CT scan should be combined with CT angiogram of the brain and the neck to rule out large vessel occlusion, should not wait for serum creatinine results. Whenever possible CT angiogram should be completed with the CT scan to save time for possible mechanical intervention.
  MRI or MR angiogram or MR perfusion is not indicated within the first 6 hours of symptom onset.
- *For patients presenting between 6 and 24 hours of symptom onset:* In selected patients with acute ischemic stroke within 6–24 hours of last known normal who have large vessel occlusion in the anterior circulation, obtaining CT perfusion, diffusion weighted-MRI, or MRI perfusion is recommended to aid in patient selection for mechanical thrombectomy.

INTRAVENOUS THROMBOLYSIS

As recommended by AHA/ASA intravenous tPA infusion is treatment modality of choice for patients presenting within first 3 hours of onset of symptoms. The treatment window can be extended to 4.5 hours for eligible patients. Use of intravenous alteplase is based on the landmark National Institute of Neurological Disorders and Stroke (NINDS) tPA trial which showed that patients who received tPA were at least 30% more likely to have minimal or no disability at 3 months on the assessment scales. Outcome measures were in favor of the group that received tPA [global odds ratio (OR) for a favorable outcome, 1.7; 95% confidence interval (CI), 1.2–2.6]. A pooled analysis of Alteplase ThromboLysis for Acute Noninterventional Therapy in Ischemic Stroke (ATLANTIS), European Cooperative Acute Stroke Study (ECASS), and NINDS was published in 2004 which showed that the tPA window could be extended to 4.5 hours with reasonable benefit to the patient. ECASS-III definitively established the efficacy of tPA within 3–4.5 hours window. ECASS-III showed that patients who received tPA within 3–4.5 hours window had a better chance to a favorable outcome with an OR of 1.42 (95% CI, 1.02–1.98, $p = 0.04$).

Intravenous tPA infusion can only be given to eligible patients and there are strict inclusion and exclusion criteria (**Box 3**) as per stroke guidelines published in 2018.

- The checklist includes some FDA-approved indications and contraindications for administration of intravenous recombinant (IV rtPA) for acute ischemic stroke. Recent guideline revisions have modified the original FDA-approved indications. A physician with expertise in acute stroke care may modify this list.
- Onset time is defined as either the witnessed onset of symptoms or the time last known normal if symptom onset was not witnessed.

BOX 3: Inclusion and exclusion criteria for intravenous tPA infusion.

Inclusion criteria:

- Diagnosis of ischemic stroke causing measurable neurological deficit
- Onset of symptoms <3 hours before beginning treatment
- Aged ≥18 years

Exclusion criteria:

- Significant head trauma or prior stroke in previous 3 months
- Symptoms suggest subarachnoid hemorrhage
- Arterial puncture at noncompressible site in previous 7 days
- History of previous intracranial hemorrhage
- Intracranial neoplasm, arteriovenous malformation, or aneurysm
- Recent intracranial or intraspinal surgery
- Elevated blood pressure (systolic > 185 mm Hg or diastolic > 110 mm Hg)
- Active internal bleeding
- Acute bleeding diathesis
- Platelet count < 100 000/mm^3
- Heparin received within 48 hours, resulting in abnormally elevated aPTT greater than the upper limit of normal
- Current use of anticoagulant with INR >1.7 or PT > 15 seconds
- Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, platelet count, and ECT; TT; or appropriate factor Xa activity assays)
- Blood glucose concentration <50 mg/dL (2.7 mmol/L)
- CT demonstrates multilobar infarction (hypodensity >1/3 cerebral hemisphere)
- Relative exclusion criteria
- Recent experience suggests that under some circumstances—with careful consideration and weighting of risk to benefit—patients may receive fibrinolytic therapy despite 1 or more relative contraindications. Consider risk to benefit of IV rtPA administration carefully if any of these relative contraindications are present.
- Only minor or rapidly improving stroke symptoms (clearing spontaneously)
- Pregnancy
- Seizure at onset with postictal residual neurological impairments
- Major surgery or serious trauma within previous 14 days
- Recent gastrointestinal or urinary tract hemorrhage (within previous 21 days)
- Recent acute myocardial infarction (within previous 3 months)

(aPTT: activated partial thromboplastin time; CT: computed tomography; ECT: ecarin clotting time; INR: international normalized ratio; PT: prothrombin time; TT: Thrombin time; IVrtPA: intravenous recombinant tissue plasminogen activator)

- In patients without recent use of oral anticoagulants or heparin, treatment with IV rtPA can be initiated before availability of coagulation test results but should be discontinued if INR is >1.7 or PT is abnormally elevated by local laboratory standards.
- In patients without history of thrombocytopenia, treatment with IV rtPA can be initiated before availability of platelet count but should be discontinued if platelet count is <100,000/mm^3.

There are additional relative exclusion criteria for patients in 3–4.5 hours window that determine if the patients are eligible for tPA or not (**Box 4**).

A primary goal of achieving door to needle time (DTN) within 60 minutes in ≥50% of acute ischemic stroke patients treated with IV alteplase should be established. It may be reasonable to establish a secondary DTN time goal of achieving DTN times within 45 minutes in ≥50% of patients with acute ischemic stroke who were treated with IV alteplase.

Dose of tPA: As per the guidelines, infuse 0.9 mg/kg (maximum dose 90 mg) over 60 minutes, with 10% of the dose given as a bolus over 1 minute.

For treatment within 3 hours of stroke onset, alteplase led to a good outcome for 33% versus 23% for control (OR 1.75; 95%, CI 1.35–2.27). The number needed to treat (NNT) for one additional patient to achieve a good outcome was 10.

For treatment from 3 to 4.5 hours, the proportion with a good outcome in the alteplase and control groups was 35 and 30% (OR 1.26; 95%, CI 1.05–1.51, and NNT 20).

The benefit of IV defibrinogenating agents and of IV fibrinolytic agents other than alteplase and tenecteplase is unproven; therefore, their administration is not recommended outside a clinical trial. Tenecteplase administered as a 0.4-mg/kg single IV bolus has not been proven to be superior or noninferior to alteplase but might be considered as an alternative to alteplase in patients with minor neurological impairment and no major intracranial occlusion.

BOX 4: Additional relative exclusion criteria.

- *Aged >80 years:* For patients >80 years of age presenting in the 3–4.5 hours window, IV alteplase is safe and can be as effective as in younger patients (New Recommendation)
- *Severe stroke (NIHSS > 25):* The benefit of IV alteplase between 3 and 4.5 hours from symptom onset for patients with very severe stroke symptoms (NIHSS > 25) is uncertain. (Class IIb; LOE C-LD) (New Recommendation)
- *Taking an oral anticoagulant regardless of INR:* For patients taking warfarin and with an INR ≤1.7 who present in the 3–4.5 hours window, IV alteplase appears safe and may be beneficial. (Class IIb; LOE B-NR) (New Recommendation)
- *History of both diabetes and prior ischemic stroke:* In patients with prior stroke and diabetes mellitus presenting in the 3–4.5 hours window, IV alteplase may be as effective as treatment in the 0–3 hours window and may be a reasonable option. (Class IIb; LOE B-NR) (new recommendation)

(IV: intravenous; INR: international normalized ratio; NIHSS: National institutes of health stroke scale)

Blood Pressure Management in Acute Ischemic Stroke

In thrombolytic candidate: *Labetalol* (if no bradycardia and bronchospasm) 5–10 mg IV every 5 minutes. If not controlled in <4 doses start infusion: *Nicardipine infusion* 5–15 mg/h: *Hydralazine* (if bradycardia and bronchospasm) 5–20 mg IV every 5 minutes. If not controlled in <4 doses change to nicardipine infusion

If not a candidate for thrombolysis: Ischemic stroke: Treat only blood pressure (BP) >230/120 mm Hg or end organ failure, and maximum reduction <20%.

Complications of Intravenous Thrombolysis

Complications related to IV rtPA include symptomatic intracranial hemorrhage, major systemic hemorrhage, and angioedema in approximately 6%, 2%, and 5% of patients, respectively. Guidelines recommend strict BP control and serial neurological exams to diagnose intracranial hemorrhage (15, 40). In the event that an intracranial hemorrhage is suspected it is recommended to stop alteplase infusion and perform stat laboratories which include a CBC, PT (INR), aPTT, fibrinogen level, and type and cross-match. An emergent nonenhanced head CT should be performed to evaluate further. Intravenous cryoprecipitate (includes factor VIII), at a dose of 10 U infused over 10–30 minutes (onset in 1 hour, peaks in 12 hours) should be administered and may be repeated for fibrinogen level of <200 mg/dL. Tranexamic acid or ε-aminocaproic acid may also be used. Stat hematology and neurosurgery consultations should be sought. Supportive therapy should continue. Angioedema should be treated like an allergic reaction and emergent intubation may be needed if breathing difficulty is present. Use of antihistamines and steroids are recommended in managing angioedema.

ENDOVASCULAR TREATMENT FOR STROKE

For almost 20 years IV tPA has been the backbone of stroke treatment. Intravenous therapy (IVT) although effective has specific inclusion and exclusion criteria which limits its use in a large number of patients. Moreover, the IV tPA cannot be used after the 4.5 hours window and has limited efficacy in patients with large vessel occlusion. Riedel et al. showed that it is almost impossible to dissolve large clots with IVT. In another study by Alexandrov and Grotta up to onethird of patients had re-occlusion of blood vessels after initial recanalization.

Over the last two decades the field of endovascular stroke intervention has grown exponentially. From initial trials of intra-arterial tPA infusion to initial clot retrieval devices and now to stent retriever technology the field has come a long way indeed. Initial trials, Pro-Urokinase for Acute Cerebral Thromboembolism I (PROACT I) and II showed promise with intra-arterial pro-urokinase infusion with improved outcomes and recanalization rates, however, pro-urokinase was never approved by the FDA citing need for further confirmatory trials. Intra-arterial therapy theoretically sounds promising but has never been shown to improve outcomes or decrease mortality in randomized trials, thus is not the preferred approach today.

First generation device, the mechanical embolus removal in cerebral ischemia (MERCI) device (**Figs. 4A** and **B**), was approved for mechanical thrombectomy by the FDA and marked the beginning of era of endovascular stroke intervention. The MERCI device was tested in the MERCI and MULTI-MERCI trials both which had significantly high mortality (44% and 34% respectively), despite that the patients who had successful recanalization had a better chance at achieving good functional outcome. These trials laid the foundation for further research in the field of acute stroke intervention.

In 2013, three landmark trials SYNTHESIS, Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE), and Interventional Management of Stroke (IMS III) were published and disappointingly all three trials ruled against endovascular stroke intervention. The SYNTHESIS trial compared treatment with IV tPA alone to intra-arterial thrombolysis with rtPA, mechanical clot disruption or retrieval or a combination of these approaches. There was no difference in good clinical outcome (42%) in the endovascular arm versus (46%) in the IV tPA arm. Mechanical device was used in only 56/181 patients and stent retrievers were only used in 23 patients. MR RESCUE trial compared patients receiving standard care versus endovascular therapy using the MERCI device and the PENUMBRA system. Patients with intracranial ICA or M1 occlusion, NIHSS ≥6 and within 8 hours of symptoms onset were enroled. This trial showed no difference in outcomes of patients in the two groups. Reperfusion, defined as modified thrombolysis in cerebral infarction score (mTICI) 2a/3 was 67% and defined as mTICI 2b/3 was only 27%. Good clinical outcome [modified Rankin scale (mRS 0–2)] was only demonstrated in 14%. IMS III trial showed a similar outcome with 41% good clinical outcome (mRS 0–2) in the combined IVT/endovascular therapy arm versus 39% in the IVT only arm. IMS III did not require demonstration of vascular occlusion until the trial was midway when CT angiogram was included in the study protocol. IMS III also did not standardize the endovascular therapy as a result; the methods were a mix of pharmacological thrombolysis, manipulation of clot with use of a guidewire or microcatheter, mechanical and aspiration thrombectomy, and stent-retriever technology. These trials failed to show any benefit of endovascular intervention over the IVT for a variety of reasons. These trials did not standardize the noninvasive vascular imaging thus in IMS III > 50% patients did not undergo vascular imaging. The endovascular therapy was performed using older devices and thus the results were often not promising. There were long delays from stroke onset to revascularization, in part due to lack of rapid workflow.

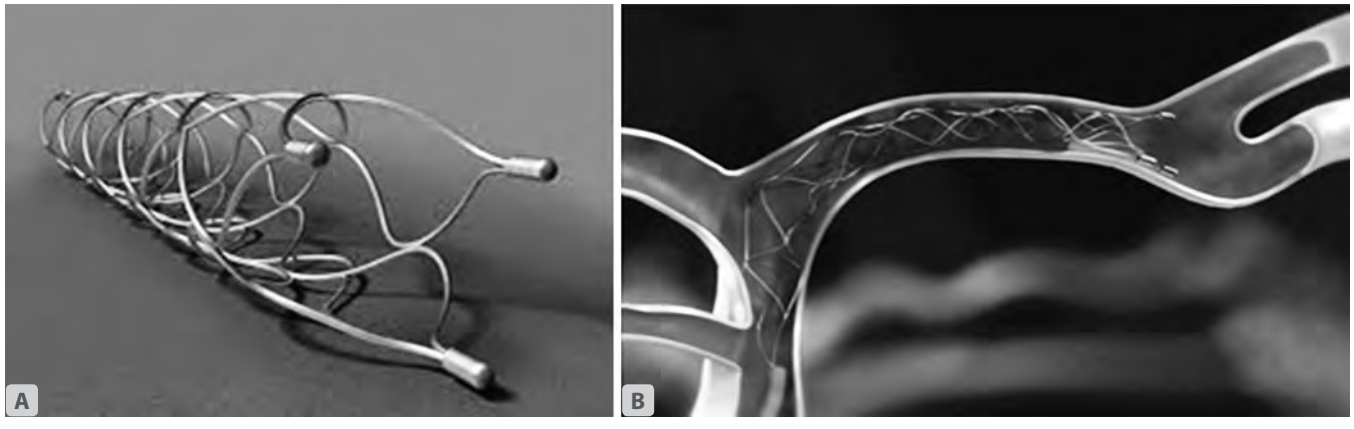
Learning from the shortcomings of the trials done in 2013, multiple trials were started using standardized endovascular and imaging approaches. Six trials published from 2014 to 2016 showed statistically significant benefit of patients with anterior circulation strokes who presented within 6 hours of onset of symptoms. These trials have established the efficacy of mechanical thrombectomy over IVT with patients doing considerably well in the endovascular arm. The meta-analysis of the trials including the three negative trials IMS III, SYNTHESIS, and MR Rescue trial have shown benefit of endovascular intervention. The adjusted combined OR for reduced disability at 90 days was 2.49, 95%, CI 1.76–3.53; $p < 0.0001$ and NNT to reduce the disability by at least one point was 2.6. The largest meta-analysis to date included the above eight trials and also preliminary data from THERAPY and THRACE trial, the rate of functional independence (i.e., a 90-day mRS score of 0–2) was significantly greater for the intervention group compared with the control group (46 vs. 27%; OR 2.35; 95%, CI 1.85–2.98).

Recent success of DAWN and DEFUSE 3 trials has further extended the window for mechanical thrombectomy from 6 to 24 hours. These trials have also made it easier to manage patients presenting with wake-up strokes or unknown time of onset in the preceding 24 hours (**Table 3**). DAWN trial enrolled 206 patients with stroke onset between 6 and 24 hours. There was a 33% adjusted difference in functional outcome in favor of the intervention arm. The NNT for one additional patient to achieve functional independence was 3. Likewise, in the DEFUSE 3 trial there was a 28% adjusted difference in functional outcome in favor of the intervention arm and therefore, the NNT for one additional patient to achieve functional independence was 3.6.

Mechanical thrombectomy—is now strongly recommended for patients in whom large arteries within the brain are blocked.

CRYPTOGENIC STROKE

Cryptogenic stroke can be defined as, if no probable cause is identified for ischemic stroke after complete standard diagnostic evaluation. Cryptogenic stroke is about 10–35% of



FIGS. 4A AND B: Mechanical embolus removal in cerebral ischemia (MERCI) device.

TABLE 3: Characteristics of DAWN and DEFUSE-3 trials.

DAWN	*DEFUSE-3 trials*
Clinical inclusion criteria age 18 years Baseline NIHSS score 10 Prestroke mRS <1	Clinical inclusion criteria age 18–90 years Baseline NIHSS score ≥6, Prestroke mRS ≤2
Eligible 6–24 hours after last seen well	Eligible 6–16 hours after last seen well
Occlusion of intracranial ICA or proximal MCA	Occlusion of extracranial or intracranial ICA or proximal MCA
• Group A: >80 years, NIHSS ≥10; infarct volume ≤21 • Group B: <80 years, NIHSS ≥10; infarct volume ≤31 • Group C: <80 years, NIHSS ≥20; infarct volume ≤51	Infarct volume <70 mL+ ratio of ischemic tissue to initial infarct volume of >1.8

(CT: computed tomography; ICA: internal carotid artery; FDA: Food and Drug Administration; MCA: middle cerebral artery; mRS: modified rankin scale)

all ischemic stroke but with availability of advanced testing in higher center, this percentage has declined to 10–15%. Cryptogenic strokes are mostly embolic in origin either from heart or right to left shunt. In young adult, patent foramen ovale and in elderly group occult paroxysmal atrial fibrillation is commonly found as a source of cryptogenic stroke.

SUMMARY

Management of acute ischemic stroke is time dependent. Efficient and effective stroke care depends on a well-functioning team from the emergency room to the neurologist and the interventional neurologist. Accurate diagnosis, emergent management to stabilize the patient, and correct choice of imaging can make a lot of difference in the outcome of a patient. Every minute lost in wrong imaging or laboratory test results in decrease in functional outcome and ultimately irreversible paralysis. Success of stroke treatment is dependent on the entire team working smoothly and efficiently. As the times evolve, more and more centers will come up with dedicated stroke teams just like cardiologists manage acute myocardial infarction. Although, future of stroke care is bright, two major roadblocks persist public awareness and hospital competence. Hopefully, this chapter will help with at least one of them.

Subarachnoid and Intracerebral Hemorrhage

120 CHAPTER

Alireza Baratloo, Arash Safaie

INTRODUCTION

When blood goes out of the vessels, it can enter into the subarachnoid or intracerebral (whether intraparenchymal and/or intraventricular) space, depending on the position of the ruptured vessels, known as hemorrhagic strokes. Hemorrhagic strokes are count for almost 10–15% of all stroke cases, but accompanied with higher mortality rate than nonhemorrhagic ones, so need different management. Due to increasing the mean age of population, it is expected that the incidence going to be raised in near future.

ETIOLOGY/CAUSES

Spontaneous hemorrhage, as the name implies, is caused by the rupture of blood vessels and the withdrawal of blood from the vascular bed. These vessels are usually those that have been damaged or weakened for various reasons, frequently in form of aneurysms and vascular malformations. Also, some categorized the etiologies based on patient's age and type of hemorrhage. When it comes to subarachnoid hemorrhage (SAH), aneurysm is the most frequent known etiology in all age groups; On the other hand, hypertensive hemorrhage and cerebral amyloid angiopathy (CAA) are the most prevalent etiologies of elderly and brain vascular malformations in both pediatrics and young/middle aged adults affected by spontaneous intracerebral hemorrhage (ICH). Neoplasms, bleeding diathesis and coagulopathies, acute ischemic stroke hemorrhagic transformation, and cerebral venous thrombosis are all among other known etiologies of hemorrhagic stroke (**Table 1**).

PATHOPHYSIOLOGY OF THE CONDITION

Various pathophysiology has been proposed based on different etiologies. Lipohyalinosis of blood vessels and also deposition of amyloid in the layers of the vessel are the most important ones that has been defined in this regard, both of which weaken the vessel wall and lead to decreased tone and poor compliance. Lipohyalinosis may also lead to aneurysmal dilatations of some vessels. As well, aneurysms can form due to micro-injuries within the vessel wall that earlier affected by hyperplastic arteriolosclerosis.

TABLE 1: Etiologies and risk factors for subarachnoid hemorrhage and intracerebral hemorrhage.

	Subarachnoid hemorrhage	
Intracerebral hemorrhage	***Aneurysmal***	***Nonaneurysmal***
• Hypertension • Cerebral amyloid angiopathy • Vascular malformations • Hemorrhagic transformation of ischemic strokes (including venous sinus thrombosis) • Septic embolism and mycotic aneurysm • Brain tumors • Bleeding disorders and antithrombotic drugs • Central nervous system infection • Moyamoya • Vasculitis • Sympathomimetic drugs	• Vascular malformations • Intracranial arterial dissection • Cerebral venous thrombosis • Sickle cell disease • Bleeding disorders and anticoagulant therapy • Traumatic • Sympathomimetic drugs • Pituitary apoplexy • Cerebral amyloid angiopathy	• Cigarette smoking • Hypertension • Autosomal dominant polycystic kidney disease • Glucocorticoid-remediable aldosteronism • Ehlers–Danlos syndrome • Family history of subarachnoid hemorrhage • Alcohol consumption • Sympathomimetic drugs • Antithrombotic drugs • Hypocholesterolemia and statin drugs

CLINICAL PRESENTATION AND RED FLAGS

Subarachnoid hemorrhage is usually present with severe thunderclap headache but may also present with syncope, decreased level of consciousness, neck pain, nuchal rigidity, seizure, and other nonspecific symptoms. The range of symptoms of spontaneous ICH is even wider, and depending on the site of bleeding and the volume, may vary from a mild headache to a deep coma with/without focal neurologic deficits. An important point is that over first hours, the symptoms may worsen or rarely improve. Taking everything into account, there is no definite finding in terms of diagnosis of hemorrhagic stroke patients, and diagnostic certainty always needs brain imaging.

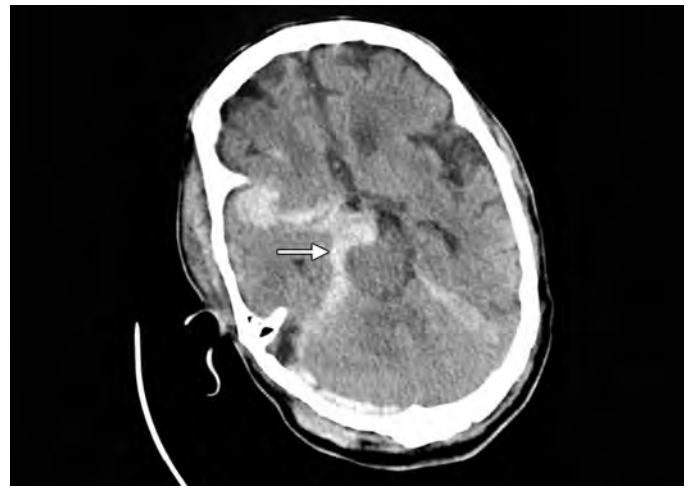
EVALUATION AND INTERPRETATION OF FINDINGS

Beside stabilization process considering airway and breathing, a brief oriented history should be taken from the patient, if possible, and his/her accompanies including: chief complaint, onset of symptom, duration of symptom, course of symptom, precipitating factors, and associated features; underline disease such as diabetes, hypertension, dysrhythmia, hypercholesterolemia, autosomal dominant polycystic kidney disease, glucocorticoid-remediable aldosteronism, and Ehlers–Danlos syndrome; recent or previous hospitalization, head trauma or any stroke event; drug history especially anti-coagulant agents; social habits such as recreational drug use (mainly sympathomimetic), smoking, and excessive alcohol intake. Apparently, measurement of all vital signs including bedside testing of blood glucose by glucometer is necessary. Thereafter, a detailed and complete neurological examination is required. These evaluations rise some differential diagnosis that needs further paraclinical investigations for rule in/out.

INVESTIGATIONS

In patients who do not need establishing a definite airway urgently, do not need respiratory support, and are not in shock state the only two recommended modalities before performing urgent brain imaging are bedside testing of blood glucose by glucometer in patients with a decreased level of consciousness and obtaining an electrocardiogram (ECG). Head computed tomography (CT) scanning is the modality of choice for detecting blood in the brain.

In most of the cases, both SAH and ICH are easily diagnosed due to hyperdense appearance of blood (density of 30–80 HU) in subarachnoid or intracerebral area (**Figs. 1** and **2**). The sensitivity of the CT scan for detecting blood in the subarachnoid space is nearly 100% in the first 6–12 hours after the bleeding. Nevertheless, the sensitivity gradually decreases over time and reaches about 90% and 50% in 24 hours and 5 days after bleeding, respectively. Therefore, when the history and the physical examination are suggestive of a SAH, the physician should perform a lumbar puncture to exclude it. This is particularly true when the imaging has been performed >6 hours after the symptoms developed. A normal head CT scan and absence of xanthochromia and zero or few red blood cells (RBCs) in cerebrospinal fluid (CSF) exclude the SAH (**Flowchart 1**). However, equivocal findings may require further evaluations or repeating the performed tests. More advanced brain imaging technique such as CT angiography, digital subtraction angiography (DSA), or magnetic resonance imaging (MRI) may be still required in further management steps but not as primary assessment.



(CT: computed tomography; SAH: subarachnoid hemorrhage)

FIG. 1: Axial view of head CT scan showing SAH (white arrow).

(CT: computed tomography; ICH: intracranial hemorrhage; IVH: intraventricular hemorrhage)

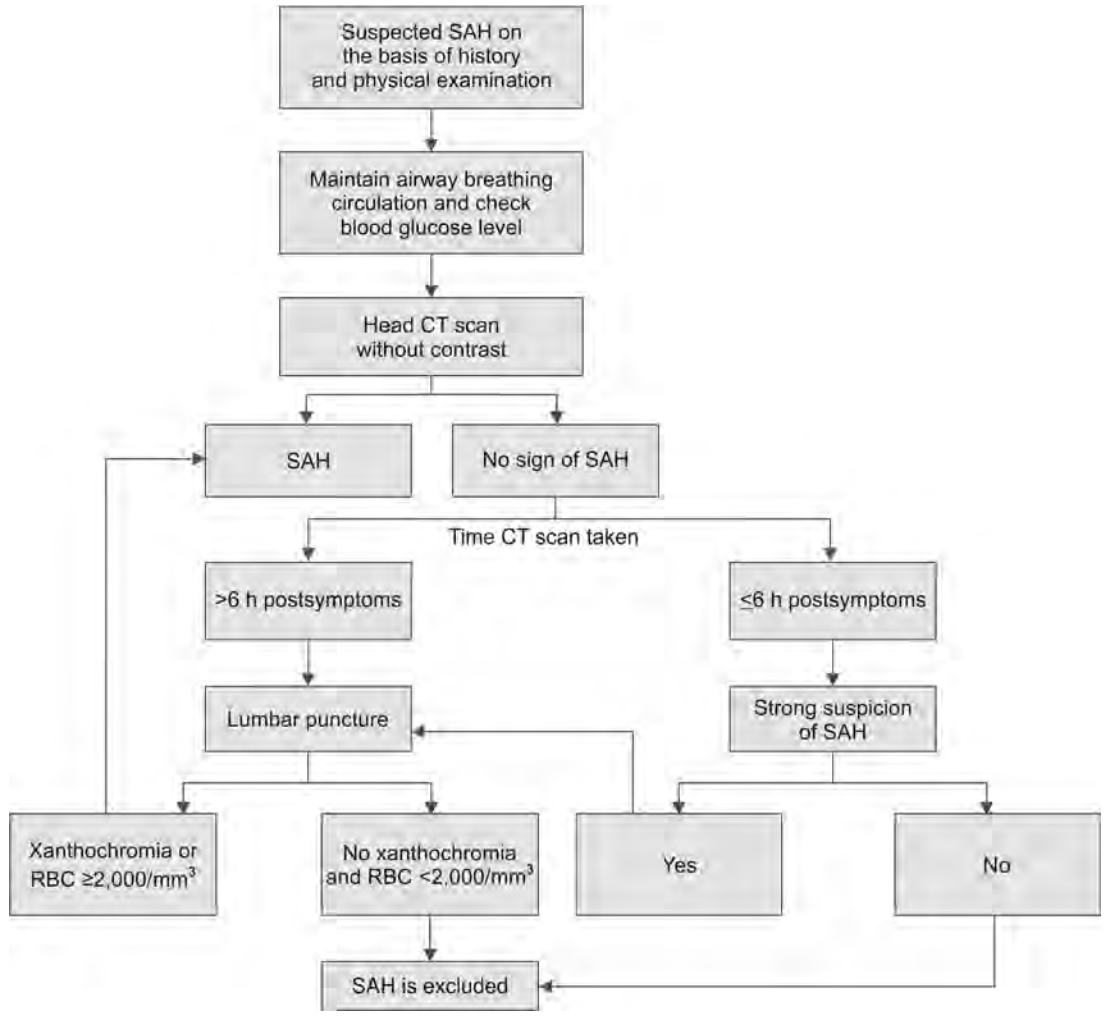
FIG. 2: Axial view of head CT scan showing ICH (white arrow) and IVH (arrowhead).

Other recommended laboratory tests for patients with SAH or ICH include complete blood count, basic biochemistry panel, coagulation profile, and cardiac troponin level.

TREATMENT

Subarachnoid hemorrhage and ICH have some same and also specific management in term of both surgical and nonsurgical interventions. All patients with SAH need neurological surgeon's consultation. Patients with ICH are generally managed medically by neurologists, though there are few indications for surgical intervention.

- *Airway management*: The physician should be warned of the risk of sudden airway compromise due to the deterioration of the neurologic status. Oral intratracheal intubation with rapid sequence induction is the method of choice



(CT: computed tomography; RBC: red blood cell; SAH: subarachnoid hemorrhage)

FLOWCHART 1: Diagnosing subarachnoid hemorrhage.

for securing the airway in these patients. The liberal use of opioids for the pretreatment is recommended to inhibit sympathetic response to laryngoscopy. Most intravenous inducting agents are safe in the setting of suspected raised intracranial pressure (ICP). Although ketamine does not rise the ICP, it is wise to avoid it in SAH and ICH patients due to the possibility of elevating blood pressure and rebleeding or hematoma growth. Either succinylcholine or nondepolarizing neuromuscular blocking agents can be used.

- *Blood pressure control*: The latest recommendation for the target point is systolic blood pressure (SBP) <140 mm Hg in ICH that should be achieved during the first hour using titratable agents to prevent the expansion of present hematoma. However, if elevated ICP presents based on signs, symptoms, and radiologic findings; the physician should decrease blood pressure to the point that cerebral perfusion pressure (CPP) remains in the range of 60–80 mm Hg. Intravenous labetalol and nicardipine are the first line agents. Angiotensin-converting enzyme (ACE) inhibitors like enalapril could be administered as the second line option. It seems that nitroprusside and nitroglycerine may increase ICP, so they should be avoided.

  In SAH the target point is SBP < 160 mm Hg that could be achieved by various titratable agents such as nicardipine or labetalol to prevent stroke and rebleeding, and also maintaining proper CPP. As mentioned in case of ICH, nitroprusside should be also avoided in SAH. Oral nimodipine improves neurological outcomes and should be administered to all patients with SAH.
- *Blood Sugar control*: Blood glucose level on admission affects the outcome of the hemorrhagic stroke patients, and it is claimed that hyperglycemia is associated with poorer prognosis, length of hospital stays, and increased risk of 30-days mortality. However, the target level is still unclear and the latest recommendation is to do not interfere unless the blood glucose level is above 180 mg/dL.
- *Reversal of anticoagulation*: The higher the international normalized ratio (INR), the higher the incidence of early neurological deterioration of hemorrhagic stroke patients. There is an agreement on that coagulopathy should be corrected, so in all hemorrhagic stroke patients who had impaired INR, early correction of coagulopathy is necessary and a combination of vitamin K, and fresh frozen plasma (FFP) or 4-factor prothrombin complex concentrates (PCC) or recombinant factor VII (rFVIIa) should be administered

with the aim of INR correction. Vitamin K should be administered intravenously (IV) that takes almost 6 hours to reach its therapeutic levels. Therefore, a rapid-acting agent should also be administered that can be chosen between FFP, 4-factor PCC or rFVIIa. Choosing either of these drugs has its advantages and disadvantages over the other that is beyond the scope of this chapter. The most serious adverse events have been associated with rFVIIa administration; therefore, it is the least recommended agent in this regard contrary to the agreement mentioned above on correction of warfarin induced coagulopathy, there is no consensus on antiplatelet medications. In general, no intervention is needed routinely in all antiplatelet users; but desmopressin (DDAVP) may have some benefits in patients with renal failure and platelet dysfunction, and also platelet transfusions in case of severe thrombocytopenia. For who are under treatment by intravenous heparin infusion, beside discontinuation of the infusion, protamine sulfate should be administered. Although reversal may be incomplete, but the same approach is also recommending for those who are receiving low-molecular-weight heparin.

- *Antifibrinolytic*: As much as there is agreement on administration of antifibrinolytic agents (e.g., tranexamic acid) in case of ICH, there are controversies in case of SAH. Early definitive obliteration of the aneurysm in SAH is generally superior to all other interventions; but in cases that neurosurgical interventions are not readily available, short-term antifibrinolytic may be beneficial. It was claimed that early administration of tranexamic acid to SAH patients lead to reduction of rebleeding rate.
- *Seizure management*: Although not frequent, but seizure can lead to rebleeding and increased ICP in SAH patients. Apparently, actual seizure should be immediately controlled, but prophylactic anticonvulsants are optional. There is no strong evidence against its use in SAH patients but may have no benefit. Overall, guidelines still recommend to administration of a short course of prophylactic anticonvulsants during immediate posthemorrhage period and before definitive aneurysm treatment in SAH patients, particularly in those with altered mental status. Routine long-term use is not recommended except in specific situation that is beyond the scope of current chapter. Newer anticonvulsants such as levetiracetam may be superior to phenytoin in terms of long-term side-effects. The role of prophylactic anticonvulsants administration in ICH cases also remains uncertain. Unlike SAH, clinical seizures have not been associated with worse outcome in ICH. Current guidelines do not recommend routine prophylactic anticonvulsants in ICH except in those who had seizures or in patients that nonconvulsive ictal activity cannot be excluded (i.e., deeply comatose patients) and continuous electroencephalography (EEG) monitoring may be valuable in the latter.
- *Intracranial pressure control*: The hematoma itself or the surrounding edema can result in elevated ICP, which can precipitate secondary brain injury and neurologic deterioration. Elevation of the head of the bed and providing the patient with adequate analgesia and sedation are the mainstay of preventing ICP elevation in ICH. The patients should be treated with normal saline and hypotonic fluids should be avoided.

  In case of elevated ICP, osmotic agents such as mannitol and hypertonic saline are the first line agents. Though the care should be taken while achieving a mild serum hyperosmolality (300–310 mOsmol/kg), maintain normovolemia and prevent marked hyperosmolality and hypernatremia. Using the barbiturate anesthesia is the next step in managing raised ICP. Nevertheless, the physician should be aware of its adverse effects including hypotension. Hyperventilation ($PaCO_2$: 25–30 mm Hg) decreases ICP markedly. However, its effect is temporarily and in the cost of decreasing CPP. Therefore, it should be avoided generally and only be used when the aforementioned steps failed to decrease ICP.

  Neuromuscular blockade can reduce ICP. However, due to its potential adverse effects including pneumonia, it is generally avoided. Glucocorticoids are ineffective in reducing or preventing increased ICP in ICH.
- *Surgical interventions*: Most patients with spontaneous ICH do not benefit from the surgical evacuation of the hematoma. The most accepted criteria for evacuating a hematoma in spontaneous ICH are cerebellar hematomas with >3 cm in diameter and lobar hematomas with >30 mL volume which are within 1 cm of the cortical surface. Aneurysmal or vascular malformation related SAH and ICH patients are treated by surgical or interventional radiology interventions. In patients with SAH or ICH who develop hydrocephalus, an external ventricular drain (EVD) may be placed.
- *Other managements*: In addition to all mentioned managements, control of pain, vomiting, fever and anxiety, and stress ulcer prophylaxis are also essential. Also, venous thromboembolism (VTE) prophylaxis with compression stockings and intermittent pneumatic compression is recommended in all hemorrhagic stroke patients as soon as possible.

DISPOSITION

All patients with diagnosis of SAH or ICH definitely need to be admitted in intensive unit care (ICU), whether candidate for neurosurgical intervention or not. If not available, close monitoring is still required.

SUMMARY

The ICH can be detected readily by head CT scan. However, detection of a SAH may need lumbar puncture and CSF analysis. There are various managements that can be considered for dealing with these patients, but all with either conditions need to be admitted in ICU and treated by neurologist and/or neurological surgeon.

121
CHAPTER

Seizures and Status Epilepticus

Gouri A Ranade, Priyanka G Mahale

INTRODUCTION

Status epilepticus (SE) is the most extreme form of seizure in which aggressive approach can save many lives. Delay in treatment can lead to significant morbidity and mortality. SE is a very common medical emergency in day to day critical care and emergency care practice. Annual incidence rates for generalized SE range from 3.6 to 6.6/100,000 in European countries. The incidence rate is significantly high if all kinds of sporadic epileptiform discharges (SED) are included and is about 41/100,000 in United States. Reported mortality rate is 17–26% and significant morbidly including disabling neurological deficits range from 10–23% among the cases who survived SE. It is very important to recognize and treat SE at an early stage as longer the duration of seizures, higher the chances of landing it into refractory SE. In emergency settings, the treating physician is the first contact and should be familiar with various steps of management of SE. He or she should not wait for the specialist to start treatment for SE. An early and aggressive treatment can lead to early control of seizures and a state of refractory status can be avoided. For further management of SE especially refractory SE a team of neurologist with expertise in electrophysiology and critical care expert is required as such patients require continuous monitoring in intensive care unit (ICU) including continuous electroencephalogram (EEG). Status epilepticus is a common neurological emergency seen in prehospital setting and in emergency department. It is necessary for all emergency physicians to recognize and promptly treat SE, as they are associated with significantly high morbidity.

Status epilepticus was earlier defined as a continuous seizure lasting >30 minutes, or two or more seizures without full recovery of consciousness between any of them. Later the definition was modified as: Status epilepticus is defined as any seizure that is prolonged after initiation of mechanisms to terminate the seizure within 5 minutes. This rephrasing ensured early and aggressive treatment of SE.

Refractory/malignant status epilepticus: Refractory SE and the continuous or repetitive seizures are unresponsive to first- and/or second-line antiepileptic drug (AED) therapy with a benzodiazepine and other anticonvulsant in adequate loading dose.

Malignant status epilepticus: Malignant SE is a variant of refractory SE which fails to respond to anesthetic agents. It is commonly associated with encephalitis.

COMMON CAUSES OF STATUS EPILEPTICUS

- *Drug related*: Discontinuation of antiepileptic medications. Few drugs may lower the seizure threshold or increase clearance of antiepileptic medications, e.g., isoniazid, erythromycin, etc.
- *Drug withdrawal*: Alcohol, barbiturates or opioid withdrawal.
- *Infection*: Meningitis, encephalitis, and brain abscess
- Stroke
- *Metabolic causes*: Electrolyte disturbances and hypoglycemia
- Hypoxia
- Central nervous system (CNS) tumors
- Traumatic brain injury

CLASSIFICATION AND STAGES OF STATUS EPILEPTICUS

Based on electroclinical features it can be classified as: Nonconvulsive status epilepticus (NCSE) and convulsive SE. NCSE refers to continuous or near continuous electrical seizure activity without any obvious physical convulsions. It may be characterized by abnormal oculomotor movements, altered mental status, and unresponsiveness. NCSE may be categorized as absence SE and complex partial SE. Convulsive SE can be classified as tonic-clonic, tonic, clonic, and myoclonic. Generalized tonic-clonic is the most common form. It is hypothesized that ineffective recruitment of inhibitory neurons with excessive neuronal activation plays a key role in initiation and maintenance of SE.

Convulsive status epilepticus: Generalized convulsive SE in adults and children >5 years is operationally defined as "≥5 minutes of (1) Continuous seizure or (2) two or more discrete seizures between which there is incomplete recovery of consciousness." Though traditionally duration of 30 minutes

or more continuous seizures were taken as SE, the duration has been reduced considering the fact that majority of generalized seizures terminate spontaneously within 2–3 minutes and seizures that do not cease in 5–10 minutes will need aggressive intervention to get controlled.

Nonconvulsive status epilepticus: NCSE is defined as a state when in an obtunded or comatose patient there are no ongoing obvious clinical seizures but the seizure activity is well seen on the EEG. The duration required to label NCSE is still >30 minutes. It is important to rule out NCSE in any patient with unexplained altered sensorium especially with reasonably normal radiological and biochemical parameters. Subtle SE may be seen in patients treated for convulsive SE. If convulsions are no longer there but the patient is comatose then a possibility of NCSE should be considered. However, discrete (subtle) clinical manifestations like perioral twitching or nystagmus or fixed gaze may be present in such patients.

Stages of status epilepticus: First stage is characterized by generalized tonic-clonic seizure. It is associated with increased autonomic activities such as increased temperature, hypertension, salivation, and hyperglycemia. After approximately 30 minutes, second stage is noticed with failure of cerebral autoregulation. It can lead to hypoglycemia, acidosis, hypoxia, hypotension, etc. The five distinct electrographic stages: (1) Discrete electrographic seizures, (2) merging of electrographic seizures-waxing and waning of ictal discharges, (3) continuous ictal discharges, (4) continuous ictal discharges punctuated by flat periods, and (5) periodic epileptiform discharges against a relatively flat background.

Status epilepticus mimics: Symptoms such as tonic-clonic movements, frothing at mouth, and involuntary passage of urine help in diagnosis of seizure. However, it is important to differentiate from other conditions which may mimic SE. Few examples of them are: Tetanus, neuroleptic malignant syndrome, and tremor mimics of partial SE are: Tic disorder and focal dystonia myoclonic jerks. Mimics of NCSE are: Locked-in syndrome, cataplexy, and periodic paralysis encephalitis. Video EEG monitoring is the gold standard to differentiate SE from mimickers.

INITIAL EVALUATION AND MANAGEMENT

Prehospital Management

Obtain history: History of trauma, substance abuse, and history of seizure.

Secure airway, breathing, and circulation: Airway, breathing, and circulation should be assessed immediately. Patient should be positioned in left lateral decubitus which will help to reduce the risk of aspiration of gastric contents. Bite block or oropharyngeal airway application may be dangerous for healthcare providers; hence, it is not recommended. If any airway adjuvant device is necessary nasopharyngeal airway may be used during active seizure.

Breathing: Respiratory failure is a known complication of seizure. Bag mask ventilation must be done cautiously as it may increase the risk of aspiration. Decision of intubation must be taken by treating physician. Rapid sequence intubation is preferred method. Succinylcholine must be used cautiously as prolonged seizure may predispose the patient to hyperkalemia as a consequence of rhabdomyolysis.

Circulation: Intravenous access should be attempted. Maintenance of hydration will reduce the risk of myoglobin induced renal injury. Point of care for blood sugar levels must be measured and corrected if necessary. Hypoglycemia may be one of the precipitating factors of SE. Prolonged seizure or fall during the episode may result in trauma. Prompt correction of blood sugar levels if they are below 60 mg% is advised.

Medication: Intramuscular or buccal administration of midazolam is recommended if intravenous access is not achieved. If intravenous access is achieved lorazepam can be administered. Benzodiazepines act by postsynaptic gamma-aminobutyric acid-nergic (GABA-nergic) inhibition, reducing repetitive firing of action potential.

Emergency Department Treatment

Primary management should aim at stabilization of airway, breathing, circulation, and administration of medications to terminate the clinical and electrical seizure. Airway, breathing, and circulation management is as described above. After stabilization of airway, breathing, and circulation arterial blood gas analysis may be performed. Initial hyperpyrexia, acidosis, and hypertension may not be immediately treated as it usually subsides without any corrective measures. All the patients should get a blood glucose levels; serum calcium, magnesium, sodium, and potassium levels. If the patient is known epileptic on medication, then blood levels of antiepileptic medications must be performed. Based on history and clinical findings other investigations such as computed tomography (CT) scan, lumbar puncture, and blood toxicology panel may be performed.

PHASE WISE MANAGEMENT OF STATUS EPILEPTICUS

Stabilization Phase (0–5 Minutes Seizure Activity)

Airway: Consider nasopharyngeal airway and suction.

Breathing: Supplement oxygen.

Circulation: Secure intravenous access. Check blood glucose levels. If sugar levels <60 mg/dL, start intravenous dextrose (D50W) 50 mL.

Initial Therapy Phase (5–20 Minutes)

Benzodiazepines are the first therapy of choice:

- 10 mg for >40 kg, 5 mg for 13–40 kg of intramuscular midazolam single dose OR
- 0.1 mg/kg/dose, maximum: 4 mg/dose of intravenous lorazepam may repeat dose once, OR
- 0.15–0.2 mg/kg/dose, maximum: 10 mg/dose of intravenous diazepam may repeat dose once.

If none of the above benzodiazepines are available any one of the following may be administered:

- 15 mg/kg/dose of intravenous phenobarbital, single dose, OR
- Intranasal midazolam and buccal midazolam, OR
- 0.2–0.5 mg/kg, maximum: 20 mg/dose of rectal diazepam, single dose

Second Therapy Phase (20–40 Minutes)

At this point, a response to the therapy administered in the previous phase should be evident. If there is a lack of response, the following can be administered as a single dose:

- 20 mg PE/kg, maximum: 1,500 mg PE/dose of intravenous fosphenytoin, single dose, OR
- Intravenous levetiracetam 60 mg/kg, maximum: 4,500 mg/dose, single dose, OR
- 40 mg/kg, maximum: 3,000 mg/dose of intravenous valproic acid, single dose.

If none of the options are available, intravenous phenobarbital 15 mg/kg, single dose can be administered. Consider definitive airway protection by endotracheal intubation and mechanical ventilation.

Third Therapy Phase (40–60 Minutes)

If the seizure persists, any drug of the second-line therapy may be repeated or administer anesthetic doses of:

- Thiopental 100–250 mg bolus with repeat bolus of 50 mg every 2–3 minutes till seizures are controlled followed by infusion of 3–5 mg/kg/h, OR
- Propofol 2 mg/kg intravenous bolus followed by 5–10 mg/kg/h infusion, OR
- Midazolam 0.1–0.3 mg/kg bolus followed by infusion at 0.05–0.4 mg/kg//h.

If patient needs third-line therapy then the airway must be protected by endotracheal intubation and mechanical ventilation. The patient should undergo continuous EEG monitoring.

Refractory Status Epilepticus

If despite giving loading doses of AEDs the seizures are going on, then the patient is considered to be in refractory SE. At this stage, there are two options to treat. Such patients will need use of anesthetic agents such as midazolam, propofol or thiopentone sodium. Midazolam may be preferred with strict monitoring in cases where intubation is to be avoided. If ICU facility with ventilator support is available then stronger anesthetic drugs such as thiopentone sodium or propofol may be a better choice. If a patient with convulsive SE is having altered sensorium with no ongoing convulsions then it may be due to nonconvulsive status and an urgent EEG monitoring is required.

Malignant/Super-refractory Status Epilepticus

If the seizures are not controlled in 24 hours or recur 24 hours or more after the onset of anesthetic therapy then this is called super refractory SE. If seizures recur on stopping or reducing anesthetic agents then also it will be termed super refractory SE. This condition requires aggressive therapies such as ketamine, hypothermia, ketogenic diet, and immunotherapy like immunoglobulin. This will help in controlling seizures, preventing excitotoxicity, and providing neuroprotection.

Reasons for Failure of Treatment in Status Epilepticus

Treatment of SE can fail due to following reasons:

- *Underdosing of antiepileptics*: Treating SE half-heartedly by going half loading dose may frequently result in failure and should be avoided. A full loading dose is quite safe to give in a patient with SE.
- *Early stoppage of treatment*: If only emergency therapy or loading dose of AEDs is given then patient may develop recurrence of seizure as most of the AEDs work for about 12 hours after loading so maintenance of antiepileptic therapy should always be given.
- *Proper diagnosis*: It is very important to keep a high index of suspicion for NCSE in a patient with unexplained altered sensorium as early treatment can result in good outcome and delayed treatment may result in refractory status.

How to do Electroencephalogram Monitoring in a Patient with Status Epilepticus?

Electroencephalogram monitoring is helpful in all the patients with SE. It can be done for short period or as continuous monitoring to rule out electrographic seizures Continuous EEG monitoring is especially required in whom the patient has not recovered even after the control of convulsions to rule out electrographic seizures. In a patient with refractory SE EEG monitoring may help in optimizing the dose of anesthetic agent with a target to achieve burst suppression pattern (BSP) on EEG. A suppression period of >10 seconds of the electrical activities on EEG will indicate adequate doses of anesthetic agents. The tapering of these agents should be considered only after 24 hours of BSP and then also it should be slow withdrawal.

SPECIAL SITUATIONS IN STATUS EPILEPTICUS

Porphyria: Many antiepileptic agents are contraindicated in porphyria. SE can be treated by lorazepam or intravenous magnesium sulfate without risk of aggravating porphyria.

Isoniazid intoxication: Status epilepticus due to isoniazid intoxication can be treated with pyridoxine.

Hyponatremia: Intravenous administration of 3% NaCl solution when hyponatremia is known cause of SE.

Pregnancy: Consider eclampsia in a pregnant female with SE. Magnesium sulfate is superior to other AEDs in eclampsia and delivery of fetus is best definitive treatment. Immediate control of seizure is essential for good fetal outcome. Phenobarbitone, phenytoin, and sodium valproate are known to have teratogenic effects, particularly in first-trimester. Levetiracetam can be considered first line of drug in pregnant patient with SE. Pregnancy results in increased volume of distribution and affects the metabolism and clearance of drugs. These factors should be considered while calculating doses of drugs.

Status epilepticus in children: The definition and management of SE are more or less same as in adult population. The main difference is in the etiology. In pediatric population especially in neonates and early infant symptomatic causes such as metabolic, infections, and structural lesion in the brain are more common. The prognosis depends upon

the primary pathology but seems to be better. Every child with SE must undergo workup for metabolic causes such as hypocalcemia, hypoglycemia, and hypomagnesemia. Early identification of the etiology can result in aggressive specific management of cause. Other investigations may include complete blood count, renal function test, liver function test, serum calcium, serum magnesium, serum electrolyte, blood urea nitrogen, glucose, and AED levels, as well as a toxicology screening. Brain imaging is an important part of investigation especially in pediatric age group. Magnetic resonance imaging (MRI) is the ideal investigation but in emergent condition it may be more convenient to do CT head. Cerebrospinal fluid (CSF) should be done in cases of suspicion of brain infection.

SYSTEMIC COMPLICATIONS OF STATUS EPILEPTICUS

- Hyponatremia
- Hyperkalemia
- Hypercarbia
- Hypoglycemia
- Lactic acidosis
- Rhabdomyolysis
- Hyperpyrexia
- Aspiration pneumonia

SUMMARY

Treat fever aggressively as it can precipitate seizure recurrences especially in pediatric population. Always look for metabolic factors such as hypoglycemia, hyperglycemia, and hypocalcemia and correct it. In case of difficult intravenous access phenobarbitone, midazolam, and fosphenytoin can be given intramuscularly.

Antiepileptic drugs level monitoring during SE is useful to determine optimal doses. Oral AEDs the patient already taking should be continued during the management of SE. Oral route can changed to intravenous if drug is available. CSF pleocytosis can also be seen in SE without any CNS infection. Avoid phenytoin in patient with myoclonic epilepsy. In patients with chronic liver disease levetiracetam is a safer option. In renal disease phenytoin/fosphenytoin can be used safely. True morbidity and mortality from SE is unclear. Age >65years is one of the most important prognostic factors. Other factors which impact the prognosis are—underlying etiology and absence of prior seizure. Treatment for SE is summarized in **Table 1**.

TABLE 1: Treatment summary for status epilepticus.

Immediate treatment (first 5–10 minutes)	
Monitoring of vitals	Airway, oxygen, and cardiac monitor
Securing IV lines	Two lines for blood samples and starting treatment
To start IV fluids	• Fluid of choice is normal saline • To give 100 mg IV thiamine and 50 mL of 50% dextrose in patients with history of alcoholism
First antiepileptic	• To give lorazepam/midazolam/diazepam IV • 0.1 mg/kg bolus dose of IV lorazepam in equal volume of diluent by slow IV push at ~2 mg/min
Repeat dose if seizure persists	Repeat another half of the bolus dose if seizures are not controlled
Early treatment for next 10–60 minutes	
Loading antiepileptic second line IV agent	• *Phenytoin*: IV infusion 15 mg/kg @ 50 mg/min • (*Fosphenytoin*: IV infusion 15 mg PE/kg @ 100 mg PE/min) • *Valproate*: IV infusion 25 mg/kg at 3–6 mg/kg/min • *Phenobarbital*: IV infusion 10 mg/kg at a maximum rate of 100 mg/min • *Levetiracetam*: 20 mg/kg bolus of dose over 15 min
If seizure persists then two options	• Repeat half dose of any of the above-mentioned antiepileptic drugs • To load with any of the other antiepileptic drug
Refractory status epilepticus (>60 minutes ongoing convulsions)	
Midazolam infusion (Possible to avoid ventilator support)	• *Loading*: 0.2 mg/kg by slow IV bolus • *Maintenance IV dose*: 0.1–0.4 mg/kg/h • *Maximum IV dose*: 2.0–3.0 mg/kg/h
Thiopental sodium	• *Loading*: 3–5 mg/kg at 0.2–0.4 mg/kg/min • *Maintenance IV dose*: 3.0–5.0 mg/kg/h • *Maximum IV dose*: 5.0 mg/kg/h
Propofol infusion	• *Loading dose*: 1–2 mg/kg at 10 mg/min • *Maintenance IV dose*: 2–10 mg/kg/h • *Maximum IV dose*: 15 mg/kg/h

Continued

Continued

Malignant/Super-refractory status epilepticus (seizures >24 hours)	
Magnesium infusion	• *Loading*: 2–6 g/h • *Maintenance*: 3.5 mmol/L
Hypothermia	• 32–35°C for <48 h • Endovascular cooling versus external cooling
Immunotherapy	• IV methylprednisolone 1 g/day × 5 days • IV immunoglobulins 0.4 g/kg/day × 5 days • Plasma exchange
Ketogenic diet	1:1 or 1:4 ketogenic diet To avoid glucose containing fluids
Epilepsy surgery	Consider surgery in special circumstances with documented brain lesions responsible for status epilepticus

122
CHAPTER

Acute Flaccid Paralysis

Priyanka G Mahale, Rahul Kulkarni, Devendra Richhariya

INTRODUCTION

Acute flaccid paralysis (AFP) is a complex clinical syndrome characterized by rapid onset of weakness of limbs, which may include muscles of respiration and swallowing, rapidly progressing to maximum severity within few days. The term flaccid indicates decreased tone of affected muscles. It includes broad spectrum of diseases which may vary with age and region. Poliomyelitis was one of the most common causes of AFP. However, because of global polio eradication initiative by World Health Organization (WHO), poliomyelitis has reached near eradication in world. Hence, other causes of AFP must be sought and evaluated. Early diagnosis in emergency department significantly improves the outcome of the patient. Etiology of AFP summarized in **Table 1**. AFP can occur in any age group and need urgent evaluation, prompt, and appropriate therapeutic intervention. Lesions at following sites explain the muscle weakness.

Muscle: Inflammatory myopathies.

Neuromuscular junction: Myasthenia gravis (MG) botulism Lambert–Eaton syndrome.

Peripheral nerves: Porphyria neuropathies and neuropathy due to metal toxicity.

Motor nerve root: Infectious polyradiculopathies and diabetic polyradiculopathies.

Anterior horn cell: Poliomyelitis.

Lower motor neurons: Antiganglioside antibody related neuropathy.

TABLE 1: Etiology of acute flaccid paralysis.

Metabolic causes	• Hypokalemia • Hyperkalemia • Hypophosphatemia • Thiamine deficiency
Muscle disorders	• Infection—viral myositis • Inflammatory myopathy—polymyositis, dermatomyositis
Disorder of neuromuscular junction	• Myasthenia gravis crisis • Lambert–Eaton syndrome • Botulism • Tick paralysis • Snake bite • Organophosphate poisoning
Neuropathy	• Guillain–Barré syndrome • Porphyria • Diphtheria • Vasculitis
Anterior horn cell disease	• Poliomyelitis • Paraneoplastic
Spinal cord diseases	• Trauma • Transverse myelitis • Anterior spinal artery syndrome

GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome (GBS) is acute inflammatory demyelinating polyneuropathy characterized by progressive sensory motor dysfunction. It is usually preceded by gastrointestinal dysfunction. It is commonly associated with areflexia. Characteristic features of GBS are:

- Progressive ascending symmetrical paralysis with symptoms reaching maximum intensity within 4 weeks of onset.
- Afebrile onset
- Involvement of sensory system
- Cerebrospinal fluid (CSF) studies demonstrate raised protein levels and cyto-albuminological dissociation.
- Decreased or absent myotatic reflexes
- Other causes of AFP are to be ruled out

Pathophysiology: GBS is considered to be an autoimmune disease. It is usually preceded by bacterial or viral infection. Commonly identifies organisms are *Campylobacter jejuni, Mycoplasma pneumoniae*, Epstein–Barr virus, etc., antibodies that are produced in response to these infection crossreact with neural antigens leading to demyelination and

inflammation. The area of nerve predominantly damaged determines to variant of GBS which will be manifested. If myelin is predominantly damaged it leads to acute inflammatory demyelinating polyneuropathy (AIDP), while nodes of Ranvier are involved in acute motor axonal neuropathy (AMAN). *GBS is classified into four subtypes*: (1) AIDP, (2) AMAN, (3) the Miller Fisher syndrome (MFS), and (4) acute motor and sensory axonal neuropathy (AMSAN).

Clinical features: Common clinical features of AIDP are weakness of limbs usually start in lower limbs and progress proximally. Limb weakness may be associated with tingling or pain. As the weakness progress it may involve respiratory muscles, as a result of which patients require mechanical ventilation. Involvement of respiratory muscles is common in patients with rapid progression of illness, involvement of upper limbs or bulbar paralysis. Other types of GBS involve facial, oculomotor, and pharyngeal muscles. Involvement of autonomic nervous system leads to fluctuations in blood pressure, cardiac arrhythmias, urinary retention, etc.

Investigations: Diagnosis of GBS is mainly dependent on clinical features. Investigations which may support the diagnosis are CSF studies which will reveal raised CSF protein level and cyto-albuminological dissociation. Investigations which will help to rule out other causes of paralysis are nerve conduction studies, electromyography (EMG), magnetic resonance imaging (MRI) brain, and spinal cord.

Treatment: The course of illness in GBS is unpredictable; hence, all patients with GBS must be admitted for observation. Involvement of respiratory of bulbar muscles can cause respiratory failure. Autonomic system involvement may cause life-threatening complications. Hence continuous hemodynamic monitoring is advised. Factors indicating need for mechanical ventilation are—inadequate cough, bulbar symptoms, vital capacity <15 mL/kg, neck muscle weakness, and declining single breath count. Definitive treatment are as follows:

- Plasma exchange aids in removal of immune complexes from circulation. It thus reduced the need or duration of mechanical ventilation, helps to reduce the severity of illness. For optimal response, plasma exchange must be initiated early in the course of illness.
- Intravenous immunoglobulin is considered in patients with rapidly progressive paralysis or respiratory muscle involvement. Recommended dose of immunoglobulin is 400 mg/kg/day for 5 days. It is less invasive than plasma exchange therapy.

Prognosis: Factors which may predict poor outcome are older age, need for mechanical ventilation, and rapid progress of symptoms. Mortality rate is approximately 3%. Approximately 20% of affected patients have persistent long-term neurological disability.

MYASTHENIA GRAVIS

Myasthenia gravis is an autoimmune disorder mainly caused by antibodies to muscle acetylcholine receptors at the level of neuromuscular junctions, leads to muscle weakness and fatigue. In >85% of patients muscle weakness become generalized affecting the limb muscle with other features such as diplopia and ptosis. Laboratory diagnosis is supported by antiacetylcholine receptor (anti-AChR) radioimmunoassay (definite diagnosis if positive >90% +ve in generalized MG and in 50% cases of ocular MG), single fiber EMG (confirmatory test), edrophonium chloride test, and repetitive nerve stimulation test.

- *Disorder associated with MG:* Thymoma hyperplasia, thymic abnormalities, and other autoimmune diseases such as thyroiditis, Graves' disease, and rheumatoid arthritis.
- *Disorders that aggravates MG:* Hyperthyroidism, hypothyroidism, and occult infections.
- *Disorders that may interfere with MG therapy*: Tuberculosis, diabetes mellitus, renal disease, hypertension, asthma, and osteoporosis.
- *Treatment modalities for M*G: There are four options for MG treatment:
  i. *Symptomatic treatment (acetylcholine inhibition)*: Amount of acetylcholine available at neuromuscular junction is increased.
  ii. *Chronic immunosuppressive therapy*: Glucocorticoid and nonglucocorticoid therapies.
  iii. *Rapid and short acting immunomodulating therapy*: Plasma exchange and intravenous immunoglobulin.
  iv. *Surgical treatment* (thymectomy).

TRANSVERSE MYELITIS

It is a neurological disorder caused by inflammation of spinal cord. It can occur at any age, but the peak of incidence is seen in age groups of 1–19 years and 30–39 years.

Etiology

- Idiopathic
- *Infections*: Syphilis, tuberculosis, Lyme disease, Epstein–Barr virus, and cytomegalovirus infection.
- *Immune system disorders*: Multiple sclerosis, postvaccine or infection.
- *Inflammatory disorders*: Sarcoidosis, scleroderma, and systemic lupus erythematosus (SLE).

Clinical Features

Pain: Symptoms usually start with pain, which may be lower backache or pain radiating from back to limbs.

Limb weakness: Weakness might start as paraparesis which later progresses to paraplegia. If the lower levels of spinal cord are involved the limb weakness occurs in lower limbs, if thoracic region is affected then both upper and lower limbs are affected. Lesions involving high cervical region result in tetraplegia and involve the phrenic nerve (C3–C5). These patients need invasive mechanical ventilation.

Sensory symptoms: Transverse myelitis can lead to paresthesia or loss of sensations.

Bowel and bladder dysfunction: Common symptoms are bowel or bladder incontinence, increased frequency, and constipation.

Investigations

Magnetic resonance imaging of spine: Lesions of transverse myelitis are seen as high signal intensity on T2–weighted images. It more commonly involves central region of spinal cord. MRI also helps to rule out other causes of paralysis. Other investigations include blood tests for infections, tests for autoimmune diseases such as Sjögren's syndrome A (SS-) antibody, Sjögren's disease, antidouble stranded deoxyribonucleic acid (anti-dsDNA) antibody, etc.

Cerebrospinal fluid analysis: Oligoclonal band is seen in multiple sclerosis associated with transverse myelitis.

Diagnostic Criteria for Acute Idiopathic Transverse Myelitis

Inclusion Criteria

- Dysfunction of sensory, motor, and autonomic nervous system due to spinal cord lesion.
- Signs and symptoms seen bilaterally.
- Clearly defined sensory level.
- Signs of inflammation seen either on CSF studies or on MRI.
- Peak of the disease seen between 4 hours and 21 days after the onset of symptoms.

Exclusion Criteria

- CSF or MRI studies suggestive of multiple sclerosis.
- History of irradiation to spine in last 10 years.
- Evidence of spinal artery thrombosis or arteriovenous malformation.
- Laboratory findings suggestive of infections such as human immunodeficiency virus (HIV), herpes simplex virus, cytomegalovirus, etc.
- Laboratory findings suggestive of systemic connective tissue diseases such as SLE, sarcoidosis, Sjögren's disease, etc.
- Neuroimaging suggestive of extra-axial compression.
- History or diagnostic studies suggest neuromyelitis optica.

Treatment

The treatment for transverse myelitis has to be individualized.

Steroids: Up to 1g of methylprednisolone for 3–5 days. Further decision to continue steroids or add a new treatment modality is decided on the initial response to steroids.

Plasma exchange: Patients who fail to respond to initial steroids or who have severe form of transverse myelitis can be offered plasma exchange.

Immunomodulators: Use of B-cell modulators or intravenous immunoglobulin is not recommended.

Analgesia: Transverse myelitis can be severely painful. Apart from analgesics such as acetaminophen and naproxen other medications which can be used are muscle relaxants (baclofen), anticonvulsants (like pregabalin or gabapentin), and antidepressants.

Rehabilitation: Patients may suffer from long-term neurological disabilities. Such patients need consultation with rehabilitation specialist such as physiotherapy, vocational therapy, occupational therapy, etc.

Prognosis: Most patients have partial recovery. Patients who fail to show any signs of improvement in initial 3–6 months usually do not have complete recovery later. Rapid worsening of symptoms usually is associated with poor outcome. Relapsing transverse myelitis symptoms are seen in patients with multiple sclerosis and neuromyelitis optica.

BOTULISM

Botulism is derived from Latin word Botulism-Sausage. In southern Germany about 1,700 people died because of eating tainted sausage. Botulism is a paralytic disease starts with the cranial nerve involvement and progress to extremities. Botulism is considered in an afebrile mentally intact patient with symmetric descending paralysis without sensory findings. Botulism may be confused with *MG* (rule out with EMG and antibodies studies), *GBS* (ascending paralysis, sensory abnormalities, and increase protein in CSF), and *Fisher variant of GBS* (descending paralysis difficult to differentiate from botulism). Demonstration of organism/toxins in vomitus or gastric fluid suggestive of diagnosis. Management includes hospitalization with close monitoring by spirometry, pulse oximetry, arterial blood gases, and intubation mechanical ventilations if respiratory failure. Use of antibiotics has no proven value.

INFLAMMATORY MYOPATHY

The inflammatory myopathies are a group of diseases, with unknown etiology, clinically presents as chronic muscle inflammation and muscle weakness. Polymyositis, dermatomyositis, and inclusion body myositis (IBM) are the three main types of chronic, or persistent, inflammatory myopathies in **Table 2**. Clinical features of inflammatory myositis other than muscle weakness are fever malaise, weight loss, arthralgia, joint contracture dysphagia, and other gastrointestinal (GI) symptoms. Cardiac manifestations are atrioventricular (AV) conduction defect, tachyarrhythmia, dilated cardiomyopathy, low-ejection fraction, congestive heart failure, and myocarditis. Pulmonary manifestations may present as thoracic muscle weakness and drug induced pneumonia. Subcutaneous calcifications shin ulceration and infections may also present. Treatment modalities for inflammatory myopathies are:

- *Glucocorticoids:* Initial treatment of choice is oral prednisolone 1 mg/kg/day, after 3–4 weeks start tapering the dose over a period of 10 weeks to 1 mg/kg alternate day. If no serious side-effects and on the basis of efficacy maintain lowest possible dose with control of disease.
- *Immunosuppressive drugs:* Generally, initiated when a patient fails to responds to glucocorticoid after 3 months of trials. Azathioprine up to 3 mg/kg/day and methotrexate (faster onset of action) 7.5 mg weekly for first 3 weeks with gradual dose escalation by 2.5 mg/week.

SYSTEMIC OR METABOLIC DISORDERS CAUSING ACUTE FLACCID PARALYSIS

While evaluating the AFP metabolic causes are also considered in differential. Rare cause of AFP is acute hypokalemic

TABLE 2: Characteristic features of various inflammatory myopathies.

Characteristics	*Polymyositis*	*Dermatomyositis*	*Inclusion body myositis*
Onset	>18 years	Adult and childhood	>50 years
Familial association	No	No	In some cases
Associated conditions	SLE RA SS MCTD	SS MCTD	In 20% cases
Malignancy	No	Yes 15% cases	No
Viruses	With HIV	Unproven	Unproven
Drugs	Yes	Yes	No
Muscles	Myopathic muscle weakness (affecting proximal > distal)	Myopathic muscle weakness (affecting proximal > distal)	Myopathic muscle weakness and early involvement of distal muscle
Muscle enzyme	Raised up to 50-folds	Raised up to 50-folds/N	Raised up to 50-folds/N
Muscle biopsy	Diagnostic	Diagnostic	Diagnostic

(MCTD: mixed connective tissue disease; RA: rheumatoid arthritis; SLE: systemic lupus erythematosus; SS: systemic sclerosis)

periodic paralysis. Hypokalemic familial periodic paralysis, a disease of autosomal-dominant inheritance. Familial periodic paralyses is divided into three main forms according to precipitating factors and the patient's potassium level at the time of an attack: (1) Hypokalemic familial periodic paralysis is usually precipitated by a meal rich in carbohydrates, and it has the tendency to manifest in the morning hours after rest. (2) Potassium-sensitive familial periodic paralysis usually has age of onset <10 years of age; considered as less severe than hypokalemic form and tend to occur during the daytime. (3) In familial adynamia episodica hereditaria, glucose prevents potassium-induced attacks of AFP. Diagnosis of familial periodic paralysis, is established by the demonstration of changes in serum potassium levels during the attack, the presence of electromyographic and electrocardiographic abnormalities, and the use of muscle biopsy, and potassium-, glucose-, or insulin-loading tests.

Thyrotoxic periodic paralysis is a syndrome manifests as clinical, electromyographic, biochemical, and microscopic features. Acute-onset progressive symmetrical weakness of the extremities and other muscle groups is the prominent clinical manifestations which is induced by excess levels of exogenous or endogenous thyroid hormones after high carbohydrate ingestion or heavy exertion.

Acute intermittent porphyria may also manifests as rapidly progressing peripheral neuropathy with motor and sensory clinical presentation and followed by AFP. Acute intermittent porphyria may have other clinical features also such as abdominal pain and psychological and neurologic signs (disturbances of consciousness and mentation, convulsions), but not all attacks progress to the neurologic stage. The initial episode often occurs in early adolescence. The classic ruby-red coloration or measurement of porphyrins (porphobilinogen and 8-aminolevulinic acid) in the urine helps to confirm the diagnosis.

WEAKNESS ASSOCIATED WITH CRITICAL ILLNESS

Acute weakness syndromes in critically ill patients can be classified into three major groups with different etiologies: (1) Critical illness polyneuropathy; (2) Neuromuscular junction abnormalities, subdivided into myasthenia-like syndromes and prolonged neuromuscular blockade; and (3) Myopathy, including acute disuse (cachectic), necrotizing, and thick filament (myosin) loss myopathy. In critically ill patients nondepolarizing neuromuscular blocking agents, is frequently used and associated with prolonged muscle weakness.

In intensive care unit status asthmaticus patients are treated with bronchodilators, antibiotics, and high-dose corticosteroids and paralyzed with vecuronium to facilitate mechanical ventilation may develop flaccid quadriplegia with areflexia. Prolonged neuromuscular blockade usually causes brief period weakness (recovers in hours to days), while more prolonged weakness (several weeks to months) is due to myopathy. Clinically, patient of AFP is differentiated by presence of intact sensation and cognition. Typical presentation of critical illness polyneuropathy is inability to wean from ventilatory support despite full cardiopulmonary recovery and flaccid quadriplegia.

Electrophysiologic studies are performed to demonstrate the presence of axonal polyneuropathies, abnormalities of neuromuscular transmission, or acute myopathies. Recovery in muscle strength usually occurs over a period of weeks to months. Variants of critical illness polyneuropathy may affect end stage renal or diabetic patients developing axonal, and predominantly motor polyneuropathy.

TRAUMA INDUCED ACUTE FLACCID PARALYSIS

Acute traumatic sciatic neuritis is associated with intramuscular gluteal injection, the potential risk of direct trauma or postinjection neuritis. A history of recent injections for febrile illness in paralyzed limbs provide important clue for diagnosing traumatic neuritis. Postoperative spinal cord damage due to ischemia (high aortic clamping and hypotension) may occur because of the interruption of critical radicular arteries at the lower thoracic or high lumbar vertebral levels, and may result in total paraplegia or paraparesis. The clinical examination in such cases reveals AFP, areflexia, sensory loss, patulous sphincter, and reflex neurogenic bladder.

EVALUATION OF ACUTE FLACCID PARALYSIS

Approach to patient with acute flaccid paralysis: History, physical examination, and investigations are important in distinguishing causes of acute flaccid paralysis (**Table 3**). Assess airway and breathing—bulbar involvement or involvement of respiratory muscles predisposes the patient to respiratory failure or aspiration pneumonia. Assess circulation—infection and autonomic involvement may lead to hypotension or hypertension, and arrhythmias. Detailed history regarding symptom must be obtained. It will help in identifying the etiology, thus helping to initiate treatment. Onset of symptoms and pattern of progression of symptoms/fluctuation in weakness.

Fatigability: Usually seen in neuromuscular junction disorders. Autonomic involvement, sensory involvement, and history of systemic symptoms such as fever, joint pain, rash, recent immunization, history of dog bite, and exposure to drugs or toxins (e.g., lead).

Physical examination: Assessment of airway, breathing, and circulation. Involvement of bulbar muscles or muscles of respiration predisposes the patient to aspiration pneumonia and respiratory failure. If the autonomic system is involved it may cause hypertension, postural hypotension, tachycardia, arrhythmia, etc. single breath count and examination of limb weakness. Evaluation of other sites for weakness—extraocular muscles, bulbar weakness, and facial muscles.

Reflexes: Reflexes may be absent in neuropathies, anterior horn cell disorders, and polyradiculopathies.

Assess for sensory impairment: Evaluate if the pathology appears to be upper motor nerve lesion or lower motor nerve lesion. Signs of upper motor nerve lesion such as brisk reflexes, definite sensory level, bladder or bowel involvement, and extensor plantar reflex.

Investigations: Arterial blood gas analysis—to evaluate for respiratory failure, complete blood count, serum electrolytes, thyroid function test, liver function tests, blood culture if suspicion of infection, and chest X-ray, Consider: MRI spine, nerve conduction studies, lumbar puncture, and CSF analysis. Summary for evaluation of AFP is given in **Flowchart 1**.

LATHYRISM

It is important to discuss lathyrism in Indian context as lathyrism has old history (since 1844 epidemic reported by Sleeman) which can develop in otherwise healthy person who consumed lathyrus sativus (grass peas) for 3–4 months. Patient can develop *severe spastic paraparesis due to* presence of potent neurotoxin 3-N-oxalyl-L-2,3-diaminopropanoic acid (β-ODAP) in the seed is the main causative factor to develop lathyrism. The first detailed description of the epidemic of lathyrism was written by General Sleeman in 1844 (Sleeman, 1844), who presented the detailed situation of lathyrism occurred in one of the Indian States, i.e., Madhya Pradesh in 1831 following prolonged consumption of lathyrus sativus as the exclusive diet.

The crop has tolerance to moisture stress, salinity, and required minimum management, thus widely grown in the States of Madhya Pradesh, West Bengal, Maharashtra, Karnataka, Telangana, and parts of eastern Uttar Pradesh. Main clinical features are pain in calf muscles especially during night, painful muscle spasm in calf (both legs) weakness and heaviness in legs, painful restriction of knee and ankle joints. Stiffness of muscles (spasticity) and atrophy of thigh and leg muscles. A detail dietary history should be taken, and differentiate from other conditions. There are no specific investigations/biomarkers for lathyrism. Lathyrism is irreversible neurotoxic damage condition and no known cure. Symptomatic treatment is the mainstay of management and prevention is preferred.

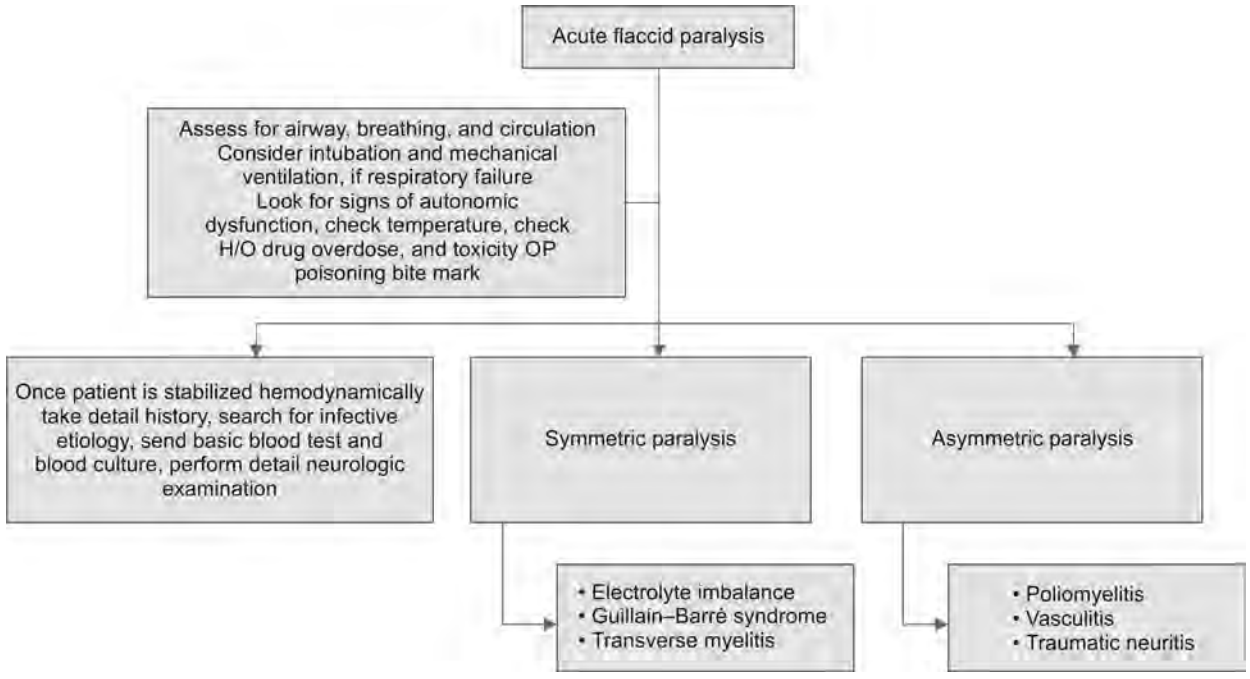
SUMMARY

Acute flaccid paralysis is a complex clinical syndrome of varied etiology characterized by rapid onset of weakness of limbs, which may include muscles of respiration and swallowing, rapidly progressing to maximum severity within few days. Early diagnosis in emergency department significantly improves the outcome of the patient. AFP can occur in any age group and need urgent evaluation, prompt, and appropriate therapeutic intervention.

TABLE 3: Distinguishing features of acute flaccid paralysis.

Causes	*Distinguishing features*	*Investigations*
Myasthenia gravis crisis	History of myasthenia gravis, descending limb weakness with ocular and bulbar involvement, sensory system spared, fatigable, and normal CSF studies	Anti-MuSK titers, anti-Ach IgM
Botulism	Weakness associated with gastrointestinal symptoms such as nausea, vomiting; dysarthria, ophthalmoplegia, and CSF studies-normal	Stool culture and culture of gastric secretions if possible
Poliomyelitis	Seen commonly in endemic areas and acute flaccid paralysis is accompanied with fasciculation and myalgia, fever, and CSF–pleocytosis	Stool sample for isolation of virus
Spinal cord diseases	Extensor plantar response and hyperreflexia	MRI spine
Vasculitis	Polyneuropathy and systemic symptoms such as rash, fever, painful, and multiorgan involvement	ESR, CRP, and specific antibodies like ANA

(ANA: antinuclear antibodies; Anti-Ach: anti-acetylcholine; Anti-MuSK: anti-muscle-specific tyrosine kinase; CRP: C-reactive protein; CSF: cerebrospinal fluid; ESR: erythrocyte sedimentation rate; IgM: immunoglobulin M; MRI: magnetic resonance imaging)



Acute flaccid paralysis
Assess for airway, breathing, and circulation
Consider intubation and mechanical ventilation, if respiratory failure
Look for signs of autonomic dysfunction, check temperature, check H/O drug overdose, and toxicity OP poisoning bite mark
Once patient is stabilized hemodynamically take detail history, search for infective etiology, send basic blood test and blood culture, perform detail neurologic examination
Symmetric paralysis
Asymmetric paralysis
• Electrolyte imbalance
• Guillain–Barré syndrome
• Transverse myelitis
• Poliomyelitis
• Vasculitis
• Traumatic neuritis

(OP: organophosphorus pesticide)

123 CHAPTER

Meningitis Encephalitis and Brain Abscess

Atul Tungikar, Priyanka G Mahale, Devendra Richhariya

INTRODUCTION

"Meningitis is a clinical syndrome characterized by inflammation of membranes of the brain or spinal cord." It is associated with high morbidity and mortality. Timely recognition of clinical features and prompt initiation of empirical antimicrobial treatment substantially improves the prognosis of the patient. Initial evaluation and treatment of patients with suspected meningitis occurs in emergency department. It is crucial for emergency physician to treat promptly patients with suspected meningitis to achieve optimal outcome.

Risk factors and etiology: Common pathogens for community acquired disease are *Streptococcus pneumonia*, *Haemophilus (H) influenzae* meningitis, and *Neisseria meningitidis*. However, *H. influenza* meningitis is seen less in vaccinated child.

- Age—elderly and younger child
  - *Neonates (<1 week)*: *Escherichia (E) coli*, *Listeria (L) monocytogens*, Group B *Streptococcus*
  - *Neonates (>1 week)*: *L. monocytogens*
  - *Infants and children*: *N. meningitidis* and *S. pneumoniae*
  - *Young adults*: Meningitides and *S. pneumoniae*
  - *Elderly*: *N. Meningitidis, S. pneumoniae*, and *L. monocytogens*
- Malnutrition, overcrowding and low social economic status, and exposure to epidemic.
- Head and neck infections—otitis media and mastoiditis
- Major medical illness—liver disease, renal disease, and diabetes mellitus (DM)
- Immunocompromised—patients on steroids, chemotherapy, cancer patients, complement deficiency, and splenectomy patients.
  - *S. pneumoniae*, *H. influenzae*, and *Listeria monocytogenes*.
- *Patients with cochlear implant or basilar skull fracture:*
  - *S. pneumoniae*, *H. influenzae*, and Group A beta-hemolytic streptococci
- *Patient with neurosurgery or basilar skull fracture:*
  - *Staphylococcus aureus*, coagulase negative staphylococci, and pseudomonas
- *Viral causes:*
  - Common viruses which can cause meningitis are arboviruses, herpes simplex viruses (HSV), coxsackieviruses, echoviruses, human enteroviruses, human immunodeficiency virus (HIV), varicella zoster, and Epstein–Barr (EB) virus.
- *Subacute causes of meningitis*: Tuberculosis, fungal, autoimmune disorders such as systemic lupus erythematosus (SLE), malignancy, and drugs are uncommon.

EVALUATION OF MENINGITIS

Clinical Presentation

Clinical features may vary depending on duration and severity of illness, causative organism, and host characteristics. Initial symptoms may be nonspecific and comprise a prodrome such as fever, malaise, and headache. Hence, emergency physician must have low threshold to suspect meningitis. Patients lying in extremes of age group, immunocompromised patient, and partially treated may not have classical symptoms. Presentation of subacute meningitis such as fungal and tuberculous meningitis is also obscure. The classic triad of fever, altered mental status, and neck stiffness is seen in <50% of patients with meningitis. At least 2 of 4 symptoms of fever, altered mental status, neck stiffness, and headache will be present in 95% of patients. Associated symptoms—genitourinary complaints, rash, and cough.

Enquire about: Comorbidities, immunization history, and history of tuberculosis.

Travel history: For example, Japanese B infection is common in south-east Asia

Social history: For example, residence in closed dormitories is risk factor for meningococcal meningitis.

Physical Examination

Kernig's signs—with the patient lying supine and hip flexed to right angle, attempt to straighten the leg to full extension inability to do so is a positive Kernig's sign.

Brudzinski's signs—with the patient in supine position attempt to passively flex the neck causes flexion at hip joint.

Head jolt test: The patient is asked to move their head back and forth in the horizontal plane at a rate of 2–3 turns/second. If the patient's headache worsens, it is considered positive.

Signs of brain parenchymal irritation: Altered mental status, seizures, personality changes, and focal neurological deficit. In advanced stages of meningitis cerebral edema develops which causes symptoms such as vomiting, headache, and cranial nerve abnormalities.

Investigations

Complete blood count: Total leukocyte count may be increased in bacterial meningitis. However, a normal total leukocyte count does not rule out meningitis. Measure blood sugar levels frequently. Coagulation profile will be required before performing lumbar puncture.

Chest X-ray: 50% of patients with pneumococcal meningitis have evidence of chests infection in initial X-ray. Blood cultures are to be collected as soon as possible in a patient suspected with meningitis. Blood cultures are positive in 50–80% cases of bacterial meningitis.

Other ancillary tests: Liver function tests and renal function test. Blood biomarkers of inflammation such as procalcitonin and C-reactive protein (CRP) can be used to guide treatment.

Neuroimaging: It is not mandatory to perform neuroimaging before initiating treatment in clinically suspected meningitis. Urgent computed tomography (CT) brain should be performed in patients with signs of increased intracranial tension before performing lumbar puncture.

Indications of Performing Computed Tomography before Lumbar Puncture

New onset seizure and signs of raised intracranial tension such as papilledema, bradycardia, focal neurological deficit, and Glasgow coma scale (GCS) < 14, immunosuppression, and history of central nervous system (CNS) disease such as stroke, neoplasm, etc. CT may demonstrate hypodense lesion on temporal lobe in cases of HSV encephalitis, though magnetic resonance imaging (MRI) demonstrates this much earlier in course of illness.

Cerebrospinal Fluid Analysis

At least 3 sterile tubes containing 1–1.5 mL of cerebrospinal fluid (CSF) each should be collected. Parameters to be assed in CSF—opening pressure, turbidity, xanthochromia, glucose, protein, CSF lactate, CSF to serum glucose ratio, cell counts, gram staining, acid fast staining, and CSF culture. CSF finding in different types of meningitis is summarized in **Table 1**.

Polymerase chain reaction (PCR) for viral nucleic acid: Commonly used test for specific diagnosis of HSV, cytomegalovirus (CMV), EBV, varicella zoster virus (VZV), enteroviral viruses, and more sensitive than viral culture. PCR is helpful for identification of CNS infection caused by *mycoplasma pneumonia.*

Serologic studies: For diagnosis of acute viral infection serology studies are commonly used. Detection of virus specific immunoglobulin M (IgM) and IgG with related to clinical presentation is helpful for diagnosis of acute viral meningitis.

MANAGEMENT OF MENINGITIS

Priority of treatment is prompt administration of antibiotics (**Flowchart 1**).

Bacterial meningitis: After stabilization of airway, breathing, and circulation appropriate empirical antibiotics must be administered. If the clinical suspicion is high, empirical antibiotics should be started before performing lumbar puncture. Choice of empirical antibiotics will depend on the infection suspected based on patient's age and premorbid condition (**Table 2**). Dexamethasone may attenuate the inflammatory response and its consequences such as vasculitis, cerebral edema, etc. and shown to reduce overall mortality and neurological sequelae. First dose of dexamethasone should be administered at least 10–20 minutes before administration of antibiotics. Dose is 0.15 mg/kg. It is continued every 6 hours for next 4 days. Other corticosteroids have poor CNS penetrations, hence not to be used. All patients with meningitis have to be hospitalized and started on intravenous antibiotic therapy.

Viral meningitis: There is no specific treatment for viral meningitis and the treatment is largely supportive. Acyclovir 10 mg/kg 8 hourly can be given in HSV meningitis/encephalitis. Other aspects which may need emergent management in meningitis are septic shock, metabolic complications such as hypoglycemia, acidosis, hypokalemia, raised intracranial tension, seizure, and coagulopathy.

Complications: Risk of development of complications is higher with *N. meningitidis* and *S. pneumoniae*. Early complications include cerebral edema and hydrocephalus. Extracranial

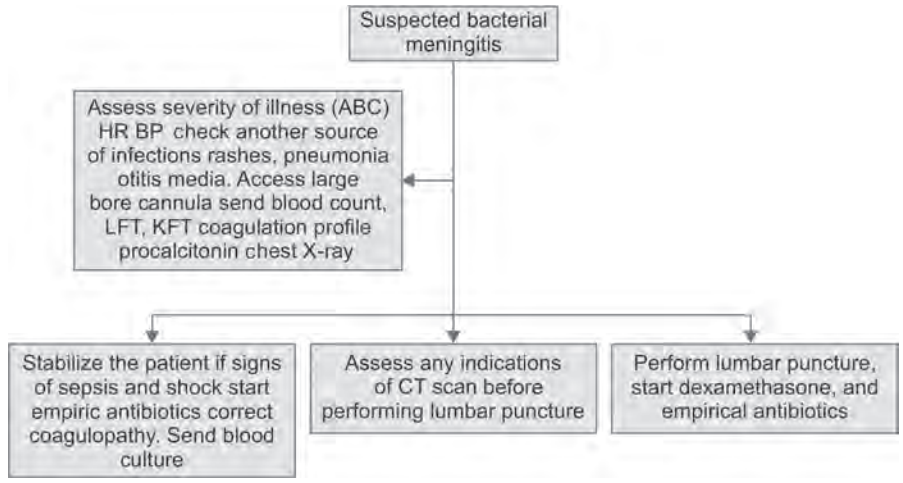
(CSF: cerebrospinal fluid; PMNs: polymorphonuclears; WBC: white blood cell)



Suspected bacterial meningitis
Assess severity of illness (ABC) HR BP check another source of infections rashes, pneumonia otitis media. Access large bore cannula send blood count, LFT, KFT coagulation profile procalcitonin chest X-ray
Stabilize the patient if signs of sepsis and shock start empiric antibiotics correct coagulopathy. Send blood culture
Assess any indications of CT scan before performing lumbar puncture
Perform lumbar puncture, start dexamethasone, and empirical antibiotics

(BP: blood pressure; CT: computed tomography; HR: heart rate; KFT: kidney function test; LFT: liver function tests)

FLOWCHART 1: Algorithm for managing bacterial meningitis.

TABLE 2: Empirical antibiotic therapy for meningitis.

Age group	*Empirical antibiotic therapy*
Neonates	Ampicillin (150 mg/kg/day) +3rd generation cephalosporin, e.g., Cefotaxime (100–150 mg/kg/day)
Infant and children	Cefotaxime or ceftriaxone (80–100 mg/kg/day) + vancomycin (60 mg/kg/day)
Adults	Ceftriaxone (80–100 mg/kg/day) + vancomycin (30–60 mg/kg/day)
Immunocompromised patient	Cefotaxime (8–12 g/day) or ceftriaxone (4 g/day) + ampicillin (12 g/day) + vancomycin (30–60 mg/kg/day)
Suspected nosocomial infection	Vancomycin (30–60 mg/kg/day) + ceftazidime (6 g/day) or cefepime (6 g/day) or meropenem (6 g/day)

complications—sepsis, multiple organ dysfunction syndrome (MODS), arthritis, and syndrome of inappropriate antidiuretic hormone (SIADH). Long-term sequelae—cognitive impairment and sensorineural hearing loss

Differential diagnosis: Meningitis should be differentiated from encephalitis, subdural hematoma subarachnoid hemorrhage, brain abscess, and brain tumor.

ENCEPHALITIS

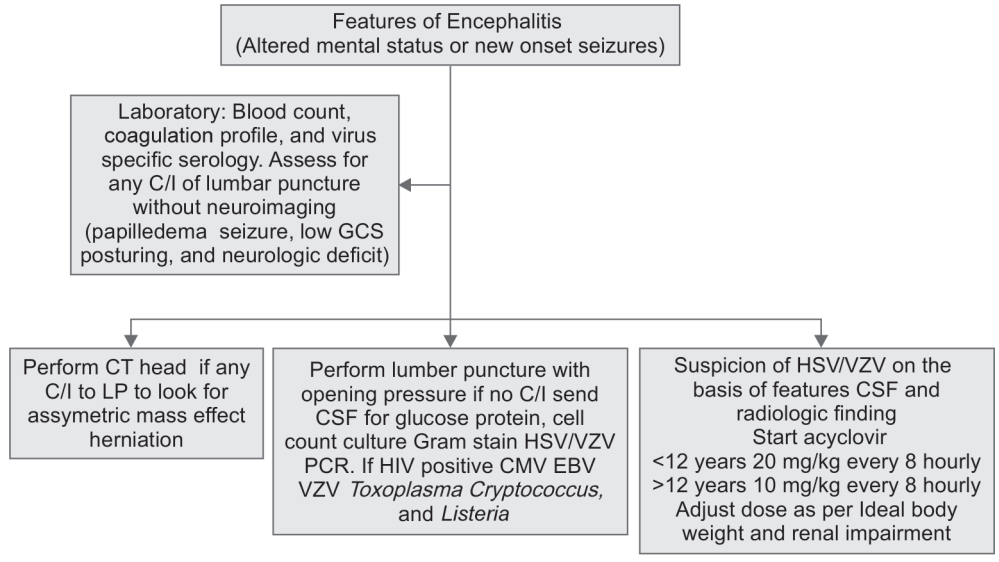
Encephalitis is the pathologic diagnosis but clinically it signifies inflammation of the brain parenchyma. Encephalitis is associated with broad differential diagnosis and possible causes are categorized into infectious (viral, bacterial, or parasitic), postinfectious, and noninfectious (metabolic, toxic, autoimmune, and paraneoplastic). Viral encephalitis may be due to either direct infection of the brain parenchyma (e.g., West Nile virus) or viral reactivation in neuronal tissue (e.g., HSV and VZV). The later (viral reactivation) is a postinfectious encephalomyelitis (also known as acute disseminated encephalomyelitis), an autoimmune phenomenon mostly seen in children and young adults after a disseminated viral illness or vaccination. Direct viral infection is responsible for majority of the acute encephalitis. Incidence of encephalitis due to all causes in adult ranges from 1 to 10/100,000 and 10 to 15/100,000 in children. Due to limited diagnostic availability and emerging pathogens most of the causative agents of encephalitis remain unidentified. Most common cause of sporadic viral encephalitis in industrialized nations is HSV encephalitis (HSV-1) followed by VZV. In immunocompromised individuals, VZV actually more common than HSV accounting for 20–30% of encephalitis.

Clinical presentation: If CNS infection is suspected in any patient, first step is to determine if bacterial meningitis is present, emergent empiric antibiotic therapy should be started. Consider encephalitis if evidence of brain parenchymal involvement and neurological findings or seizures are present. Brain parenchymal involvement (functions of involved part of brain) and clinical presentation correlates well (**Table 3**). HSV encephalitis is typically involving the temporal lobes. Personality changes, psychosis, and olfactory or gustatory hallucinations are the clinical features which may be mistaken as psychiatric disorder initially. Upper-quadrant visual field defect and inability to recall new information are the features if there is inferior frontal and temporal lobe involvement. When the dominant hemisphere is involved hemiparesis with greater involvement of the face and arm, or aphasia is presenting features. Tremors or other movement disorders also presentation of West Nile virus and eastern equine encephalitis virus (basal ganglia and thalamus involvement). Brainstem encephalitis clinically presents as autonomic dysfunction, lower cranial nerve involvement, and respiratory drive disturbance, e.g., enterovirus-71, flaviviruses (e.g., West Nile virus and Japanese encephalitis virus), and alphaviruses (e.g., eastern equine encephalitis virus). One thing need to know that no individual signs and symptoms or CSF finding alone or in combinations with other clinical features can distinguish one cause of encephalitis from another.

Approach to diagnosis: The initial approach to diagnosis of encephalitis is almost similar to meningitis (**Flowchart 2**). Evaluate the patient for any contraindications of lumbar puncture and need for CT head before lumbar puncture procedure. All patients should have lumbar puncture done unless contraindicated (a coagulation abnormality,

TABLE 3: Clinical presentation and treatment of selected causes of viral encephalitis.				
Pathogen	***Other neurologic symptoms (fever, headache altered mental status are common in all)***	***Nonneurologic features***	***Diagnostic test***	***Treatment***
HSV (Usually young and elderly; no seasonal predilection)	Seizures, olfactory/gustatory hallucinations, aphasia, personality changes, hemiparesis (face/arm > leg), and upper visual field defect	Rash	HSV-1, HSV-2 PCR (CSF)	Acyclovir 10 mg/kg every 8 h (adjust for renal function)
VZV (Most common in immuno-compromised)	Cranial nerve palsies and cerebellitis	Shingles	VZV PCR (CSF)	Acyclovir 10 mg/kg every 8 h (adjust for renal function)
CMV (Immuno-compromised)	Behavior changes and coma	Pneumonitis, retinitis, and myelitis	CMV PCR (CSF)	Ganciclovir 5 mg/kg every 12 h
Enterovirus (Usually young)	Rhombencephalitis (myoclonus, tremors, ataxia, cranial nerve palsies), polio such as acute flaccid paralysis and neurogenic shock	Hand-foot-mouth disease, rash, myocarditis, pericarditis, conjunctivitis, and pulmonary edema	Enterovirus PCR (CSF)	Supportive care

(HSV: herpes simplex virus; VZV: varicella zoster virus; CMV: cytomegalovirus; PCR:polymerase chain reaction)



Features of Encephalitis
(Altered mental status or new onset seizures)
Laboratory: Blood count, coagulation profile, and virus specific serology. Assess for any C/I of lumbar puncture without neuroimaging (papilledema seizure, low GCS posturing, and neurologic deficit)
Perform CT head if any C/I to LP to look for assymetric mass effect herniation
Perform lumber puncture with opening pressure if no C/I send CSF for glucose protein, cell count culture Gram stain HSV/VZV PCR. If HIV positive CMV EBV VZV Toxoplasma Cryptococcus, and Listeria
Suspicion of HSV/VZV on the basis of features CSF and radiologic finding
Start acyclovir
<12 years 20 mg/kg every 8 hourly
>12 years 10 mg/kg every 8 hourly
Adjust dose as per Ideal body weight and renal impairment

(HSV: herpes simplex virus; VZV: varicella zoster virus; CMV: cytomegalovirus; PCR: polymerase chain reaction; EBV: Epstein Barr virus; CSF: cerebrospinal fluid; CT: computed tomography; HIV: human immunodeficiency virus; GCS: Glasgow coma scale)

FLOWCHART 2: Approach to encephalitis.

local infection at the lumbar puncture site, or evidence of significant mass effect on imaging studies). Indications of performing CT head before lumbar puncture are: moderate-to-severe impairment of consciousness, focal neurologic deficit, posturing, papilledema, seizures, relative bradycardia with hypertension, or immunocompromise. All patients with suspected encephalitis should be tested for HIV infection in addition to a standard laboratory evaluation, because subsequent diagnostic testing and empiric treatment will be changed.

In HSV encephalitis, CSF findings are variable (normal/lymphocytic pleocytosis/hemorrhagic). No CSF findings can reliably distinguish HSV from other causes of viral encephalitis. Thus, molecular (e.g., PCR) and serologic testing are important for establishing a specific diagnosis. Other point to note that initial diagnostic tests may be negative during early infection, normal CSF profile, and a negative HSV PCR. Repeat lumbar puncture at 24–48 hours if diagnosis is strongly suspected.

From the emergency medicine perspective, antibiotic therapy should be initiated rapidly in a patient with suspected CNS infection, the most frequent question to ask when you suspect encephalitis is whether a patient requires antiviral coverage in addition to standard antibiotics. Treatable causes of viral encephalitis are HSV and VZV, and immediate care in emergency department is not influenced by sending a battery of expensive diagnostic molecular test. However, CSF specimen can be preserved so that other clinicians (neurologist) can expand the initial diagnostic workup as needed without repeating the lumbar puncture.

Magnetic resonance imaging is more sensitive than CT in detecting the early changes of viral encephalitis, and with the most characteristic findings there are edematous changes in the orbital surfaces of the frontal lobes and medial temporal lobe. MRI also able to identify alternative causes of encephalitis, with suspected encephalitis in whom the diagnosis remains uncertain. An electroencephalogram (EEG) is not indicated

routinely for encephalitis but useful adjunct in patients who are comatose or poorly responsive, EEG may reveal nonconvulsive status epilepticus requiring antiepileptic management.

Treatment: In any patient suspected to have viral encephalitis, empiric treatment with intravenous acyclovir is indicated until a definitive diagnosis can be achieved. Antiviral treatment should be started as early as possible, ideally within 6 hours of presentation.

Acyclovir dose is calculated according to weight and age. The ideal body weight (IBW) should be calculated for the acyclovir dose [Males: IBW (kg) = 50 kg + 2.3 kg for each inch over 5 feet; females: IBW (kg) = 45.5 kg + 2.3 kg for each inch over 5 feet].

The dose should be reduced in patients with pre-existing renal impairment because acyclovir is renally excreted. Patients should be well hydrated to maintain adequate urine output in order to prevent acyclovir-induced crystalluria and nephrotoxicity. Concurrent administration of nephrotoxic drugs should be minimized.

BRAIN ABSCESS

Brain abscess is collection of infective and purulent materials within CNS. It may be located in subdural, epidural or intracranial location. It also may be found in intramedullary or epidural spinal locations. Cerebral abscess is representative of localized infection of brain parenchyma characterized by pus collection within a well vascularized capsule. They begin as a localized area of cerebritis and develop into an encapsulated collection of pustular materials presenting as a mass-like lesion, similar to the abscess in other sites. Incidence is more among male as compared to female. Pulmonary infections and endocarditis are one of the common causes of hematogenous spread. Contiguous spread from dental infections, mastoiditis, etc. Other causes are neurosurgical intervention and penetrating head injury cryptogenic.

Microbiology: varies as per the etiology of abscess.

Clinical features: Most patients will have nonspecific symptoms; hence, high degree of clinical suspicion is needed for clinical diagnosis. Classical triad of fever, headache, and focal neurological deficit is seen only in minority of patients. Brain abscess should be suspected in patients with progressive headache, gradual onset of neurological deficit, and signs of increased intracranial tension.

Investigations: Laboratory investigations are not very helpful for diagnosis. Leukocytosis and elevated erythrocyte sedimentation rate may be found. CSF may be normal or have low glucose and elevated proteins. Neuroimaging is one the most important tools for definitive diagnosis. MRI has better specificity and sensitivity than CT scan to diagnose pyogenic infections. Diffusion weighted MRI may help to differentiate from neoplastic lesion.

Treatment: Treatment of brain abscess may require both medical and surgical intervention. Prompt administration of empirical antibiotics should be ensured. Antibiotic coverage should extend to gram-positive, gram-negative, and anaerobic organisms. The choice of antibiotics is based on patient factors such as age, prior comorbidities, immunity status, and local microbiological profile of causative organisms. Intravenous cefotaxime and metronidazole are preferred as empirical therapy. In patient with immune-compromised condition empirically sulfadiazine and pyrimethamine is considered. Corticosteroids are not routinely considered, and should be used only in patients with evidence of significant perilesional edema causing mass effect or raised intracranial tension. Surgical therapy is required in most cases. Patients who are to be managed only medically should be carefully selected. Patients with intact mental status and without signs of increased intracranial pressure in whom there is little doubt of diagnosis. All patients have to be admitted and they require prolong duration of intravenous antibiotic administration.

Prognosis: Prognosis has improved in recent times due to better suspicion, availability of neuroimaging, and effective antibiotics. Severity of neurological deficit at the time of initial presentation is a strong predictor for outcome. Patients with rapid progression of disease have relatively poorer outcome.

Common residual effects of brain abscess are epilepsy and focal neurological deficit like hemiparesis.

124 CHAPTER

Coma: Evaluation and Management

Noel Fernando

INTRODUCTION

Consciousness has spectrum of clinical presentation. Coma lies at the extreme end of the spectrum. Coma is one of the most common presentations to emergency department. It is a life-threatening emergency and needs urgent attention. As an emergency physician, we should develop the skill of quick examination, appropriate investigation, and management.

PATHOPHYSIOLOGY

Consciousness refers to one's self-awareness to environment which includes arousal and awareness. The cerebral cortex is responsible for maintaining a person's consciousness.

The arousal is initiated by subcortical structures, most importantly by ascending reticular activating system (ARAS). The ARAS neurons are located in the pons and midbrain. It receives all sensory inputs (such as visual, auditory, olfactory, and gustatory…) and relays them to thalamus and cerebral cortex. Any damage to these cortical, subcortical structures or axonal projections may lead to depressed consciousness or coma.

DIFFERENTIAL DIAGNOSIS

As an emergency physician, we should keep broad differential diagnosis in an undifferentiated coma patient which could avoid a diagnostic error. A quick focused history and physical examination helps to narrow down the differentials. Also, this kind of vigilant approach helps us to initiate an urgent treatment for the patients.

Even though the differential diagnosis of coma is broad, the basic pathology is the brain dysfunction involving any area from cortex to brainstem. It can be a massive neuronal dysfunction to small injury to the critical areas of brain. This can be due to structural brain disease or nonstructural causes such as electrolyte imbalance, drug induced, and infections.

Special consideration should be given to geriatric population and immunocompromised patients. The older population are prone for frequent infections, accidental drug overdose, and drug interactions. Immunocompromised patients like cancer patients undergoing chemotherapy are prone for infections which have a higher possibility for altered conscious levels. There are also few coma mimics which should also be considered during the diagnosis.

The differentials are broad, we can grossly divide into structural, nonstructural causes, and coma mimics (**Table 1**).

CLINICAL FINDING

It will be a challenge for us to get history from a patient with depressed consciousness. We should focus on the information from the prehospital team, which could guide you through the management. It is also very essential to focus on collateral history from any family, friends, next of kin, and police officers at scene. The time and pattern of onset of depressed consciousness is very important. This information will help us immensely in diagnostic evaluation. An abrupt onset of coma suggests a stroke, cardiac event or any acute poisoning, whereas a gradual onset suggests more of infectious or metabolic cause.

Any information on the prodromal symptoms is also very essential in the evaluation.

A preceding headache suggests—intracerebral hemorrhage, cervical artery dissection, and cerebral venous sinus thrombosis.

A preceding fever suggests—meningitis or encephalitis.

The patient's medication history should be reviewed carefully, as any change in the medication doses or new medications to the list may also be a probable cause. Nowadays most of the patient carry a medical file or medical alert bracelet. Therefore, it is important to get essential information from history which is very useful in diagnosis.

CLINICAL EXAMINATION

Once the patient is received in the emergency department, the initial observations such as heart rate, blood pressure, respiratory rate, oxygen saturations, blood glucose, and the level of consciousness should be recorded.

Immediate ABCDE assessment and stabilization should be done. Following which a complete head to toe examination is required. If head injury is suspected, look for any external injuries such as scalp lacerations, hematoma, periorbital ecchymosis (raccoon eyes), retroauricular ecchymosis (battle sign), hemotympanum, cerebrospinal fluid (CSF) otorrhea

TABLE 1: Causes of coma: Differential diagnosis.

	Nonstructural causes		
Structural CNS diseases	***Metabolic***	***Toxic***	***Coma mimics***
• Intracranial hemorrhage • Cerebellar infarct • Cortical infarct • Hydrocephalus • Neoplasia • Metastatic lesions	• Electrolyte imbalance (Hypo- and hyperglycemia, hyponatremia, and hypercalcemia) • Endocrine (Adrenal crisis, pituitary apoplexy, thyrotoxic crisis, and myxedema coma) • Hepatic encephalopathy • High altitude cerebral edema	• Hypoglycemic agents • Opioids • Carbon monoxide • Methemoglobinemia • Sedatives • Toxic alcohols • Anticonvulsants • Anticholinergics • Psychiatric medications • Beta-blockers • Salicylates • Neuroleptic malignant syndrome • Serotonin syndrome	• Locked in syndrome • Neuromuscular paralysis • Psychogenic unresponsiveness

(CNS: central nervous system)

or rhinorrhea. Any tongue laceration suggests a possible seizure. Always it's better to immobilize the C-spine unless any C-spine injuries are rule out. The presence of meningismus suggests meningitis, subarachnoid hemorrhage or any space occupying lesions. Look for stridor which indicates large airway obstruction possibly caused by infection, anaphylaxis, trauma or foreign body. Most of the patients with altered mental status due to myxedema coma or thyroid storm will be having a goiter.

A quick examination of chest should be done, looking for any tracheal deviation, external injuries, dilated veins, any rashes, and chest movements. More focused examination of heart rate, rhythm, murmurs, and abnormal lung sounds is essential. A 12 lead electrocardiogram (ECG) is mandatory to rule out any arrhythmias or any acute cardiac event.

Abdominal examinations should focus on the abdominal distension, any dilated veins, hepatosplenomegaly, and pulsatile abdominal mass. A quick focused assessment with sonography for trauma (FAST) and extended (E)-FAST scan may provide more information essential for diagnosis. Bladder scan helps to rule out any urinary retention. A rectal examination should be done to look for gastrointestinal bleeding and foreign bodies.

The patient should be undressed fully to start the evaluation of skin. A dry skin with loss skin turgor suggests dehydration. Look for rashes, patches, signs of infection or trauma. Also look for signs of liver cell failure such as jaundice, palmar erythema, spider angiomata, and caput medusae. Petechiae or purpura could suggest meningitis, vasculitis or disseminated intravascular coagulation (DIC). Unusual odors also provide additional diagnostic clues.

Neurologic examination should include evaluation of patients level of consciousness, cranial nerves, brainstem reflexes, and motor responses. In an emergent situation alert, verbal, pain, unresponsive (AVPU) scale can be used to assess the level of consciousness. The two most widely used scales are the Glasgow coma scale (GCS) and full outline of unresponsiveness score (FOUR). While comparing both the scores, the FOUR score has higher reliability than GCS scale as it incorporates more detailed assessment of brainstem reflexes and has greater predictive value in intubated patients.

The cranial nerves should be assessed for all comatose patients, in particular for eyes. The pupillary size, symmetry, and reactivity provides important diagnostic clues. *Pinpoint pupils* pontine hemorrhage/infarction, drugs opioids, clonidine, and organophosphates dilated *pupils* oculomotor nerve injury/brain injury, and brain herniation

Eye position and movements should be noted, as it gives us a lot of important information.

- *Horizontal conjugate eye gaze*: Brain injury (ipsilateral) or pontine injury (contralateral), and seizures.
- *Horizontal disconjugate eye gaze*: Sedation, intoxication, and metabolic disorders.
- *Vertical disconjugate gaze*: Cerebellum or brainstem lesion.
- *Roving eyes*: Bihemispheric dysfunction.
- *Nystagmus*: Brainstem dysfunction, overdose (anticonvulsants, lithium, ketamine, and ethanol)

Fundoscopic Examination

It is a valuable examination tool to identify the raised intracranial pressure (ICP) quickly. The presence of papilledema, and retinal hemorrhages suggest raised ICP, which could be confirmed by optic nerve sheath measurement with ultrasound.

We can evaluate the brainstem function by various brainstem reflexes such as oculocephalic reflex, oculovestibular reflex, corneal reflex, and gag reflex. Always make sure that there is no suspicion for C-spine injury. Motor function should be assessed by spontaneous movements or reflexive response to noxious stimuli. Reflexive responses such as decorticate rigidity, and decerebrate rigidity is usually seen in focal brain lesions. But this is not very conclusive, as it is also seen in toxic and metabolic disorders. Muscle tone is assessed by passive movement of extremities. Muscle rigidity occurs most commonly with upper motor neuron (UMN) brain lesions, malignant hyperthermia, and neuroleptic malignant syndromes and in certain intoxications. Myoclonus is very

poor prognostic marker which is usually seen in brain injuries, nonconvulsive status epilepticus, and hypercarbic respiratory failure.

GRADING OF COMA

Two major grading systems are used to assess the depths of coma (**Table 2**). Grading systems allow emergency physician to quickly convey a general sense of the patient's condition. This grading is helpful during emergency medical service communications when one provider conveys the grading to emergency department physician/nurses over telephonic discussion who cannot examine the patient. The GCS, first described in 1974, GCS is a 15-point composite score of eye, motor, and verbal responses developed to assess patients with head trauma. The FOUR score, first described in 2005, is a 16-point scale that assesses eye, motor, brainstem reflexes, and respirations. Both gradings rely on clinical findings and can be performed quickly. The FOUR score has a benefit over GCS in that one of three of the GCS criteria is unreliable in intubated patients. The FOUR score is also a better predictor of mortality in critically ill patients.

TABLE 2: Grading of coma.

Glasgow coma scale (GCS)	***Full outline of unresponsiveness score (FOUR)***
Eye opening response: • Spontaneously, 4 • To speech, 3 • To pain, 1	*Eye response:* • Open and tracking or blinking to command, 4 and open but not tracking, 3 • Closed but open to loud voice, 2 • Closed but open to pain, 1 • Closed with pain, 0
Best verbal response: • Oriented, 5 • Disoriented, 4 • Inappropriate words, 3 • Incomprehensible sounds, 2 • No response, 1	*Motor response:* • Thumbs up, fist or peace sign, 4 • Localizes pain, 3 • Flexion response to pain, 2 • Extension response to pain, 1 • No response to pain or myoclonic status, 0
Best motor response: • Obeys commands, 6 • Localizes pain, 5 • Withdrawal from pain, 4 • Decorticate flexion, 3 • Decerebrate extension, 2 • No movement, 1	*Brainstem reflexes:* • Pupil and corneal reflexes present, 4 • One pupil wide and fixed, 3 • Pupil or corneal reflexes absent, 2 • Pupil and corneal reflexes absent, 1 • Absent pupil, corneal, and cough reflex, 0
	Respiration: • Not intubated, regular pattern, 4 • Not intubated, Cheyne–Stokes pattern, 3 • Not intubated, irregular breathing, 2 • Breathes above ventilator rate, 1 • Breathes at ventilator rate or apnea, 0

INVESTIGATIONS

General Management

The most important bedside investigation for patients with reduced consciousness is blood glucose levels to rule out hypoglycemia. The routine blood investigations such as full blood count, urea, electrolytes, coagulation profile, renal function, ammonia, and liver function test should be done. This helps us to rule out infections, anemia, thrombocytopenia, and electrolyte imbalance, renal and hepatic dysfunction. Blood gas gives plenty of information about the patient's clinical status. It helps us to assess the oxygen and carbon dioxide levels. In a patient with metabolic acidosis, widened metabolic acidosis suggests ketosis, lactic acidosis, uremia, or intoxications. An elevated prothrombin and activated partial thromboplastin time (aPTT) is usually seen in liver disease, blood dyscrasias, and anticoagulant use. Urinary catheterization must be done in comatose patients to monitor the fluid status. Urinalysis helps to rule out dehydration (high specific gravity), infections (positive leukocytes and nitrates), and ethylene glycol ingestion (presence of calcium oxalate crystals).

Toxicologic screen including paracetamol and salicylate levels should be done as they are prone to cause unexplained acidosis. Serum alcohol levels could also be included. In carbon monoxide/methemoglobinemia poisoning co-oximetry is very useful. Blood and urine cultures should be sent to rule out infections.

Electrocardiogram is very useful to look for arrhythmias, electrolyte abnormalities, hypothermia, and structural brain lesions.

Chest X-ray helps to look for pneumonia, pneumothorax, foreign body, cardiomegaly, and aortic dissection.

Noncontrast computed tomography (CT) scan of brain is the most commonly used modality of imaging in comatose patients. This helps to identify any ischemic stroke, subarachnoid hemorrhage, intracranial hemorrhage, cerebral edema, hydrocephalus, and mass lesions. CT angiography is useful in identifying intracranial aneurysm, cerebral venous thrombosis, basilar, and vertebral artery stenosis. Magnetic resonance imaging (MRI) helps us to identify posterior circulation lesions and brainstem lesions. Even though it is much superior than noncontrast CT brain in identifying the brain lesions, it is not used much in emergency department due to its restricted availability during out of hours.

Electroencephalogram (EEG) is not only used in nonconvulsive status epilepticus, but also used in patients with refractory seizures.

It is better to have quick algorithm guide to run through during the management of the comatose patients in emergency department.

TREATMENT

Treatment of coma is based on the three basic causes such as structural, metabolic, or toxins (**Table 3**).

First: Coma from structural cause can be treated surgically targeted medication or mechanical ventilation. Neurosurgeon is involved for early intervention for intracranial hemorrhage and hydrocephalus.

Second: Coma due to metabolic induced neuronal dysfunction, conditions such as hypoglycemia and hyponatremia should be corrected.

TABLE 3: Coma: Causes, clinical findings, and treatment.

Diagnosis	*Causes*	*Examination findings*	*Treatment*	*Comments*
Structural	*Intracranial hemorrhage*	Headache—sudden onset, blurred vision, and raised ICP signs	• CT brain • Reversal of anticoagulation —if drug induced	Early neurosurgical team involvement
	Cerebral infarct	Sudden drop in GCS and focal neurological deficit	• CT brain • Stroke team review • Thrombolysis	If patient is in the window period—thrombolysis is indicated
	Cerebellar infarct	Headache, nausea, vomiting, vertigo unsteady gait, and cerebellar signs-nystagmus dysarthria, in coordination	• MRI—gold standard investigation • Stroke team review • Thrombolysis	Early stroke team and neurosurgical team involvement
Metabolic derangement	*Hypoglycemia*	Tachycardia, diaphoresis, drowsy, seizures, and coma	• Oral carbohydrate • Oral glucogel • IV dextrose • IV/IM glucagon • IV octreotide	Check BM for all patients with reduced consciousness. Do not give glucagon in liver failure and alcohol dependent patients due to low stores of glucose
	Hyperglycemia	Nausea, vomiting, tachypnea, abdominal pain, and signs of dehydration	• IV fluid (normal saline) • IV insulin	Identify the severity of ketoacidosis and start insulin infusion early
	Hyponatremia	Headache, nausea, vomiting, confusion, anorexia, and seizures	• Hypertonic saline—in emergency situations • Water restriction	Rapid administration of hypertonic saline—pontine myelinolysis
	Hypercalcemia	Lethargy, polyuria, dehydration, and constipation	• IV fluids • Diuretics • IV bisphosphonates • Prednisolone	Suspect malignancy
Endocrinal disorders	*Adrenal crisis*	Weight loss, weakness, hypotension, and hyperpigmentation	• IV fluids • IV hydrocortisone • IV glucose • Antibiotics—for infections	• Biochemical abnormalities • Metabolic acidosis • Hyperkalemia • Hyponatremia, low urea, and hypoglycemia
	Pituitary apoplexy	Headache-acute onset, nausea, vomiting, visual impairment, and hormonal imbalance	• IV fluids • Correct electrolyte abnormalities • IV hydrocortisone	Common in postoperative period, during pregnancy
	Thyrotoxic crisis	Tachycardia, fever, sweating, vomiting, and diarrhea	• IV fluids • Beta-blockers • Propylthiouracil	Give antibiotics if infection suspected
	Myxedema coma	Bradycardia, weight gain, tired, lethargy, edema, depression, hair loss, and constipation	• IV fluids • Thyroxine • IV hydrocortisone	
Hepatic disorders	*Hepatic encephalopathy*	Jaundice, lethargy, fetor hepaticus, asterixis, ascites, and dilated veins	• Lactulose • Ascitic drainage	Anticipate SBP, sepsis, and GI hemorrhage
Altitude illness	*High altitude cerebral edema (HACE)*	Headache, rapid ascent, vomiting, confusion, and irritability	• Hyperbaric oxygen • Rapid descent • IV dexamethasone	More common in Amateur Trekkers
Toxic-drug induced	*Opioids*	Drowsy, bradypnea, confusion, irritability, seizure, and respiratory arrest	• Oxygen • Naloxone • Intubation if retaining CO_2	Early ITU involvement required

Continued

Continued

Diagnosis	Causes	Examination findings	Treatment	Comments
	Hypoglycemia agents	Drowsy, confusion, seizures, and suicidal symptoms	• IV glucose • IV octreotide-refractory hypoglycemia	Look for acidosis especially I metformin overdose
	Sedatives	Drowsy, bradypnea, respiratory arrest, confusion, and seizures	• Identify the sedative • Supportive	Most common—benzodiazepines do not use flumazenil in mixed overdose and long term benzodiazepines dependent patients
	Alcohols	Nausea, vomiting, drowsy, vision loss, confusion, seizures, reduced urine output, and renal failure	• IV fluids • Fomepizole • Folic acid	• Increased osmolar gap • Early dialysis required
	Carbon monoxide	Headache, nausea, vomiting, drowsiness, confusion, and seizures	Hyperbaric oxygen	More common due to fuel combustion
	Methemoglobinemia	Headache, cyanosis, lethargy, malaise, and seizures	• 100% oxygen • Methylene blue	Always do ABG to rule out hypoxia in these patients
	Anticonvulsants	Drowsiness, confusion, and slurred speech	Supportive	
	Anticholinergics	Tachycardia, hyperpyrexia, sweating, pupillary dilatation, and urinary retention	• Pyridostigmine • Benzodiazepines • IV fluids	
	Psychiatric medications	Tachycardia, sweating, drowsiness, hypotension, wide QRS, and metabolic acidosis	• IV fluids • Sodium bicarbonate	Most common is tricyclic antidepressants
	Beta-blockers	Bradycardia, hypotension, hypoglycemia, and seizures	• Atropine • Glucagon • Epinephrine • Transcutaneous pacing	Lipid emulsion will be necessary if initial measures fail
	Salicylates	Nausea, vomiting, delirium, drowsiness, tinnitus, and mixed acid base disorders	• IV fluids • Sodium bicarbonate • Hemodialysis	
	Neuroleptic malignant syndrome	Hyperpyrexia, drowsiness, delirium, autonomic instability, and raised creatine kinase	• IV fluids • Cooling methods • Benzodiazepines • Dantrolene sodium	• More common with depolarizing muscle relaxants • Prone for rhabdomyolysis and renal failure
	Serotonin syndrome	Tachycardia, hyperpyrexia, hypertension, muscle rigidity, autonomic instability, and raised creatine kinase	• IV fluids • Cyproheptadine • Benzodiazepines	• More common with depolarizing muscle relaxants • Prone for rhabdomyolysis and renal failure

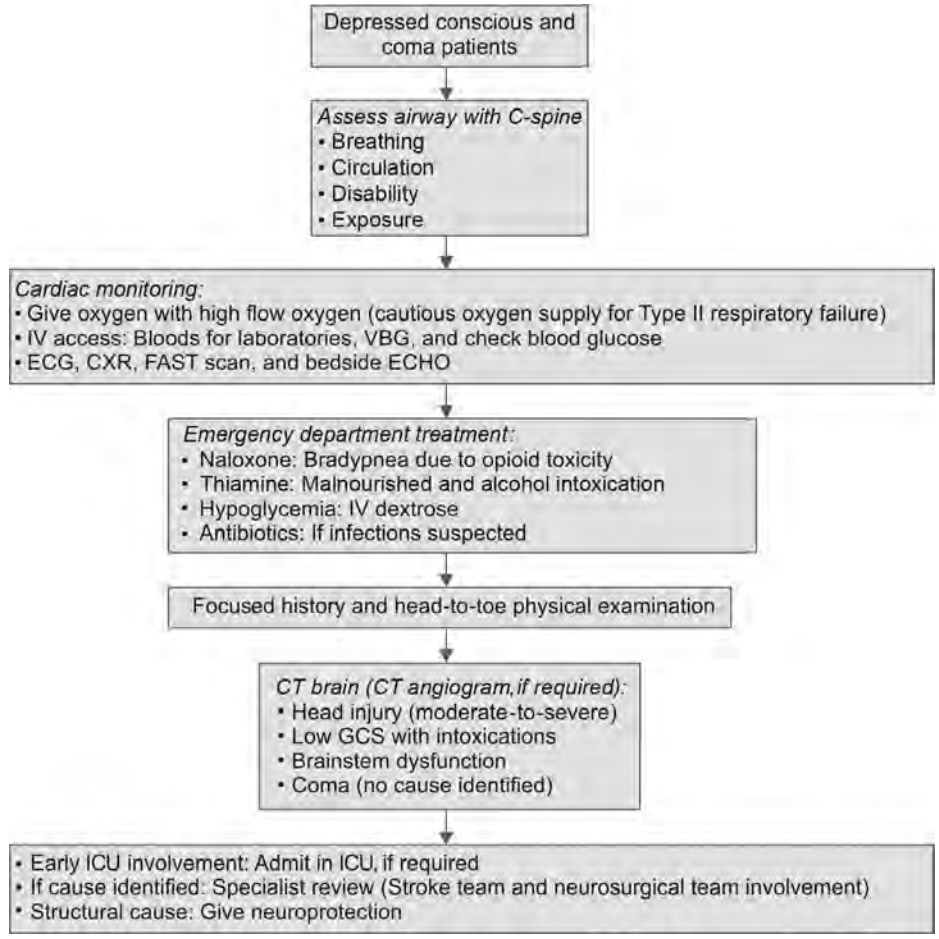
(ABG: arterial blood gas; CT: computed tomography: GCS: Glasgow coma scale; GI: gastrointestinal; ICP: intracranial pressure; IV/IM: intravenous/intramuscular; MRI: magnetic resonance imaging; SBP: spontaneous bacterial peritonitis; ITU: intensive treatment unit)

Third: Toxin induced neuronal dysfunction is managed by initiating the supportive care securing airway, adequate oxygenation, and ventilation, intravenous fluid, inotropes, and vasopressors if required and specific antidote if toxin is identified.

SUMMARY

Coma requires immediate stabilization and a structured approach to diagnosis and management because coma is a life-threatening process. The differential diagnosis for

coma is descriptive, and can be divided into structural and diffuse neuronal dysfunction either due to toxic or metabolic imbalance. History from reliable sources to determine the etiology of coma; focused physical examination can be helpful to narrow down diagnosis. The definitive management of coma is disease-specific and toxin induced coma is treated with conservative management and specific antidote. Approach to patient with coma is summarized in **Flowchart 1**.



Depressed conscious and coma patients
Assess airway with C-spine
• Breathing
• Circulation
• Disability
• Exposure
Cardiac monitoring:
• Give oxygen with high flow oxygen (cautious oxygen supply for Type II respiratory failure)
• IV access: Bloods for laboratories, VBG, and check blood glucose
• ECG, CXR, FAST scan, and bedside ECHO
Emergency department treatment:
• Naloxone: Bradypnea due to opioid toxicity
• Thiamine: Malnourished and alcohol intoxication
• Hypoglycemia: IV dextrose
• Antibiotics: If infections suspected
Focused history and head-to-toe physical examination
CT brain (CT angiogram, if required):
• Head injury (moderate-to-severe)
• Low GCS with intoxications
• Brainstem dysfunction
• Coma (no cause identified)
• Early ICU involvement: Admit in ICU, if required
• If cause identified: Specialist review (Stroke team and neurosurgical team involvement)
• Structural cause: Give neuroprotection

(CT: computed tomography; CXR: chest X-ray; ECG: electrocardiogram; ECHO: echocardiogram; FAST: focused assessment with sonography for trauma; GCS: Glasgow coma scale; ICU: intensive care unit; IV: intravenous; VBG: venous blood gas)

FLOWCHART 1: Approach to patient of depressed conscious and coma.

CHAPTER

Type 1 Diabetes Mellitus and Insulins

Amit Gupta, Vinod Kumar

INTRODUCTION

Type 1 diabetes mellitus (T1DM) is a chronic autoimmune disease presenting with increased blood glucose levels (hyperglycemia), primarily because of the insulin deficiency that occurs as the consequence of the loss of the pancreatic islet β-cells. In majority of patients (70–90%), the loss of β-cells is the main cause of T1DM (formation of T1DM-associated autoantibodies); in a smaller group of patients, no autoantibodies are detected, and the cause of β-cell destruction remains unknown (idiopathic T1DM or type 1b diabetes mellitus); unless otherwise specified, the term T1DM refers to autoimmune T1DM. The diagnosis of T1DM in the absence of ketoacidosis and symptoms will be key to a better prognosis, particularly in the very young. Nowadays novel insulin analogs, pumps, pens, continuous glucose monitoring devices, in combination with better psychosocial support are available and all are important ways to improve the quality of life, of those already affected by T1DM.

TYPE 1 DIABETES MELLITUS

Diabetes mellitus is classified on the basis of etiology into T1DM, type 2 diabetes mellitus (T2DM), and gestational diabetes mellitus (**Table 1**). Type 1 diabetes mellitus is one of the most common chronic childhood disorders characterized by immune-mediated destruction of beta cells of the islet of Langerhans in pancreas leading to absolute deficiency of insulin. The child may present with classical signs of hyperglycemia such as increased thirst (polydipsia), increased urination (polyuria), and weight loss while diabetic ketoacidosis (DKA) remains the second most common presentation of T1DM. Most of the patients with T1DM have circulating antibodies against glutamic acid decarboxylase 65 (GAD65), zinc transporter 8 (ZnT8), and islet cell autoantibodies (IA2). The management of T1DM requires setting realistic goals balancing glycemic control and avoiding severe hypoglycemia, educating the patient and the family, and at the same time ensuring normal growth and development. The insulin therapy assumes the central role in management of hyperglycemia in patients with T1DM.

DIAGNOSIS

Diagnosis of diabetes can be done by any one of the criteria set by American Diabetic Association (**Box 1**). The criteria for prediabetic are fasting plasma glucose 100–125 mg/dL, glycated hemoglobin (HbA1c) 5.7–6.4%, 2-hour plasma glucose, and oral glucose tolerance test 140–199 mg/dL. Glycated HbA1c represents the average blood glucose level over the 2–3-month period. In emergency department, patient may present with higher level of blood sugar and features of hyperglycemia polydipsia and polyurea) or if they are in hyperglycemic crisis, should be considered as diabetic.

TABLE 1: Etiological classification of diabetes mellitus.

Type 1 diabetes mellitus (Destruction of β cell—absolute insulin deficiency)	• Idiopathic • Immune mediated
Type 2 diabetes mellitus (Relative insulin deficiency and insulin resistance secretory defect)	• Genetic defect of β-cell function • Genetic defects of insulin action • Exocrine pancreas disease (pancreatitis, trauma, and cystic fibrosis) • Endocrinopathies (Cushing's disease, pheochromocytoma, and hyperthyroidism) • Drug induced-steroids, thiazides, and thyroid hormone • Infections—congenital rubella and cytomegalovirus) • Immune-mediated diabetes (rare)—lupus • Diabetes associated with congenital syndrome—Down's, Klinefelter's, and Turner's syndrome)
Gestational diabetes mellitus	

BOX 1: Criteria for diagnosing the diabetes—American Diabetic Association.

- Glycated hemoglobin A1c (HbA1C) ≥6.5%
- Fasting blood glucose ≥126 mg/dL (fasting–no calorie intake for at least 8 h)
- Random blood sugars ≥200 mg/dL with symptoms of hyperglycemia or hyperglycemic crisis
- Oral glucose tolerance test (OGTT) 2-h plasma glucose ≥200 mg/dL

Hundred Years of Insulin Therapy (1921–2020)

It has been a hundred years since the discovery of insulin in 1921. Fred Banting and Charles H Best began their research in May 1921 with John R Macleod as formal supervisor. In August of 1921, Banting and Best after several failures, prepared an extract from the atrophied pancreas of a dog and conducted their famous experiment on the Marjorie (The Dog). The discovery of insulin in 1921 was a milestone in the world of medicine because before that everyone with T1DM was destined to die within weeks to year of the diagnosis. The Leonard Thompson, 14-year-old boy was the first human who received insulin prepared by Banting and Best on January 11, 1922. However the first test failed and could not bring down the sugar levels. JB Collip prepared a series of purified insulin preparations (bovine) and it was able to bring down the blood sugar levels of Leonard and he started to gain weight and after that everything is a history now. Over the last hundred years the landscape of insulin therapy has undergone dramatic changes. The first bottle of insulin contained U-10 insulin and 3–5 mL of it was injected at one time.

Protamine and protamine zinc insulin were developed in 1936, while neutral protamine Hagedorn (NPH) came into existence in 1946. In the year 1952 lente zinc insulin was developed, while the first human synthetic insulin was developed in 1965. In the late 70s, first recombinant human insulin was developed. It was also the time when lots of researchers were working on improving the delivery of insulin through insulin pumps. Insulin pen devices came into existence in 1981. The first human analog insulin lispro was approved for use in the USA in 1996. Insulin glargine and insulin detemir were approved in 2000 by the United States Food and Drug Administration (USFDA). Inhaled insulin was developed in the year 2006. In the last one decade with the launch of new preparations such as insulin degludec, glargine U300, Fiasp (fast-acting insulin aspart), and U-500 insulin, a wide range of insulins are available for use. The year 2020 has generated new hope with the talks of smart insulin and weekly insulin therapy. Advances in insulin therapy coupled with technology have led to availability of a variety of glucose sensors and insulin pumps. Do It Yourself (DIY) movement initiated by many patients and their parents with T1DM all across the world has accelerated the development and incorporation of newer technologies.

INSULIN

Insulin therapy is the principal treatment of patients with T1DM with a goal of replacing the deficient hormone and achieving good glycemic control. Endogenously insulin is secreted in the portal vein and there are minute-to-minute physiological variations in insulin secretion. It is extremely difficult to match the physiological insulin secretion and hence the idea of a near physiological replacement of insulin in T1DM remains elusive; however, with the development of newer insulins and sensor augmented closed loop insulin pumps the future is promising. The side effects of insulins are rare and hypersensitivity is uncommon. Hypoglycemia, weight gain, and lipohypertrophy are the other adverse effects of insulin therapy.

Insulin Preparations/Types of Insulin (Duration of Action)

- *Ultra-rapid-acting insulin*: Fiasp enters the bloodstream within 2–3 minutes of subcutaneous administration with onset of action in 10–15 minutes, peak in 1–3 hours and total duration of action 3–5 hours or even shorter. Till the time of writing this article, Fiasp is not approved for use in the pediatrics population.
- *Rapid-acting insulin analogs*: Insulin aspart (Novorapid), lispro (Humalog), and glulisine (Apidra) are rapid-acting insulins with onset of action within 15–30 minutes and peak in 1–3 hours with total duration of action 3–5 hours. Rapid-acting insulins are usually given 5–15 minutes before a meal. In younger children where meal intake is unpredictable, it can also be administered after the meal.
- *Short-acting insulin*: These insulin analogs have onset of action in 30 minutes to 1 hour with a peak effect in 2–4 hours, and with a duration of action 5–8 hours (e.g., Actrapid, Humulin, and regular human insulin). Short-acting insulin is given 20–30 minutes before the meals.
- *Intermediate-acting insulin*: NPH and lente insulin are intermediate acting as the onset of action is within 1–2 hours, with peak activity in 6–10 hours and duration of action varying from 10 to 16 hours.
- *Long/ultra-long-acting insulin*: Insulin glargine, biosimilar insulin glargine, and detemir are long acting while degludec and glargine-U300 are ultra-long-acting insulins. Insulin glargine, biosimilar insulin glargine, and detemir have duration of action up to 24 hours. Glargine-U300 has duration of action up to 36 hours while effective duration of action of insulin degludec is up to 42 hours. These insulins are usually given once or twice a day.

Insulin Delivery Devices

- *Syringe and needle*: Insulin syringes have been long in use. One advantage is that it is possible to mix two different types of compatible insulins in a syringe while key limitations are risk of incorrect dosing, difficulty in carrying along, and psychological impact.
- *Insulin pens*: A variety of insulin pens are available. Compared with syringes, pens are more convenient and flexible to use with greater accuracy, patients have greater acceptability for pens. They are also cost effective and easy to carry. The smallest needle is 31 gauge in size, and available in 4 mm and 6 mm length.
- *Insulin pumps*: Insulin pump is an electronic device which can automatically deliver insulin to the patient. Insulin pump represents an advancement in diabetes technology

and in a suitable patient it can help in improving glycemic control and minimize the risk of hypoglycemia.
- *Inhaled insulin*: A rapid-acting insulin (Technosphere approved by USFDA, Afrezza) is also available in the form of inhaler. The inhaled insulin is having many challenges such as inconsistent dose delivery, requires more training, and there are concerns regarding adverse effects on pulmonary functions.

Insulin Regimens

Insulin therapy regimens are of two types; conventional and intensive.

A conventional regime is simpler and requires administration of a short-acting insulin (e.g., NPH) with a rapid-acting insulin (e.g., regular insulin). Two insulins can be mixed in a syringe or a premixed insulin formulation can also be used. Two-thirds of the insulin dose is given in the morning before breakfast and one-third of the total insulin dose is given at the time of the dinner. The usual ratio in which short-acting and rapid-acting insulin are mixed is two-thirds short acting and one-third rapid acting. Some of the premixed insulin formulations are also available as 50:50 insulins. One of the major drawbacks of this regimen is that dose of the insulin is relatively fixed; allowing less flexibility in titration and at the same time it requires more lifestyle adjustment from the patient as well. However, there are various other regimens which use a variety of insulin preparations tailored according to the need of the patient.

An intensive insulin therapy regimen aims at achieving a stricter glycemic control with an intent to match the physiological insulin release as much as possible. It involves administration of a basal insulin to provide for basal insulin levels and use of rapid- and short-acting insulins before meals to cover the postprandial glucose excursions. The dose of prandial insulin is calculated by carbohydrate counting and the present blood glucose of the patient. This type of regimen requires proper education of the patient regarding carbohydrate counting and hypoglycemia. Since the dose of prandial insulin varies as per the carbohydrate intake, this allows greater meal flexibility. Use of insulin pump is also an intensive regimen. In the Diabetes Control and Complications Trial (DCCT), intensive glycemic control with intensive regimen was found to reduce the overall glycemic control and long-term risk of microvascular complications.

Multiple Daily Injections

Multiple daily injection (MDI) regimen combines a basal insulin at bedtime or in morning with multiple doses of prandial insulin given as pre meal bolus. The approach has shown better glycemic control and lesser incidences of hypoglycemia. The dose of prandial insulin is decided by blood glucose levels before meals, amount of carbohydrate in the meal, and expected level of activity or exercise before and after meals. Insulin glargine is one of the most common basal insulin used in children and is approved by the USFDA for use in children above 6 years of age however the benefit has also been seen in younger children. The use of insulin glargine and lispro has shown lesser incidences of nocturnal hypoglycemia when compared to NPH insulin in adolescents and young children.

Insulin Pump

Continuous subcutaneous insulin infusion (CSII) by insulin pumps is now widely used worldwide for pediatrics T1DM population. Use of insulin pumps is recommended in T1DM patients with recurrent severe hyperglycemia and large variations in blood glucose levels. Patients whose diabetes is suboptimally controlled, those who have microvascular complications, and those patients who have risk factors for macrovascular complications may also benefit from CSII. Some patients may choose CSII over conventional insulin therapy for the sake of greater flexibility. Insulin pumps may also be of value in infants, young children, and adolescents, during pregnancy and in T1DM patients involved in competitive sports. Rapid- or short-acting insulins are used in insulin pumps. When an insulin pump is combined with a continuous glucose monitoring sensor, it is called sensor augmented insulin pump therapy. A closed loop system is one which is fully automated, meaning the pump can reprogram itself based on automatically detected glucose values. Studies have shown that pump therapy may only be slightly better than MDI when it comes to glycemic control and frequency of hypoglycemia in adults. However, in the pediatric population, a meta-analysis on insulin pump therapy has shown to reduce the requirement of daily insulin with less frequent hypoglycemic episodes, better glycemic control, and lesser incidences of ketoacidosis. However, there are studies which have shown that it may not be possible to achieve similar results in newly diagnosed patients.

Insulin Dose

A child with newly diagnosed diabetes usually requires a dose of 0.5–1.0 unit of insulin per kg. The dose of insulin in children may also depend upon the age and pubertal stage of the child. Prepubertal children may require 0.25 units/kg of insulin while insulin requirement may increase during puberty. Basal insulin requirements are usually 40–50% of the total daily insulin dose. It is important to know about the insulin correction factor which is estimated as the amount of blood glucose reduced by injecting one unit of rapid-acting insulin. It is calculated by dividing 1,500 by total daily insulin dose. It is equally helpful to know insulin to carbohydrate ratio and is defined as the number of grams of carbohydrate which will be covered by 1 unit of insulin. It is usually calculated by dividing 500 with total daily insulin dose.

Honeymoon Phase and Type 1 Diabetes Mellitus

In patients with newly diagnosed T1DM, following initiation of insulin therapy there is a period in which insulin requirement may decrease as some of the beta cells may still be functioning. One should be judicious and frequently monitor blood glucose levels as likelihood of hypoglycemia is increased with insulin therapy. The phase may last from weeks to several years.

Diabetic Ketoacidosis and Insulin

The International Society for Pediatric and Adolescent Diabetes (ISPAD) defines DKA as blood glucose >200 mg/dL with metabolic acidosis (pH <7.3), and bicarbonate <15 mEq/L with presence of ketones in the blood and the urine. Though it is

beyond the scope of this chapter to discuss in detail regarding DKA, it is important to highlight some key points of insulin therapy in the management of DKA. An initial bolus dose of insulin is not necessary. The insulin is started as intravenous infusion and this rapidly archives the steady state levels in the serum. The rate of insulin infusion is usually 0.1 unit/kg/h; however, no difference in rate of fall of blood glucose is seen in some studies with lower doses of 0.05 units/kg/h.

SUMMARY

Insulin therapy is the cornerstone of T1DM management. The journey of insulin from discovery to completion of 100 years in 2021 is fascinating and an entire book can be written on insulin itself. We have tried to highlight the key points relevant to insulin therapy in management of type of diabetes.

126 CHAPTER

Type 2 Diabetes Mellitus: Management

Ashok K Taneja

INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a global noncommunicable lifestyle disease (NCD) prevalent all over the world. The unfortunate part of this disease is its ever-increasing incidence in all socioeconomic groups of population. As per estimate of the World Health Organization (WHO) incidence of non-insulin-dependent diabetes mellitus (NIDDM) is 10% of world population. Whereas in India, the incidence is 11–14%. It is manifested by a chronic hyperglycemic state in conjunction with other metabolic derangements. If left untreated or treated poorly, it leads to complications such as end-stage renal failure, heart failure, coronary artery disease CAD, peripheral artery disease (PAD), strokes, retinopathy, erectile dysfunction, and many others. This leads to increased morbidity and mortality in general population.

Type 2 diabetes mellitus is primarily due to either insulin deficiency or insulin resistance or both. Both the states result in increased hepatic glucose output, reduced utilization of glucose by various organs, increased renal reabsorption of glucose, reduced incretin hormones, and increased production of glucagon among others.

Currently there is no known cure for the disease but can be controlled enabling the individual to have an improved quality of life. The main aim of management is directed at reducing acute and chronic complications, i.e., microvascular and macrovascular.

EPIDEMIOLOGY: PREVALENCE IN WORLD AND INDIA

There are estimated 72.96 million cases of diabetes in adult population of India. The prevalence in urban areas ranges between 10.9% and 14.2% and prevalence in rural India was 3.0–7.8% among population aged 20 years and above with a much higher prevalence among individuals aged over 50 years (INDIAB Study). Kerala has the largest number of diabetes patients followed by Tamil Nadu and Punjab.

World: It is estimated that 415 million people are living with diabetes in the world, which is estimated to be 1 in 11 of the world's adult population (9.9%). 46% of people with diabetes remain undiagnosed till complications ensue. The figure is expected to rise to 20% worldwide by 2040. China, followed by India has the highest incidence of T2DM. Lithuania, Sweden, Estonia, Ireland, and 35 more nations has the lowest incidence. Though, there is no sex preponderance in incidence of diabetes mellitus (DM) in males or females. Both are equally affected. Genetic effects, epigenetic mechanisms, nutritional factors, pregnancy, and sedentary lifestyle affect the risk and complications differently in both sexes. However, obesity, psychological stress, and higher incidence of myocardial infarctions are more prevalent in females.

The population above 18 years of age are most concerned group who are unaware of their diabetic status (52% of diabetes). The percentage of undiagnosed diabetes is highest among the Malays (53%) followed by the Chinese (49%) and the Indians (42%). In terms of diabetes control, only 23.8% of patients in primary care and 12.7% in tertiary institutions were able to achieve their specified glycemic targets.

RISK FACTORS

- *Biological risk factors*: Body mass index (BMI), body fat distribution, brown adipose tissue, metabolic syndrome, adipokines, imbalance of sex hormones, gestational diabetes mellitus (GDM), and insulin resistance (metabolic syndrome).
- *Health related*: Smoking, alcoholism, and lifestyle disorders including sedentary life. Excessive intake sugar sweetened beverages.
- *Psychological*: Stress, economic status, sleep deprivation, and drugs abuse.
- Pharmacological drug induced like steroids, etc.
- Genetics

ETIOLOGY AND PATHOGENESIS

Blood glucose levels are dependent on carbohydrate intake, hepatic glucose production, peripheral uptake, secretion, and action of insulin and glucagon. The basic pathophysiology of T2DM includes defect in insulin secretion or action or both at pancreatic or peripheral receptors level. The resistance to insulin action at muscles or adipose tissues level increase

insulin hypersecretion which ultimately leads to beta cell fatigue and dysfunction (cause of metabolic syndrome, i.e., insulin resistance, dyslipidemia, and hyperglycemia). There is fine balance between regeneration and apoptosis of islet cells. In beta cell fatigue or failure this balance is altered leading to T2DM. Multiple factors affect this balance. Factors contributing to beta-cell dysfunction are age, genetics, insulin resistance, incretin failure, lipotoxic glucotoxicity, amylin, and others including hexosamines.

Insulin resistance is an altered physiological phenomenon due to impaired response of insulin on glucose, lipids, and protein metabolism. The insulin resistance is mediated at liver, muscles, and adipose tissue levels and it leads to endothelial dysfunction affecting micro- and microvasculature.

Combination of insulin resistance and beta-cell dysfunction is termed as "the triumvirate".

Obesity also plays a very important role in insulin resistance, dyslipidemia, and hyperglycemia. Adiposity leads to increased levels of proinflammatory cytokines such as tumor necrosis factor alpha (TNF-alpha), monocyte chemoattractant protein-1 (MCP-1), and interleukin-6 and 8.

Genetic predisposition also plays a role in development of T2DM. Presence of single nucleotide polymorphisms (SNPs) is associated with higher incidence of beta-cell dysfunction.

Dopamine and vitamin D also play very important role on glucose homeostasis.

DIAGNOSIS AND SCREENING

Blood glucose levels either in fasting state or postprandial, oral glucose tolerance test (OGTT) with 75 g glucose and lately glycated hemoglobin (HbA1c) are the mainstay of diagnosis and screening tools [American Diabetes Association (ADA) 2009 and International Diabetes Federation 2009 and Research Society for the Study of Diabetes in India (RSSDI) 2010]. Diagnostic criteria for diagnosis of diabetes are presented in **Box 1**. *In the presence of classical signs and symptoms*: Random blood sugar >200 mg%. *In the absence of classical symptoms*: OGTT with 75 g glucose (five readings to be taken every ½ hour): If two readings >200 status: Diabetes; if one reading 200 but 2 hours reading returning close to fasting (90–110) status: Impaired glucose tolerance (IGT), if all readings <200 and fasting (80–100)—post 2 hours (120–140) status: Normal but to be monitored periodically. Mass screening should be done in the society for asymptomatic individuals to detect undiagnosed cases. Criteria for screening in asymptomatic individuals are presented in **Box 2**.

BOX 1: Criteria for diagnosis of diabetes (DCCT and WHO protocol).

HbA1c > 6.5%. The test should be performed using NGSP certified and DCCT assay standardized.

OR fasting plasma glucose (FPG): 126 mg%. No calorie intake for 8 hours.

OR 2 hours plasma glucose (PP): >200 mg on OGTT with classical symptoms.

OR 2 hours post full meal plasma glucose: >160 mg%. If 140–160 mg% IGT, repeat periodically.

(DCCT: Diabetes Control and Complications Trial; HbA1c: glycated hemoglobin; IGT: impaired glucose tolerance; NGSP: National Glycohemoglobin Standardization Program; OGTT: oral glucose tolerance test; PP: postprandial; WHO: World Health Organization)

BOX 2: Criteria for screening in asymptomatic individuals.

1. **Individuals who are overweight (BMI >25 kg/m^2) with additional risk factors of:**
   - Physical inactivity
   - First-degree relative of diabetics
   - Women who delivered a baby weighing >4 kg or diagnosed with GDM
   - HDL cholesterol, 35 mg% or triglycerides >350 mg% on 12 h fasting
   - Glycated hemoglobin (HbA1c) >5.7%, IGT on previous testing
   - Insulin resistance syndrome, e.g., acanthosis nigricans
   - Nonhealing ulcer but no classical symptoms
   - Women with polycystic ovarian disorder
   - If lifestyle changes not working
   - NASH and NAFLD (nonalcoholic fibrotic liver disease)
   - Frequent burnout syndrome
2. **In the absence of above criteria, routine testing for all >45 years of age.**
3. **Prediabetes status—periodic testing.**

(BMI: body mass index; GDM: gestational diabetes mellitus; HDL: high-density lipoprotein; IGT: impaired glucose tolerance; NASH: nonalcoholic steatohepatitis)

MANAGEMENT

Type 2 diabetes mellitus is basically a combination of lifestyle disorder with genetic predisposition superimposed by pollution and other environmental factors. Obesity or metabolic syndrome further compounds the problem. Nonpharmacological measures are the most important faculties in managing diabetes. Next step is to add oral hypoglycemic agents (OHAs)-insulins. Surgery, especially in diabesity or stem cell, and pancreatic transplantation are the other options, but reserved for highly morbid conditions. *Author postulate 10 commandants for the management of T2DM: (1) nutrition therapy, (2) micronutrient therapy, (3) exercise, (4) sweeteners, (5) tobacco, (6) alcohol, (7) sex, (8) stress management, (9) environmental pollution, and (10) pharmacotherapy.*

Nonpharmacological Therapy

Nutrition (Diet) Therapy

Medical nutrition therapy (MNT) has a great role in preventing or delaying the onset of T2DM specifically with obesity (**Table 1**). The basic idea is to control the calories intake as appropriate for the body weight of the individual. Calorie intake depend on work style, BMI, place of work, gender, and ethnicity (decides muscle mass of the body). However, the calorie composition should be: Carbohydrates: Normal = 60% (diabesity = 40–50%); Proteins: Normal = 25–30% (diabesity = 30%, not to exceed 1 g/kg body weight); Fats:

TABLE 1: Recommended dietary composition for diabesity.	
Component	Energy intake (%)
Carbohydrates (sucrose should be <10%)	40–50%
Proteins	20–30% (not to exceed 1 g/kg body weight)
Fats	20–30%
n-6 PUFA	<10%
n-3 PUFA	<2%) oily fish is the main source. Once a week
MUFA	10–20%
Saturated	7–10%

- *Reduce saturated fat by 10% of total intake*
- *Increase MUFA by 40% of balance fat intake*
- *Increase PUFA by 40% of balance fat intake*
- *Eliminate transfats totally*
- *Increased vegetables to six servings/day*
- *Reduce refined carbohydrates. Use complex carbohydrate*
- *Consume high-quality protein*
- *Exercise 60 minutes daily including aerobics and resistance training*
- *Achieve ideal body weight, BMI, waist circumference, and body fat composition*

(BMI: body mass index; MUFA: monounsaturated fatty acid; PUFA: polyunsaturated fatty acid)

normal = 25–30% [diabesity = <30%, of which monounsaturated fatty acid (MUFA) = 10–20%, polyunsaturated fatty acid (PUFA) = 7–10%, and saturated = 7–10%). In weight reducing diets, a calorie reduction of 500–1,000 calories are planned with simultaneous increase in expenditure of 500–1,000 calories in the form of exercise. ADA, Diabetes Control and Complications Trial (DCCT), RSSDI, and Diabetes India recommend the healthy choice of foods and good physical activity to decrease the risk of diabetes and prevention of cardiovascular (CV) morbidity and mortality. Dietary Approaches to Stop Hypertension (DASH), Mediterranean, and ketogenic diets are other concepts for control of diabesity.

Micronutrient Therapy

Although use of micronutrients as nutrition therapy is a cornerstone of the management of diabetes, but uncertainty prevails in its guidelines. Zinc, chromium, iron, vitamin D, alpha-lipoic acid, carotenoids, vitamins E and C, selenium, and some of the B vitamins, notably folate, pyridoxine, and cyanocobalamin play an important role in managing diabetes. Best source of micronutrients are fruits, nuts, fresh vegetables, sprouts, seeds, sun-shine, fatty fish, egg, and supplements. Cooking oils, flours, rice, cereals, and juices are now being available in the market with fortified vitamin A, D, calcium, etc.

Exercise

Regular moderate exercise not only utilizes blood sugar but improves blood circulation removing oxidants from the body. It further, reduces the development and progression of atherosclerosis, hence reduction in cardiovascular disease (CVD)-related mortality. Exercise induces longevity by 1.1/2 years in moderate and 3.1/2 years in vigorous exercise individuals. The beneficial effects include reduction in HbA1c, blood sugar levels, triglycerides (TGs) (9.5%), low-density lipoprotein (LDL) (13.7%), and increase high-density lipoprotein (HDL) (9.6%). American College of Sports Medicine and American Heart Association (AHA) current recommendation for exercise is:

- 30 minutes of moderate exercise, i.e., mild increase in heart rate (HR) and breathing—5 days a week.
- 20 minutes of vigorous exercise, i.e., noticeable change in HR and breathing—5 days a week.

In addition, resistance training (weight training × 10 min) daily is recommended. All major muscle groups should be involved using 8–10 repetitions.

The WHO recommends 10,000 steps per day for a healthy living. Those who cannot walk should do sitting exercise, exercise on bicycle ergometer, swimming, pushups, weight training, and upper/lower body exercises depending on the deformity. Aerobic exercise, especially jogging/cycling/swimming are considered the best.

Sweeteners

Sweeteners are the ingredients that are added to food to bring sweetness, which can be sugar (nutritive) or sugar (non-nutritive) substitutes. Nutritive sweeteners are those sugars which contain carbohydrates and provide calories. Whereas, non-nutritive sugars provide only sweetness for taste and no calories. These are:

- Monosaccharides—sugar, jaggery, khand, etc.
- Disaccharides—fruit sugars
- Polysaccharides—honey and polyols
- Non-nutritive sugars: Artificial sweeteners—aspartame, sorbitol, stevia, tagatose, sucralose, etc.

Which sugars to be used in diabetes?

- *Naturals*: Polyols or polysaccharides-disaccharides with low glycemic index
- *Artificial*: Plant product-stevia or sucralose (minimum side effects)

Fresh or dried fruits can be used as adjuvants without much rise in blood sugar levels. Additional benefit is that these fruits add vitamins, minerals, and antioxidants to diet. One type (color) of fruit must be taken at least once a day. Fruits with moderate or high glycemic index should be taken before meals as it does not increase the blood sugar levels much.

Tobacco

Tobacco smoking and chewing are the leading causes of preventive mortality. The acute effects of tobacco smoking are sharp rise in blood pressure (BP) acutely and enhanced risk of renovascular, malignant, and masked hypertension. The effect is due to stimulation of sympathetic nervous system. Whereas chronic use promotes atherosclerosis with fall in HDL, rise in LDL cholesterol (LDL-C), rise in perfluorinated fatty acids (PFFAs) levels, thickening of arterial walls, especially the peripheral arteries, increased levels of carboxyhemoglobin with resultant coronary insufficiency, high platelets adhesiveness, high plasma fibrinogen levels, and increased risk of subarachnoid hemorrhages. A study from Canada indicated that women who smoke are more at

risk of preeclampsia and eclampsia. Smoking in diabetes increases the risk of CV mortality and peripheral neuropathy.

Alcohol

Alcohol use has been a very debatable issue for a very long time. Safe limit, however, is no alcohol.

Mild level of alcohol intake lowers the risk of thrombosis due to decreased inflammation markers and increased HDL levels. Moderate to heavy drinking impairs insulin release and hyperglycemia with increase in CVD-related mortality and liver failure and pancreatitis. Chronic and more than permissible alcohol intake is associated with increased LDL, TGs, increased inflammatory markers, insulin resistance, increased incidence of cardiomyopathy, vent, arrhythmias, and endothelial dysfunction.

One standard drink is 10 g of pure ethyl alcohol. This amounts to 375 mL of beer (5% alcohol); 150 mL of wine (12% alcohol), and 45 mL of whiskey (40% alcohol). This is considered safe limit in a day for men. For women it is 75% of above values. Red wine offers better protection due to presence of plant sterol-resveratrol. But wines and beers contain high levels of carbohydrates; hence, calorie count is must while taking alcohol. No alcohol is the best option.

Sex

Studies show that men with diabetes often have reduced testosterone levels, which can affect their sex drive. Moreover, diabetes damages the blood vessels, which affect blood flow to the penis leading to erectile dysfunction. Intimacy is ageless. It makes you young, energetic, and you live longer with good quality life.

Psychological Stress

Stress result in imbalance of hormones and catecholamines which has deleterious effects on blood sugar levels and BP. Stress act primarily on hypothalamus pituitary axis to produce more steroidal hormones, decrease insulin sensitivity and alter calcium-vitamin D metabolism, increased sympathetic stimulation, and decreased parasympathetic system. A variety of measures have been suggested to overcome stress and improve lifestyle. Yoga, meditation, music therapy, dancing, and laughter therapy are very helpful in alleviating stress. Professional counselors also play a very important role in managing stress. Enjoying holidays, family vacations, going to movies or theatres, doing arts, paintings, etc., also help in stress management. The United Kingdom Prospective Diabetes Study (UKPDS) over 12 years, observed the beneficial effects of stress management.

Lifestyle Heart Trial: Pranayama, surya namaskar, meditation, group support sessions, and music therapy all lead to correction of glycosylated HbA1c levels, dyslipidemias with reversal of atherosclerotic plaques.

Meditation, sound sleep for 6–7 hours, listening to music, and dancing all lead to reduction of stress hormones, relaxation of mind and body. This results in improving good quality of life.

Environmental Pollution

Air pollution: Particulate matter (PM) 2.5—SO_2 and CO_2 are the main culprits from vehicles, thermal plants, and increased construction activity. *Water pollution*: Contamination of underground water table with heavy metals such as arsenic and mercury. *Earth pollution*: Overuse of pesticides, chemical fertilizers, etc. *Noise pollution*: Affects catecholamine secretion and stress hormones such as corticosteroids and dopamine.

Pollutions affect the general health leading to anemia, hypocalcemia, vitamin D deficiency, and other micronutrients deficiency which alters sympathetic-parasympathetic axis dysfunction and hence, poor control of T2DM. The pollutants increase stress levels also, especially noise pollution. This leads to poor insulin secretion and efficacy.

Pharmacologic Therapy

Pharmacologic therapy (**Box 3**) includes oral hypoglycemia drugs, incretins, insulins, surgery like bariatric surgery, duodenal mucosal resurfacing (DMR), islet cells and pancreatic transplants, and genetic engineering to alter genes.

Oral Hypoglycemic Agents

Oral hypoglycemic drugs remain the mainstay of T2DM management after lifestyle modification (LSM) does not yield desired results. Different drugs with multiple, different pathophysiologic functions have been developed. Many new molecules have been developed. Different class of OHAs are available for clinician to manage T2DM. However, clinician has to decide himself the choice of drug to be used either singly or in combination.

Biguanides (Metformin)

Metformin lowers blood glucose, especially fasting blood glucose by decreasing hepatic glucose production and increasing the sensitivity of peripheral receptors to insulin. Metformin reduces A1c by about 1.5%. Usage in combination with other oral antidiabetic (OAD) agents has synergistic effect for further reduction in blood glucose levels and insulin requirements. It has beneficial effects on lipids also by reducing LDL and very low-density lipoprotein (VLDL). Metformin use shows improvement in diastolic dysfunction,

BOX 3: Pharmacologic therapy.

1. Biguanides
2. Sulfonylureas
3. Thiazolidines
4. Meglitinides
5. Sodium-glucose cotransporter-2 (SGLT-2) inhibitors
6. Drugs working on gut peptides:
   - Dipeptidyl peptidase-4 (DPP-4) inhibitors
   - Incretins
7. Alpha glucosidase inhibitors
8. Dopamine receptor agonist
9. Others:
   - Hydroxychloroquine
   - Amylin agonist: Pramlintide
   - Probiotics
10. Insulins

reduction in plasminogen activator inhibitor, C-reactive protein (CRP), and platelets aggregation. It is useful for weight reduction also. Most common adverse effects are nausea, anorexia, and diarrhea. These are minimized if metformin is taken together with/or after meals. Or taking extended release (ER) formulation.

Sulfonylureas (Glibenclamide, Gliclazide, Glipizide, and Glimepiride)

Sulfonylureas (SU) reduces plasma glucose by increasing insulin secretion from pancreatic beta cells. In this era we use second-generation SUs, examples given above. They are available as normal preparations or ER.

Mechanism of action of SUs is that it binds to receptors on beta cell surface via kir6.2 channels to open calcium channels, which, in turn release insulin. When used as monotherapy it reduces an average A1c by 0.4–1.6%. Various SUs available have almost similar efficacy and UKPDS has demonstrated significant reduction of microvascular and macrovascular complications with all second-generation SUs. The major adverse effect is hypoglycemia. The risk is higher in renal impairment, liver cirrhosis, and the elderly. Glibenclamide is more intense to cause hypoglycemia, hence used very uncommonly these days. Whereas, gliclazide and glimepiride cause less incidence of hypoglycemia. Another unwanted side effect is the weight gain; in the range of 1.5–2.5 kg. Gliclazide versus glimepiride versus glipizide: Gliclazide has proved to have an edge: CV safety-better control. SUs can be prescribed as monotherapy or in combination. Works better in combination with other OHAs.

Thiazolidines (Glitazones): Pioglitazone

Thiazolidines (TZDs) modulates peroxisome proliferator-activated receptors (PPAR). TZDs are insulin sensitizers and increase insulin sensitivity in muscle, adipose tissue, and liver. Troglitazone and rosiglitazone are not used now, only pioglitazones being used. Glitazones are the most debated OHAs. Recently, few studies on pioglitazones showed increased incidence of bladder cancer. However, there is a sufficient data to suggest otherwise and has shown beneficial evidence of beta-cell rejuvenation, hepatic fat deposits, and CV risk reduction. Because of its effects on PPAR-alpha and gamma, TZDs play a very important role in glucose, fatty acids, and cholesterol metabolism. Hence, the effects include increasing insulin sensitivity, enhanced lipolysis, reduced levels of cytokines such as TNF-α, serum leptin levels, plasminogen activator infibitoe-1, endothelial dysfunction, vascular reactivity, albumin urea, and increased adiponectin and HDL levels. TZDs reduce A1c by 0.5–1.4%. It has rapid action but improvement in glycemic control may only be seen after 6 weeks with maximum effect at 6 months. They can be used as monotherapy or combined with other OAD(s).

Side effects include weight gain (due to redistribution of body fat), fluid retention, anemia, heart failure, macular edema, and osteoporosis. The majority of fractures associated with TZD use were in the distal upper or lower limb, as opposed to the classic sites of osteoporotic fractures.

Caution

TZDs are contraindicated in patients with congestive cardiac failure (CCF) and liver failure.

Meglitinides: Repaglinide

These are short-acting insulin secretagogues that bind to SU receptors but at different sites. Action is similar to SUs but insulin release is dependent on glucose levels. Hence risk of hypoglycemia is less. They stimulate first phase insulin release, hence very rapid acting. It has a shorter half-life and is rapidly absorbed from the gastrointestinal tract (GIT) with peak levels 1–2-hour postmeal intake. It reduces A1c by 1.0–1.2%. It is very good drug for postprandial hyperglycemia. So should be used with major meals and in patients who need flexible meal timings or Hindu people, who keep 8–12 hours fasts.

Sodium-glucose Transport Protein 2 Inhibitors

Gliflozins (canagliflozin, dapagliflozin, empagliflozin, and remogliflozin) are the newer class of drugs acting on proximal renal tubules. This class of drugs selectively inhibits SGLT-2, a transporter in the proximal tubule, thus reducing glucose reabsorption leading to an increase in urinary glucose excretion. It reduces A1c by 0.2–0.8%. Weight loss (2.5–3.0 kg) and modest BP reduction is the hallmark of this class of drugs. Has good CV safety with risk reduction in CV events. It is estimated that by blocking this transporter release up to 119 g of blood glucose per day, which corresponding to 476 kcal. Additional water is eliminated by osmotic diuresis, resulting in a lowering of BP.

Dapagliflozin is the most widely studied molecule. It has a profile of once daily dose drug with good oral bioavailability. Peak plasma concentration is reached in 2 hours with half-life of 11–17 hours. Canagliflozin and empagliflozin are now also being used extensively showing good CV risk reduction. However, it is not recommended for those on concomitant treatment with loop diuretic. Efficacy of SGLT-2-i is dependent on renal function and it is not recommended in patients with moderate-to-severe renal impairment [estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2]. It also increases glucagon level and hence, using it with dipeptidyl peptidase-4 (DPP-4) inhibitor gives symbiotic results.

Side effects include significant increased genitalia and urinary tract infection. The United States Food and Drug Administration (USFDA) has issued a warning for canagliflozin related to reduced bone mineral density and increased risk of bone fracture.

A few cases of euglycemic diabetic ketoacidosis (DKA) also had been reported and caution should be exercised when prescribing these agents in those with severe beta-cell insufficiency, latent autoimmune diabetes, and in postsurgical patients.

The EMPA-REG clinical trial conducted in patients with T2DM at high risk for CV events showed a lower rate of cardiovascular events and all-cause mortality.

Drugs Working on Gut Peptides (Incretin-based Drugs)

There are two major glucose-dependent incretin hormones—insulinotropic polypeptide [gastric inhibitory polypeptide (GIP)] and glucagon-like peptide-1 (GLP-1). Both are gut based peptides and promote beta cell growth DPP-4 is an enzyme which degrades GIP (active 1–42 and inactive 3–42), secreted from K cells of duodenum. Whereas GLP-1 is the product of glucagon gene, being processed in L cells of ileum and colon.

Individuals with normal glucose metabolism, postprandial glucose levels stimulate the release of GLP-1 and GIP from the gut. These peptides regulate the release of insulin and glucagon from the pancreas and this process is termed as the incretin effect. In patients with T2DM, postprandial GLP-1 secretion is modestly impaired; while, GIP secretion is normal in T2DM patients. In this category, we have two classes of drugs, i.e., DPP-4 inhibitors and GLP-1 analogs.

Dipeptidyl Peptidase-4 Inhibitors (Gliptins) (Sitagliptin, Saxagliptin, Vildagliptin, and Teneligliptin)

Dipeptidyl peptidase-4 inhibitors (DPP-4Is) are the class of drugs which enhances the activity of hormone GLP-1, GIP, gastrin-releasing peptide and thus stimulate the release of insulin and inhibits the release of glucagon. After the meal GLP-1 levels increase three- to fourfold and DPP-4 inhibits the action of GLP-1. DPP-4Is drugs inhibit DPP-4 enzyme and increase the availability and half-life of GLP-1, which in turn stimulates the release of insulin. It lowers A1c by 0.5–0.8% as monotherapy and can be combined with other OHAs with synergistic effect. Good combinations are metformin and pioglitazones. DPP-4Is are weight neutral and has minimal risk of hypoglycemia. Its efficacy is not influenced by the duration of T2DM. Sitagliptin and vildagliptin are the most studied and used molecule. Recent introduction is the teneligliptin because of cost and OD dose. The common side effects are gastritis, upper respiratory infections, and diarrhea. Caution is reduction of dosage in chronic kidney disease (CKD) where GFR is <50 (half dosage) and <30 mL/min (one-fourth dosage). Hence, renal functions need to be assessed before starting DPP-4Is.

The SAVOR-TIMI 53 clinical trial has shown that saxagliptin use is associated with increased risk of heart failure. But the more recent TECOS study did not show any increased risk. In general, the use of DPP-4Is is not associated with any adverse cardiovascular outcomes.

Glucagon-like Peptide-I Analogs (Incretins) (Exenatide and Liraglutide)

Glucagon-like peptide-I is an incretin mimetic, stimulates insulin secretion and suppress glucagon secretion. GLP-1 levels are markedly reduced in T2DM. GLP-1 analogs are recombinant receptor agonists and are to be given by injectable form only since it is a peptide. They are of two types: (1) Human GLP-1 based; and (2) Exendin based.

Caution: GLP-1 analogs are not substitute for insulin. GLP-1 analog should not be used in patients with a history of pancreatitis. Exenatide should not be used if eGFR <30 mL/min and liraglutide if eGFR <60 mL/min.

Liraglutide

It is used as monotherapy with a once daily dose of 1.2 and 1.8 mg subcutaneous (S/C). It produces mean reduction of HbA1c by 1–1.5%. Welcome effects include weight reduction (2–4 kg); improvement in systolic BP and beta-cell functions. Risk of hypoglycemia is quite less, but increases if used in combination with SUs. It can be used as a part of combination therapy also. There are no major adverse effects except nausea, but may be associated with medullary thyroid carcinoma.

Exenatide

Immediate release (IR) and ER. This is a synthetic exendin-based GLP-1 analog peptide. It enhances the glucose dependent insulin secretion, suppresses elevated levels of glucagon and slows the gastric emptying. When used as monotherapy it reduces HbA1c by 0.5–1%. Exenatide (IR) is administered S/C twice a day with a dose of 5–10 μg, 60 minutes before meals. Can be used in combination therapy with metformin, pioglitazones, or SUs with good synergistic effect (HbA1c reduction 1.5–1.8%). 4–6 kg weight reduction is reported. ER formulation of exenatide is also available and used as 2 mg S/C once a week with or without meals. Side effects include nausea and vomiting and sometimes pancreatitis.

Alpha Glucosides Inhibitors (Acarbose and Voglibose)

Alpha glucosides inhibitors (AGIs) act on the proximal part of small intestine to reduce or delay the absorption of polysaccharides. AGIs work on intestinal brush borders to inhibit enzymes responsible for breaking oligosaccharide and disaccharides into monosaccharides. Thus, it reduces the sudden surge of plasma glucose levels. Hence has potential use in lowering postprandial glucose without causing hypoglycemia. It reduces HbA1c by 0.5–0.8%, but is less effective than SUs or metformin as a monotherapy. But, when used in combination, produce remarkable effects in lowering plasma glucose levels. AGIs also reduce serum TGs levels. The most common side effects are bloating, abdominal discomfort, diarrhea, and flatulence. Voglibose is used more often than acarbose because it inhibits all pancreatic enzymes.

Dopamine Receptor Agonist: Bromocriptine

This is an ergoline derivative, dopamine receptor agonist, mainly used in treatment of pituitary tumors, Parkinsonism, neuroleptic syndrome, acromegaly, hyperprolactinemia, and recently as antidiabetic.

It acts by reducing hyperglycemia by decreasing prolactin. This drug is mainly used in combination therapy with other OHAs, where hyperglycemia is not controlled. Major side effects include nausea, orthostatic hypotension, headaches, angina, Raynaud's phenomenon, panic attacks, and withdrawal symptoms.

Others

Hydroxychloroquine

Recently added to the armamentarium for the treatment of T2DM as anti-inflammatory drug with the belief that it may reduce degradation of insulin and increase its efficacy in tissues. It is not used as monotherapy but in a combination therapy along with SUs, metformin, DPP-4I, or SGLT-2-i. It can be used in combination with insulins also as it has synergistic effect on insulin. Dose: 200–400 mg/day. Hydroxychloroquine (HCQS) can be used in prediabetics and IGTs for prevention or retardation of progression of DM. It exhibits HbA1c reduction by 0.6–0.8% (>24 weeks). It has beneficial effect on lipid metabolism by reducing LDL.

Amylin Agonist: Pramlintide

Amylin is a hormone jointly secreted with insulin, hence, is deficient or inappropriate in DM. This hormone inhibits

glucagon, delays gastric emptying, and produces satiety. Pramlintide is a synthetic analog, available as S/C injection. Several large phase III clinical trials have shown its efficacy in lowering HbA1c both in T1DM and T2DM. This is used as premeal injection for postprandial hyperglycemia. It has low incidence of side effects and weight gain (unlike insulin).

Probiotics

Researchers have shown that T2DM and obesity are characterized by altered gut microbiota, inflammation, and gut barrier disruption, but the exact mechanism responsible for this is still not clear. Using probiotics, especially *Akkermansia* (common bacteria of gut flora) has shown tremendous potential in treating diabesity.

Insulin

Insulin is synthesized by beta cells situated in islet cells of the pancreas. Apart from beta cells secreting insulin, there are alpha cells secreting glucagon, pancreatic polypeptide (PP) cells and gamma cells secreting somatostatin. Glucagon stimulates secretion of insulin, whereas insulin inhibits secretion of glucagon, whereas, somatostatin inhibits both glucagon and insulin. Primary structure of insulin has two polypeptide chains linked with disulfide bridge. Pancreas forms proinsulin which is converted to single amino acid chain insulin and connecting peptide (C-peptide). All the insulin molecules are manufactured on this principle. Different types of commercial insulins are produced by recombinant deoxyribonucleic acid (rDNA) technology with the main differences in onset of action, duration of action, and rate of absorption. Different types of insulins available are given in **Table 2**.

Surgery—Bariatric and Duodenal Mucosal Resurfacing

Surgery is very effective in morbid diabesity and complicated diabetes with life-threatening comorbidities. Previously surgeons have been focusing on obesity with BMI >36 and now BMI of >32 is being included for criteria of bariatric surgery. Since Indian population have waistline obesity and hypertriglyceridemia, poor lifestyle, and as more population is inching towards diabetic status, many people are opting for bariatric surgery. In bariatric surgery, a part of stomach is ligated or cut to reduce the amount of ingested food and retard the absorption by creating malabsorption like condition. This helps in reducing weight, blood sugar, and lipid levels in the body. Types of bariatric surgeries are gastric bypass, sleeve gastrectomy, gastric band or balloon, and biliopancreatic diversion with duodenal switch. In DMR, duodenal mucosa is subjected to hypodermal circumferential ablation. This results in altered duodenal mucosal exposure to nutrients, hence reduction in blood sugar and lipid levels.

TABLE 2: Insulins.

Prandial insulin	• Short acting: Regular (onset: 30–60 min; peak: 2–4 h; duration: 6–10 h) • Analogs: Aspartate and lispro (onset: 0–20 min; peak: 1–3 h; duration: 3–5 h)
Basal insulin	• Intermediate acting: NPH (onset: 1–2 h; peak: 4–8 h; duration: 8–12 h) • Long-acting analogs: Glargine and detemir (onset: 30–60 min; duration: 16–24 h)
Premixed	• Mix 30:70 (regular + basal) (onset: 30–60 min; Peak duration: 16–24 h) • Mix 25:75 (regular + basal) (onset: 10–20 min; peak: 1–4 h; duration: 16–20 h) • Mix 50:50 (regular + basal) (onset: 10–20 min; peak: 0.5–2.5 h; duration: 16–18 h)
Inhalational	• Ultrafast acting: Afrezza

(NPH: Neutral Protamine Hagedorn)

Stem/Progenitor Cells Transplant

Researchers implanted insulin-producing cells into a fatty membrane in the stomach cavity. The resultant progress in controlling blood glucose and HbA1c levels is paving the way towards more people receiving artificial pancreases.

Pancreas Transplantation

It is usually done along with either liver or kidney transplants as a part of treating high comorbid complications of diabetes with CKD or liver failure.

STEPWISE APPROACH OF MANAGING TYPE 2 DIABETES MELLITUS

Stepwise approach is beneficial in managing the T2DM (**Box 4**):

- After LSM initiation if hyperglycemia not controlled then start OHAs.

BOX 4: Stepwise approach of type 2 diabetes mellitus management.

Plan A

Calculate body mass index, check HbA1c, and check presence of comorbidity

HbA1c <9.0:

1. Begin therapy with metformin. Except: Lean body weight/peptic ulcer/gastritis
2. Sulfonylureas: Gliclazide/glimepiride
3. DPP-4 inhibitors: Sitagliptin/Saxagliptin/Vildagliptin. *Teneligliptin (OD dose)

HbA1C >9.0:

1. Combination of sulfonylurea and metformin or DPP-4 inhibitor (Tenegliptin/Vildagliptin) and metformin

Postprandial hyperglycemia:

1. Combination of sulfonylurea + metformin + voglibose/acarbose/repaglinide

Severe comorbidity:

Add insulin

Continued

Continued

Plan B

If the first-line therapy fails or does not yield desired result:

1. Add SGLT-2-i—four drug combination or three drugs: Metformin + DPP-inhibitor + SGLT-2-i
2. Add insulin: Premix insulin (30:70) or Humalog (25:75) twice a day or basal at bed time
3. Alpha glycoside inhibitors are attractive options in Indian diabetics because of high carbs meals
4. Thiazolidinediones are also good option
   Author's experience of DPP-4 inhibitor + metformin + pioglitazone, especially in obese with fatty liver is encouraging
5. If infections or surgery or pregnancy: Insulin

Plan C

In case of failure of second line:

- Use of 4-OHA plus insulin (premix) twice a day
- Use of 4-OHAs plus basal insulin at bed time
- OR three to four drugs with multiple timing regular insulin
- One can use newer insulin such as ultra-long-acting insulin detemir (Levemir) and insulin degludec
- One can opt for GLP-1 analogs like insulin liraglutide (Victoza) or insulin exenatide (Byetta). Additional benefit is weight reduction
- In all these insulins cost is the major issue
- Surgery like bariatric or DMR for morbid obesity
- Pancreatic transplant/stem cell/islet cells transplant, etc.

(DMR: duodenal mucosal resurfacing; DPP-4: dipeptidyl peptidase-4; GLP-1: glucagon-like peptide-1; HbA1c: glycated hemoglobin; SGLT-2-i: sodium-glucose cotransporter-2 inhibitor; OHA: oral hypoglycemic agent)

- Choice of medication should be based on individual needs, cost-benefit ratio, economic conditions, drug interactions, and presence of other comorbidities.
- Each initiation or dose increment should be monitored for response in 8–10 weeks.
- Patients compliance with the dosage schedule is must and check every time he/she visits you.
- Side effects and inadequacy of effect warrants immediate withdrawal.
- Talk to the patient particularly about hypoglycemia or weight gain/loss.

SUMMARY

Goals of therapy for T2DM patients include evaluation of diabetic status, BMI, work style (i.e., sedentary or hard worker), socioeconomic status, presence of comorbidities, and patient's willingness or compliance with the drugs management. Always start with LSM followed by oral drugs with or without insulin, depending on the patient's condition and parameters. Diet prescribed to the patient must confirm to his/her tastes, availability, and affordability. Diet should be a balanced diet, rich in proteins, must include seasonal fruits. Drugs used should also be easily available, affordable, and the regime should be tailor made to the patient. If socioeconomic status is not good, there is no fun of writing fancy, expensive medicines, which, patient will not take in long run. Patient counseling is must so that he/she understands the modality of treatment and the need of initiating insulin therapy or undergoing surgery. The ideal target of control of diabetes is HbA1c of 6.5–7.0% in Indian population. Though, it may be difficult to achieve in elderly, but tight control always give benefit in terms of reducing complications and hence, enhanced morbidity and mortality.

127
CHAPTER

Hypoglycemia

Jugal Kishor Sharma, Dinesh Sharma

INTRODUCTION

As defined by American Diabetes Association (ADA) and European Medicines Agency, hypoglycemia is any abnormally low plasma glucose concentration that causes potential harm to a subject with plasma glucose value <70 mg/dL (<3.9 mmol/L). The problem of hypoglycemia was recognized since the use of insulin in 1922. In Diabetes Complications and Control Trial (DCCT), it was found that intensive glycemic control decreased the long-term complications of diabetes with increased frequency of hypoglycemia. The United Kingdom Prospective Diabetes Study (UKPDS) and recent population-based data showed that hypoglycemia continues to be a major problem in both type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM). Based on clinical manifestations, hypoglycemia can be classified into mild (blood sugar 60–70 mg/dL), moderate (blood sugar 50–60 mg/dL), severe (blood sugar <40 mg/dL). The blood glucose (BG) level that produces symptoms of hypoglycemia varies from person to person and in the same person under different circumstances. Hypoglycemia is a medical emergency; however, most individuals recover completely. Hypoglycemia, which is not reversed, can progress from lethargy to coma, and finally death. There are some cases of long-lasting severe hypoglycemia which can lead to transient and even permanent cerebral damage. Iatrogenic hypoglycemia associated with diabetes medications are the most common causes of hypoglycemia in patients with diabetes. It is common in insulin-treated diabetic patients, more common in T1DM and may occur in patients taking an insulin secretagogue. Hypoglycemia may also result from certain other conditions such as pancreatic or nonislet cell tumors, autoimmune conditions, endocrine diseases, dietary toxins, alcohol consumption, organ failure, inborn errors of metabolism, stress, starvation, severe excessive exercise, infections, and sepsis. Patient education, timely detection of hypoglycemic symptoms, and early treatment of hypoglycemia can prevent the serious complications and death of a patient.

ETIOLOGY

Several factors can cause hypoglycemic episodes in a person living with diabetes such as a mismatch in the timing, amount or type of insulin, and the food intake. Diabetic patients who are undergoing therapeutic intervention with meglitinides, sulfonylurea, or insulin, these drugs are the most common cause of hypoglycemia. Hypoglycemia is not seen in patients with diabetes who are treated with medical nutrition therapy, metformin, glucagon-like peptide-1 (GLP-1) receptor agonists, sodium-glucose cotransporter-2 (SGLT-2) inhibitors, dipeptidyl peptidase-4 (DPP-4) inhibitors, and thiazolidinediones, and it is rare in people taking alpha-glucosidase inhibitors. Other causes of hypoglycemia include pancreatic or nonislet cell tumors, organ failure, autoimmune conditions, inborn errors of metabolism, alcohol consumption, stress, starvation, severe excessive exercise, infection, and sepsis. Risk factors for hypoglycemia are summarized in **Table 1**.

TABLE 1: Rick factors for hypoglycemia.

Common risk factors	• Mismatch of insulin timing, amount, or type of carbohydrate intake • Oral secretagogues without appropriate carbohydrate intake • History of severe hypoglycemia • General anesthesia or sedation that places the patient in an altered consciousness • Reduction of oral intake • New nil per orally (NPO) status • Unexpected transport after injection of rapid- or fast-acting insulin • Critical illnesses (hepatic, cardiac, and renal failure; sepsis; and severe trauma)
Less common risk factors	• Endocrine deficiencies (cortisol, growth hormone, or both), non-β-cell tumors • Ingestion of large amounts of alcohol or salicylates • Sudden reduction of corticosteroid dose • Emesis • Reduction of rate of intravenous dextrose • Unexpected interruption of enteral feedings or parenteral nutrition • Drug dispensing error

PATHOPHYSIOLOGY

The counterregulatory mechanism of the body prevents the hypoglycemic episodes, which includes the interplay of hormones and neural signals to regulate the release of endogenous insulin, increase the hepatic glucose output, and alter peripheral glucose utilization. The regulation of insulin production plays a significant role in the counterregulatory mechanism. The decrease in insulin production is the first-line defense response to low BG in the body. Low insulin levels are necessary for the endogenous glucose production in the liver by glycogenolysis. Low insulin levels in response to decreased BG level leads to increased hepatic/renal gluconeogenesis and hepatic glycogenolysis. Glycogenolysis can maintain serum glucose levels up to 8–12 hours until the glycogen stores are depleted; in the meantime, hepatic gluconeogenesis also contributes to maintaining that euglycemic state of a person. Other counterregulatory measures occur once the serum glucose level falls beyond the physiological range. Secretion of glucagon from pancreatic alpha cells is the next defense against hypoglycemia followed by adrenomedullary epinephrine secretion as the next counterregulatory mechanism. All three counterregulatory mechanisms occur in the acute stage of hypoglycemia. After the failure of all the above counterregulatory mechanisms growth hormone and cortisol release is also seen in cases of prolonged hypoglycemic conditions

CLINICAL FEATURES

Clinical features of hypoglycemia can be classified as neuroglycopenic or neurogenic (**Table 2**). Neuroglycopenic signs and symptoms result from decreased BG supply to the central nervous system (CNS) as the brain has limited glycogen stores. This results in rapid CNS dysfunction. If warning signs are not taken care, the BG continues to fall leading to more severe hypoglycemia and alteration in the mental function which causes impairment of concentration, confusion, headache, disorientation, irritability, slurred speech, lethargy, malaise, irrational behavior, focal seizures, and hemiplegia. If BG continues to fall, then shallow breathing, bradycardia, hypertonicity, coma, and finally death. Neurogenic signs and symptoms can be adrenergic or cholinergic. These symptoms are anxiety, irritability, dizziness, diaphoresis, tachycardia, headache, pallor, shakiness, and hunger. These signs and symptoms may not be present when there are sympathetic dysfunctions such as in the case of diabetic autonomic neuropathy or when adrenergic blocker drugs are being used. The neurogenic and neuroglycopenic symptoms usually occur below the blood sugar level of 50–55 mg/dL, but this can vary from individual to individual. Diabetic patients may develop hypoglycemic symptoms at relatively higher BG levels because chronic hyperglycemia alters the set point where these symptoms become apparent. This phenomenon is referred to as "pseudohypoglycemia" because the serum glucose levels are within normal limits, but the patient is having the symptoms of hypoglycemia.

TABLE 2: Clinical features of hypoglycemia.

Early adrenergic symptoms	• Pallor • Diaphoresis • Tachycardia • Shakiness • Hunger • Anxiety • Irritability • Headache • Dizziness
Neuroglycopenic signs	• Confusion • Slurred speech • Irrational or uncontrolled behavior • Extreme fatigue • Disorientation • Loss of consciousness • Seizures • Pupillary sluggishness • Decreased response to noxious stimuli

DIAGNOSIS

Since 1938, Whipple's triad has been used to describe hypoglycemia, which includes recognition of symptoms of hypoglycemia, low blood sugar detection, and relief of symptoms by correction of the low blood sugar levels. Other tests such as insulin, proinsulin, and C-peptide levels are to be measured, if insulin levels are high in the presence of low C-peptide levels then it show that the patient has received the exogenous insulin. Elevated insulin levels with elevated C-peptide levels are seen with secretagogue agents such as sulfonylurea administration. Other routine investigations such as hemogram, liver function test (LFT), kidney function test (KFT), chest X-ray, ultrasonography, CT, and MRI abdomen/brain may be required to rule out other causes of hypoglycemia.

CLASSIFICATION OF HYPOGLYCEMIC EVENTS

The ADA workgroup on hypoglycemia in June 2004 classified hypoglycemic events as:

- Severe hypoglycemia which requires assistance from another person to administer carbohydrates, glucagon, or other resuscitative measures. These episodes are associated with neuroglycopenia to induce seizure and coma. Plasma glucose measurements may not be available, but neurological recovery to the restoration of a normal glucose is sufficient evidence to confirm hypoglycemic events.
- Symptomatic hypoglycemia which shows typical hypoglycemic symptoms and documented plasma glucose concentration is <70 mg/dL (3.9 mmol/L).
- Asymptomatic hypoglycemia—there are no typical symptoms of hypoglycemia, but blood sugar is <70 mg/dL (3.9 mmol/L) because the activation of glucagon and epinephrine secretion is normally at 65–70 mg/dL glucose concentration.
- Probable symptomatic hypoglycemia in which symptoms of hypoglycemia are not associated with plasma glucose determination, but probably caused by plasma glucose concentration <70 mg/dL. These people with diabetes treat

symptoms with oral carbohydrates without plasma glucose measurement.
- Relative hypoglycemia—in this diabetic patient reports the symptoms of hypoglycemia, but the measured plasma glucose is >70 mg/dL. This is experienced by patients with chronically poor glycemic control.

TREATMENT

In hypoglycemic episodes, assess the patient for level of consciousness, respiratory and circulatory status, blood sugar level, take the history about insulin dosage and antidiabetic medicines, food intake, and look for other causes of hypoglycemia such as renal, hepatic, and alcohol intake. If the patient is conscious, follow the rule of 15–15. Give 15 g of carbohydrate orally and check the blood sugar after 15 minutes if the blood sugar is still below 70 mg/dL then again give 15 g of carbohydrate and recheck. Repeat the step till the BG levels reach above 70 mg/dL. The readily available 15 g carbohydrate is present in 4 oz orange juice or apple juice, 4 oz regular sugar-sweetened cola, 6 oz sugar-sweetened ginger ale, 3 BD glucose tablets, and 4 Dextrose 4 glucose tablets. Once BG returns to normal, give a meal or snack to the patient so that the blood sugar does not fall again. If the patient is unresponsive to oral treatment or is on nil per orally (NPO), then intravenous (IV) administration of dextrose or intramuscular (IM) injection of glucagon is to be given—25 g (50 mL) 50% dextrose or glucagon 1 mg IM. Be careful not to overtreat hypoglycemia. Monitor blood sugar frequently until the glucose levels stabilize. After treatment of hypoglycemia, we should search for the cause and correct accordingly. Hospitalization is required of emergency room patient with hypoglycemia (BG <70 mg/dL). Treat according to severity, if there are risk factors. Evaluate for a cause in all patients and treat the cause.

Patient Able to Eat

Give 30 g (two tablespoons) of oral glucose or milk for patients on alpha-glucosidase inhibitors. Follow-up with some complex carbohydrates:
- One cup fruit juice
- One slice bread
- One cup milk
- Two to three biscuits

Patient not Able to Eat

Administer 20 mL of 50% dextrose IV bolus and then 5% and 10% dextrose fluids IV at 100 mL/h until stabilized. If available, injection glucagon 1 mg (1 mL) single dose can be administered instead of dextrose. Monitor BG every 30 minutes till >100 mg/dL. Once BG >100 mg/dL, evaluate for cause. Change in medication/diet/activity, infection, new medication, etc. Decide if further monitoring and observation required.

PREVENTION

In patients living with diabetes, controlling the hyperglycemia without causing hypoglycemia is the main aim of treatment.

Patient Education

Patients must understand and adhere to the treatment plans in terms of lifestyle modification, diet, and medications. Educate the patient and his family members about early identification of hypoglycemic symptoms, its causes, preventive measures, and the treatment options. Also educate about the importance of frequent self-monitoring of blood glucose (SMBG), regular follow-up with their doctor, and record-keeping preventing hypoglycemic episodes.

Blood Glucose Monitoring

Regular BG testing is the most effective way of identifying asymptomatic hypoglycemia. This is an effective component of self-management in people with diabetes with insulin treatment. Glucose monitoring can be done either by SMBG or by continuous glucose monitoring (CGM). SMBG can help and detect early hypoglycemia and will help the appropriate insulin dose adjustment. This is usually advised in T1DM and T2DM patients who are on insulin therapy. To detect hypoglycemia or a high-risk pattern, periodic 7-point profile testing should be performed. The recent ADA Standards of Care recommends SMBG testing at least six to eight times daily for patients using multiple daily insulin injections or continuous subcutaneous insulin infusion.

Use of Agents with a Low Hypoglycemic Incidence

Selection of appropriate regime with no hypoglycemic risk and good glycemic control prevent the risk of hypoglycemia. Low risk hypoglycemic agents are metformin, DPP-4 inhibitors, and GLP-1 receptors agonists. DPP-4 inhibitors inhibit the prolonged activity of endogenously released GLP-1 and gastric inhibitory polypeptide (GIP) by inhibiting the DPP-4 enzyme. They have extremely low hypoglycemic risk because of their glucose-dependent action. Alpha-glucosidase inhibitor and thiazolidinediones may be considered in place of high-risk category hypoglycemic agents such as insulin, sulfonylurea, and meglitinides.

Insulin Therapy

The standard insulin sliding scale should be avoided as it is ineffective, having a high risk of hyperglycemia and hypoglycemia. The basal and bolus insulins provide more physiological response to insulin treatment. Ideal insulin therapy should include the long-acting basal insulin, which mimics the 24 hours insulin secretion and bolus or short-acting insulin which mimics the normal physiological insulin response to the meal. The development of insulin analogs which are closer to endogenous insulin with better glycemic control reduces the risk of hypoglycemia as compared to traditional human insulin should be used. Newer insulin analog which mimics 24-hour endogenous insulin secretion are long-acting basal insulin such as detemir, glargine, short/rapid-acting insulin analogs such as aspart, glulisine and premixed insulin analogs such as biphasic insulin aspart and insulin lispro are to be preferred. Recognition of causative factors such as the timing of meals, oral hypoglycemic drugs, and insulin doses can avoid

hypoglycemia. Presence of other comorbid conditions such as adrenal, renal, and pituitary insufficiency which may lead to increased risk of hypoglycemia can be identified in time will prevent hypoglycemia.

SUMMARY

Hypoglycemia which is often neglected complication of diabetes therapy is one barrier to provide optimal glycemic control in diabetic patients. This has clinical, economic, and social impact in the management of diabetes, identifying the risk factors, avoiding traditional sliding scale of insulin regimes, implementation of protocols, effective patient education, use of newer antidiabetic medications with little or no risk of hypoglycemia, and use of newer insulins. Making aware of the risk of hypoglycemia, preventive strategies, and individualized treatment plan can decrease the frequency and severity of hypoglycemia.

128
CHAPTER

Diabetic Ketoacidosis

Rajeev Chawla, Shalini Jaggi, Sidhant Trehan

INTRODUCTION

Diabetic ketoacidosis (DKA) is an acute, major, and life-threatening complication of diabetes caused by insulin deficiency. It is characterized by hyperglycemia, hyperketonemia, and metabolic acidosis. It occurs in patients with type 1 diabetes mellitus (T1DM), but it is not uncommon in some patients with type 2 diabetes mellitus (T2DM). Although the incidence of this complication has been reducing due to increased awareness among patients and physicians, this tends to cause serious effects in patients, resulting in significant mortality and morbidity. A recurring and central theme in the management of diabetes and related complications is the need for implementing preventive strategies, which include routine monitoring and patient education.

EPIDEMIOLOGICAL ASPECT

Available data indicate the incidence of DKA at 1 per 2,000 patients. Results of the Rhode Island Hospital Study from Fishbein et al. showed an estimated DKA incidence of 4.6 per 1,000 diabetic patients per year with a greater incidence in younger age groups and women. DKA occurs mostly in patients with T1DM, but is not uncommon among patients with T2DM. The mortality rate is 5% in experienced centers.

PATHOGENESIS OF DIABETIC KETOACIDOSIS

Relative or absolute insulin deficiency in the presence of catabolic counter-regulatory hormones (glucagon, catecholamines, growth hormones, and cortisol) is the basic underlying mechanism (**Fig. 1**). This leads to hepatic overproduction of glucose, unrestrained hepatic fatty acid oxidation, and release of free fatty acids (FFAs) into the circulation from adipose tissue (lipolysis) and to production of ketone bodies [β-hydroxybutyrate (β-OHB) and acetoacetate], resulting in ketonemia and metabolic acidosis. Hyperglycemia results in osmotic diuresis leading to dehydration and loss of electrolytes. Sodium depletion is worsened as insulin deficiency further diminishes renal sodium reabsorption. Metabolic acidosis leads to loss of intracellular potassium in exchange for hydrogen ions, and insulin deficiency also causes potassium loss from cells. Thus, there is high circulating plasma potassium.

PRECIPITATING FACTORS FOR DIABETIC KETOACIDOSIS

The most common precipitating factor is intercurrent infection. The other common factors are listed in **Box 1**. The frequency of each factor varies according to the age and ethnicity. Many a times, no obvious cause could be determined. Recurrent DKA is particularly seen in young girls.

PRESENTING FEATURES FOR DIABETIC KETOACIDOSIS

The symptoms of DKA include increasing polyuria and thirst, weight loss, weakness, drowsiness, and eventually coma (in about 10% of cases) (**Box 2**).

On physical examination, there is dehydration, hypotension, tachycardia, and hypothermia. Acidosis stimulates the respiratory center resulting in deep and rapid (Kussmaul) respiration. In some patients, the smell of acetone may be obvious in patient's breath.

KETOSIS PRONE TYPE 2 DIABETES MELLITUS

Diabetic ketoacidosis commonly occurs in T1DM. However, it can also occur in African American and Hispanic population who subsequently can be treated without insulin and thus behave as T2DM patients. This phenomenon is termed as ketosis prone T2DM. Their clinical features are listed in **Box 3**.

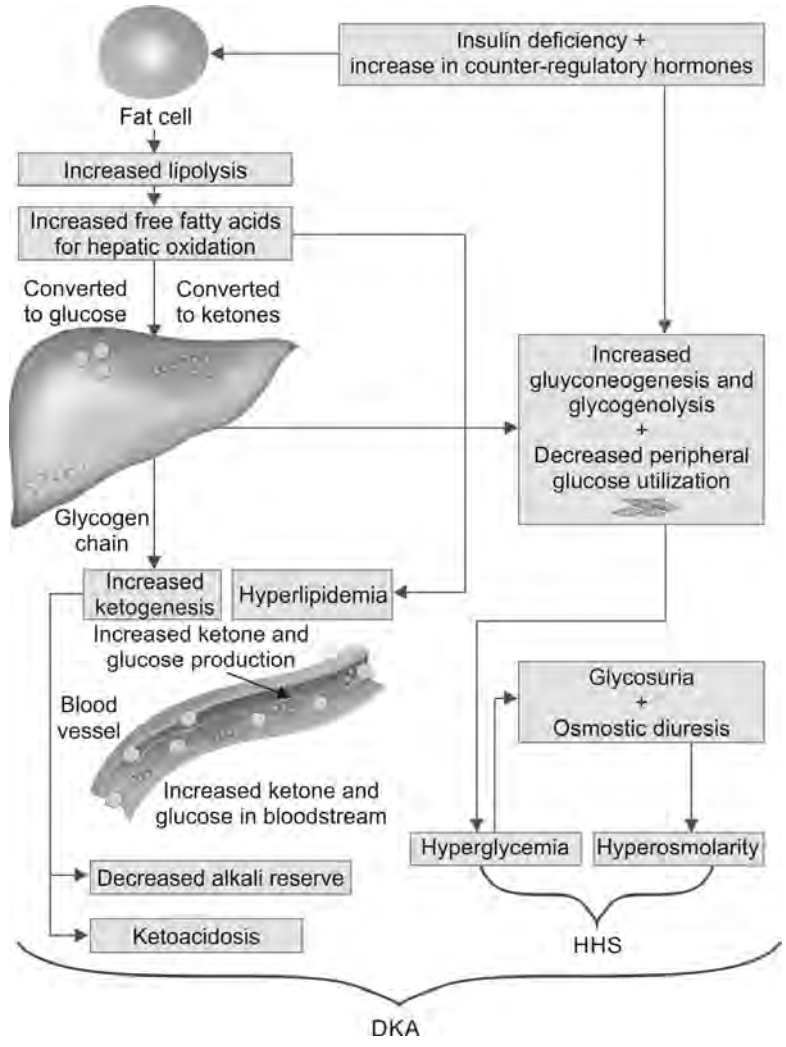

FIG. 1: Schematic representation of pathogenesis of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic state (HHS).

BOX 1: Precipitating factors for diabetic ketoacidosis.

- Infection
- Insulin error/omission
- Newly diagnosed cases
- Cardiovascular (myocardial infarction/stroke)
- Pancreatitis
- Pulmonary embolism
- Alcohol excess
- Steroid use

BOX 2: Clinical features of diabetic ketoacidosis.

- Polyuria and nocturia
- Thirst
- Weight loss
- Weakness
- Blurred vision
- Acidotic (Kussmaul) respiration
- Abdominal pain, especially in children
- Leg cramps
- Nausea and vomiting
- Confusion and drowsiness
- Coma

EVALUATION OF PATIENT FOR DIABETES KETOACIDOSIS

Diabetic ketoacidosis is a medical emergency. Therefore, a rapid history, physical examination, and bedside tests should allow a provisional diagnosis in the emergency department and avoid treatment delays (**Fig. 2**).

DIAGNOSTIC CRITERIA FOR DIABETIC KETOACIDOSIS

Based on the biochemical and clinical characteristics, DKA can be arbitrarily divided into mild, moderate, and severe (**Table 1**).

BOX 3: Features of ketosis prone type 2 diabetes mellitus (T2DM).

- Acute presentation
- Mean age > 40 years
- Male preponderance
- BMI ≥ 28 (for African American, less for Hispanic and Taiwanese)
- Newly diagnosed diabetes
- Strong family history of T2DM
- HbA1c > 12% at presentation
- Autoimmune markers of T1DM negative
- Fasting C-peptide detectable
- Most do not require long term insulin therapy

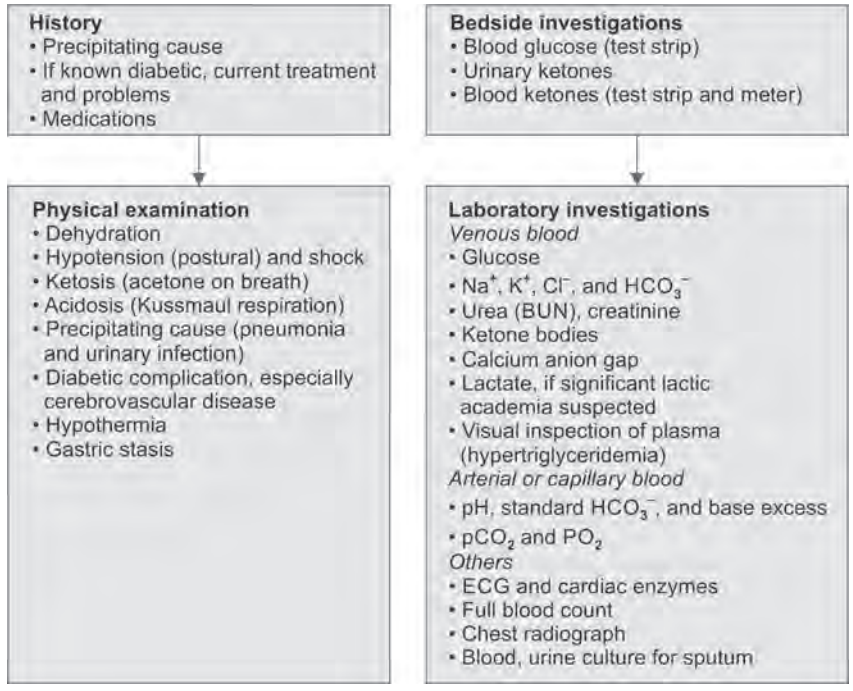
(BMI: body mass index; HbA1c: glycated hemoglobin)

TREATMENT GOALS FOR DIABETIC KETOACIDOSIS

Successful treatment of DKA aims for correction of dehydration, hyperglycemia, and electrolyte imbalances and identification of comorbid precipitating events; and above all, frequent patient monitoring (**Flowchart 1**).

Fluid Correction in the Management of Diabetic Ketoacidosis

The total body water and electrolyte deficit is shown in **Table 2**. Initial treatment involves rehydration, usually with isotonic saline (0.9% NaCl) at a rate of 15–20 mL/kg body weight/h or greater during the first hour (1–1.5 L in the average adult). Fluid therapy is directed toward expansion of the intravascular



History
• Precipitating cause
• If known diabetic, current treatment and problems
• Medications
Bedside investigations
• Blood glucose (test strip)
• Urinary ketones
• Blood ketones (test strip and meter)
Physical examination
• Dehydration
• Hypotension (postural) and shock
• Ketosis (acetone on breath)
• Acidosis (Kussmaul respiration)
• Precipitating cause (pneumonia and urinary infection)
• Diabetic complication, especially cerebrovascular disease
• Hypothermia
• Gastric stasis
Laboratory investigations
Venous blood
• Glucose
• Na+, K+, Cl−, and HCO3−
• Urea (BUN), creatinine
• Ketone bodies
• Calcium anion gap
• Lactate, if significant lactic academia suspected
• Visual inspection of plasma (hypertriglyceridemia)
Arterial or capillary blood
• pH, standard HCO3−, and base excess
• pCO2 and PO2
Others
• ECG and cardiac enzymes
• Full blood count
• Chest radiograph
• Blood, urine culture for sputum

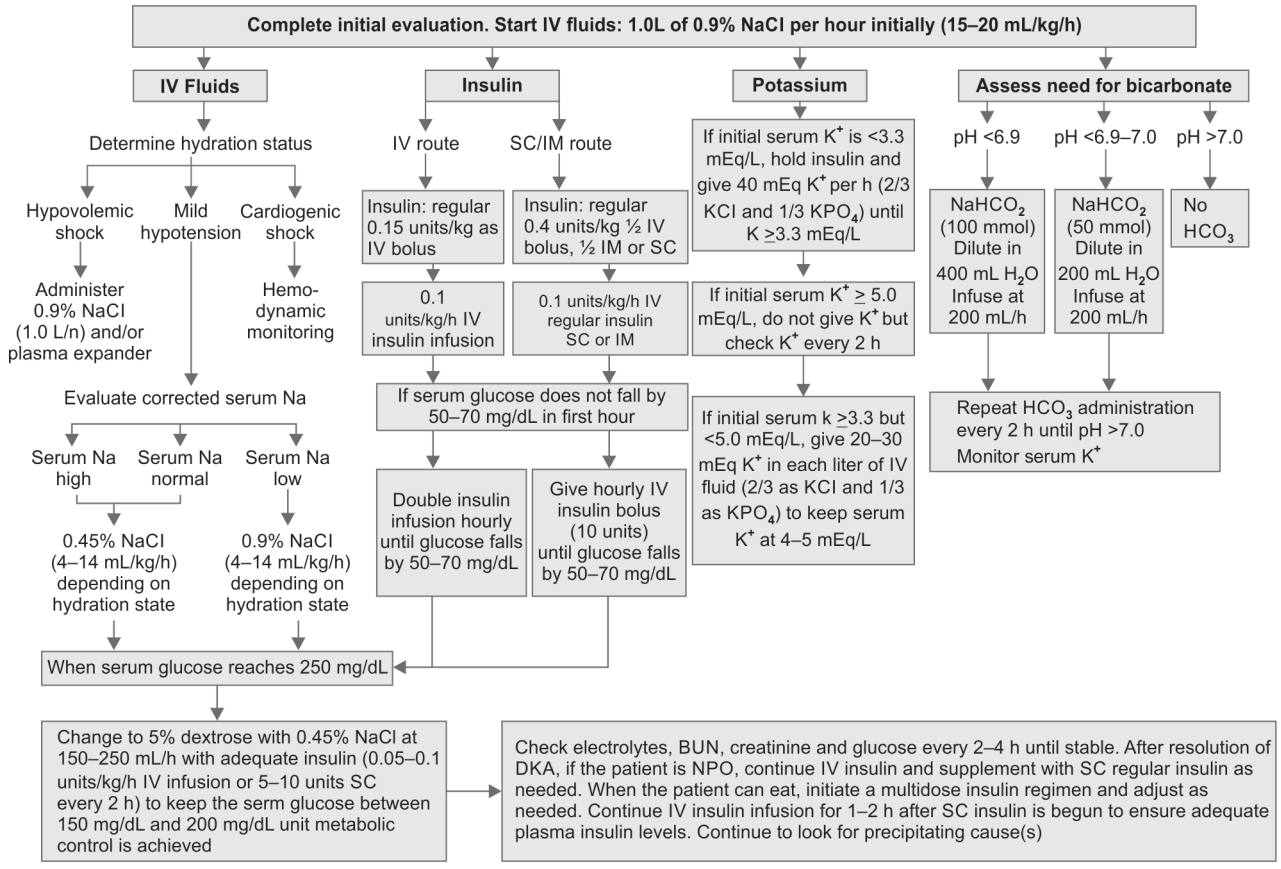
(BUN: blood urea nitrogen; ECG: electrocardiogram; pCO_2: partial pressure of carbon dioxide; PO_2: partial pressure of oxygen)

FIG. 2: Initial evaluation for diabetic ketoacidosis.

TABLE 1: Diagnostic criteria for diabetic ketoacidosis.

	Mild	*Moderate*	*Severe*
Plasma glucose (mg/dL)	>250	>250	>250
Arterial pH	7.25–7.30	7.00–7.24	<7.00
Serum bicarbonate (mEq/L)	15–18	10–15	<10
Urine ketones*	Positive	Positive	Positive
Serum ketones*	Positive	Positive	Positive
Effective serum osmolality (mOsm/kg)†	Variable	Variable	Variable
Anion gap‡	>10	>12	>12
Alteration in sensoria or mental obtundation	Alert	Alert/drowsy	Stupor/coma

*Nitroprusside reaction method; †calculation: 2[measured Na (mEq/L)] + glucose (mg/dL)/18; ‡calculation: (Na^+) (Cl + HCO_3) (mEq/L)



Complete initial evaluation. Start IV fluids: 1.0L of 0.9% NaCl per hour initially (15–20 mL/kg/h)
IV Fluids
Insulin
Potassium
Assess need for bicarbonate
Determine hydration status
IV route
SC/IM route
If initial serum K+ is <3.3 mEq/L, hold insulin and give 40 mEq K+ per h (2/3 KCl and 1/3 KPO4) until K ≥3.3 mEq/L
pH <6.9
pH <6.9–7.0
pH >7.0
Hypovolemic shock
Mild hypotension
Cardiogenic shock
Insulin: regular 0.15 units/kg as IV bolus
Insulin: regular 0.4 units/kg ½ IV bolus, ½ IM or SC
NaHCO2 (100 mmol) Dilute in 400 mL H2O Infuse at 200 mL/h
NaHCO2 (50 mmol) Dilute in 200 mL H2O Infuse at 200 mL/h
No HCO3
Administer 0.9% NaCl (1.0 L/n) and/or plasma expander
Hemo-dynamic monitoring
0.1 units/kg/h IV insulin infusion
0.1 units/kg/h IV regular insulin SC or IM
If initial serum K+ ≥ 5.0 mEq/L, do not give K+ but check K+ every 2 h
Evaluate corrected serum Na
If serum glucose does not fall by 50–70 mg/dL in first hour
Repeat HCO3 administration every 2 h until pH >7.0
Monitor serum K+
Serum Na high
Serum Na normal
Serum Na low
Double insulin infusion hourly until glucose falls by 50–70 mg/dL
Give hourly IV insulin bolus (10 units) until glucose falls by 50–70 mg/dL
If initial serum k ≥3.3 but <5.0 mEq/L, give 20–30 mEq K+ in each liter of IV fluid (2/3 as KCl and 1/3 as KPO4) to keep serum K+ at 4–5 mEq/L
0.45% NaCl (4–14 mL/kg/h) depending on hydration state
0.9% NaCl (4–14 mL/kg/h) depending on hydration state
When serum glucose reaches 250 mg/dL
Change to 5% dextrose with 0.45% NaCl at 150–250 mL/h with adequate insulin (0.05–0.1 units/kg/h IV infusion or 5–10 units SC every 2 h) to keep the serm glucose between 150 mg/dL and 200 mg/dL unit metabolic control is achieved
Check electrolytes, BUN, creatinine and glucose every 2–4 h until stable. After resolution of DKA, if the patient is NPO, continue IV insulin and supplement with SC regular insulin as needed. When the patient can eat, initiate a multidose insulin regimen and adjust as needed. Continue IV insulin infusion for 1–2 h after SC insulin is begun to ensure adequate plasma insulin levels. Continue to look for precipitating cause(s)

(BUN: blood urea nitrogen; DKA: diabetic ketoacidosis; IM: intramuscular; IV: intravenous; NPO: nil per os; SC: subcutaneous)

FLOWCHART 1: The protocol for the management of adult patients with DKA.

TABLE 2: Typical total body deficits of water and electrolytes in diabetic ketoacidosis.

Total water (L)	6
Water (mL/kg)	100
Na^+ (mEq/kg)	7–10
Cl (mEq/kg)	3–5
K^+ (mEq/kg)	3–5
PO_4 (mmol/kg)	5–7
Mg^{++} (mEq/kg)	1–2
Ca^{++} (mEq/kg)	1–2

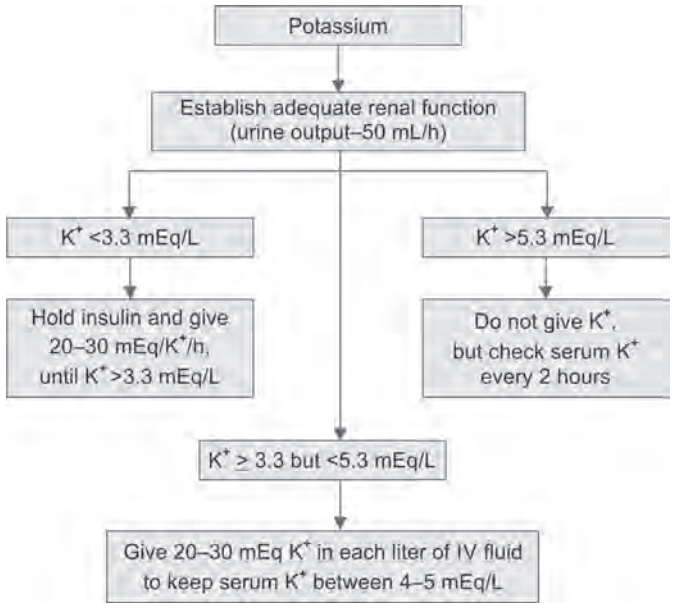
and extravascular volume and restoration of renal perfusion. Subsequent choice for fluid replacement depends on the state of hydration, serum electrolyte levels, and urinary output. In general, 0.45% NaCl infused at 4–14 mL/kg/h is appropriate if the corrected serum sodium is normal or elevated; 0.9% NaCl at a similar rate is appropriate if corrected serum sodium is low.

The success of fluid replacement is observed by hemodynamic monitoring (improvement in blood pressure), measurement of fluid input/output, and clinical examination. Fluid replacement should correct estimated deficits within the first 24 hours. The induced change in serum osmolality should not exceed 3 mOsm/kg H_2O/h. In patients with renal or cardiac compromise, monitoring of serum osmolality and frequent assessment of cardiac, renal, and mental status must be performed during fluid resuscitation to avoid iatrogenic fluid overload.

Correction of Electrolyte Imbalance and Acidosis

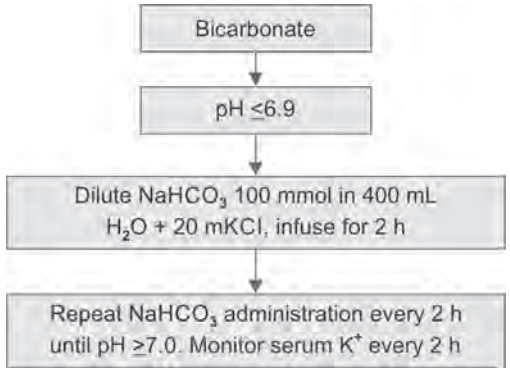
Sodium deficit is corrected by normal saline. Once renal function is assured, the infusion should include 20–30 mEq/L potassium (2/3 KCl and 1/3 KPO_4) until the patient is stable and can tolerate oral supplementation. Although phosphate and magnesium depletion are also present, there is no evidence that routine replacement is beneficial. However, serum phosphate levels < 0.35 mmol/L can cause muscle weakness and myocardial dysfunction and need correction. Similarly, serum magnesium levels <0.7 mmol/L should also be corrected (**Flowcharts 2** and **3**).

The role of intravenous (IV) bicarbonate is controversial. There is no proven benefit in patients with arterial pH ≥6.9. There are good theoretical reasons why IV bicarbonate should not be added and its use is associated with the development of cerebral edema. The American Diabetes Association (ADA) guidelines recommend 100 mmol diluted and given over 2 hours in patients with a pH <6.9 or in whom the acidosis is thought to be contributing to deteriorating clinical status.



Potassium
Establish adequate renal function (urine output–50 mL/h)
K+ <3.3 mEq/L
K+ >5.3 mEq/L
Hold insulin and give 20–30 mEq/K+/h, until K+ >3.3 mEq/L
Do not give K+, but check serum K+ every 2 hours
K+ ≥ 3.3 but <5.3 mEq/L
Give 20–30 mEq K+ in each liter of IV fluid to keep serum K+ between 4–5 mEq/L

FLOWCHART 2: Protocol for correcting electrolyte imbalance.



Bicarbonate
pH ≤6.9
Dilute NaHCO3 100 mmol in 400 mL H2O + 20 mKCl, infuse for 2 h
Repeal NaHCO3 administration every 2 h until pH ≥7.0. Monitor serum K+ every 2 h

FLOWCHART 3: Management of acidosis.

Management of Hyperglycemia in Diabetic Ketoacidosis

Unless the episode of DKA is mild, regular insulin by continuous IV infusion is the treatment of choice. In adult patients, once hypokalemia (K^+<3.3 mEq/L) is excluded, an IV bolus of regular insulin at 0.15 units/kg body weight, followed by a continuous infusion of regular insulin at a dose of 0.1 unit/kg/h (5–7 units/h in adults), should be administered.

When the plasma glucose reaches 250 mg/dL, it may be possible to decrease the insulin infusion rate to 0.05–0.1 unit/kg/h (3–6 units/h), and dextrose (5–10%) may be added to the IV fluids. Thereafter, the rate of insulin administration or the concentration of dextrose may need to be adjusted to maintain the above glucose values until acidosis is resolved.

Patients with mild DKA should first receive a "priming" dose of regular insulin of 0.4–0.6 units/kg body weight, half as an IV bolus and half as a subcutaneous or intramuscular injection. Thereafter, 0.1 unit/kg/h of regular insulin should be given subcutaneously or intramuscularly.

Criteria for resolution of DKA include a glucose <200 mg/dL, serum bicarbonate ≥ 18 mEq/L, and a venous pH of > 7.3. Once DKA is resolved, if the patient is nil per os (NPO), continue IV insulin and fluid replacement and supplement with subcutaneous regular insulin as needed every 4 hours. In adult patients, this can be given in 5-unit increments for every 50 mg/dL increase in blood glucose above 150 mg/dL for up to 20 units for blood glucose of 300 mg/dL. In case the patient is able to eat, a multiple-dose schedule should be started that uses a combination of short- or rapid-acting and intermediate-or long-acting insulin as needed to control plasma glucose. Continue IV insulin infusion for 1–2 hours after the subcutaneous regimen is begun to ensure adequate plasma insulin levels on board. **Table 3** presents key features in management of DKA.

TABLE 3: Key features in management of DKA.

Insulin treatment	Immediate insulin therapy is extremely crucial for reversal of DKA and must be initiated at the earliest
Electrolyte imbalance	Potassium loss is lesser in DKA as compared to HHS; however, potassium replenishment is needed in patients with DKA

(DKA: diabetic ketoacidosis; HHS: hyperosmolar hyperglycemic state)

COMPLICATIONS OF DIABETIC KETOACIDOSIS

The most common complications of DKA include:

- Hypoglycemia due to overzealous treatment with insulin
- Hypokalemia due to insulin administration and treatment of acidosis with bicarbonate
- Hyperglycemia secondary to interruption/discontinuance of IV insulin therapy after recovery without subsequent coverage with subcutaneous insulin
- Hyperchloremia caused by the use of excessive saline for fluid and electrolyte replacement and transient nonanion gap metabolic acidosis as chloride from IV fluids replaces ketoanions lost as sodium and potassium salts during osmotic diuresis

Cerebral edema is a rare but frequently fatal complication of DKA, occurring in 0.7–1.0% of children with DKA. Hypoxemia and, rarely, noncardiogenic pulmonary edema may also complicate the treatment of DKA.

PREVENTIVE MEASURES FOR DIABETIC KETOACIDOSIS

Better access to medical care, proper education, and effective communication with a healthcare provider during an intercurrent illness may be helpful in preventing many cases of DKA. Cessation of insulin therapy for economic reason is disturbing and needs to be addressed.

Better education of care givers as well as patients regarding signs and symptoms of new-onset diabetes; conditions, procedures, and medications that worsen diabetes control; and the use of glucose monitoring could potentially decrease the incidence and severity of DKA.

SUMMARY

- Insulin deficiency with raised levels of counter regulatory hormones leads to DKA and hyperosmolar hyperglycemic state (HHS).
- DKA occurs mostly in T1DM, whereas HHS is more common in T2DM.
- Increased lipolysis and increased supply of FFA for hepatic fatty acid oxidation lead to ketoacidosis.
- The most common symptoms of DKA are polydipsia and polyuria. The most common symptom of HHS is altered sensorium.
- Metabolic acidosis in DKA needs to be corrected by IV bicarbonate infusion, only if pH ≤6.9.
- Glucose levels must be reduced with caution in children to avoid cerebral edema.

129 CHAPTER

Hyperosmolar Hyperglycemic Syndrome

Dheeraj Kapoor

INTRODUCTION

Hyperosmolar hyperglycemic syndrome (HHS) is a metabolic derangement that arises from a complication of diabetes mellitus mostly associated with type 2 diabetes mellitus (T2DM). In 1880s, Won Frerichs and Dreschfeld described the first cases of HHS in patients with an "unusual diabetic coma" characterized by severe hyperglycemia and glycosuria, positive urine acetone test, and fruity smell in breath but absence of Kussmaul breathing. The nomenclature of clinical situation such as nonketotic hyperglycemic coma, hyperosmolar hyperglycemic nonketotic syndrome, and hyperosmolar nonketotic coma (HONK) are no longer used.

DIABETES OVERVIEW

Diabetes is a metabolic disorder of multiple etiology characterized by chronic hyperglycemia with disturbances of carbohydrate, fat, and protein metabolism resulting from defects in insulin secretion, insulin action, or both. Insulin is an anabolic hormone produced by the beta cells in the islets of Langerhans in the pancreas in response to the physiological rise in blood glucose associated with a carbohydrate meal. The primary action of insulin is to maintain blood glucose levels between 3 and 8 mmol/L or 60–140 mg/dL and this is done through three actions of insulin:

1. Promoting uptake of glucose by the target cells and its subsequent breakdown into energy (glycolysis) or storage as glycogen (glycogenesis)
2. Inhibiting gluconeogenesis (formation of new glucose from noncarbohydrate source such as fats and protein) or production of glucose by the liver
3. Suppressing lipolysis (breakdown of fat)

Types of Diabetes Mellitus

Type 1 diabetes mellitus (T1DM) results from the autoimmune destruction of pancreatic beta cells. The autoimmune component appears to be influenced by genetic predisposition, as it is strongly associated with the major histocompatibility complex human leukocyte antigen (HLA) class II region on chromosome 6p21. The attack on the beta cells appears to be triggered or modified by environmental or biologic events such as viral infections, early infant diet, and toxins. Approximately about 5–10% of all diabetes falls into this category and the most common complication is diabetic ketoacidosis (DKA).

Type 2 diabetes mellitus is a metabolic disorder with multiple causes, characterized by chronic hyperglycemia with disturbances of carbohydrate, fat, and protein metabolism, accounts for about 90–95% of diabetes cases. It generally results from a combination of insulin resistance and loss of beta-cell function. Insulin resistance places an increased secretory demand upon the beta cell, leading to beta-cell dysfunction as the disease progresses. Type 2 diabetes mellitus affects a number of organs in the long-term and is associated with increased risk of macrovascular disease and also microvascular complications such as retinopathy, nephropathy, and neuropathy. Most of the time T2DM remains unnoticed for many years and studies suggest >50% of individuals have evidence of vascular disease at diagnosis.

Hyperosmolar hyperglycemic syndrome is a serious and potentially life-threatening complication of T2DM accounting for about 0.5% of primary diabetes hospital admissions. The mortality rate in HHS is 20% much higher than seen in DKA. Factors that determined clinical outcome and prognosis in HHS are age, the degree of dehydration, and the presence or lack of other comorbidities.

ETIOLOGY

History of T2DM is a main risk factor for HHS. But some time HHS may occur in those without a prior history of diabetes or with T1DM. Triggers include infections, stroke, trauma, certain medications, and heart attacks. Other risk factors include:

- Lack of sufficient insulin (but enough to prevent ketosis) or noncompliance with oral hypoglycemic or insulin therapy can result in HHS
- Poor kidney function
- Poor fluid intake (dehydration)
- Older age (50–70 years)
- Certain medical conditions [cerebral vascular injury, MI, sepsis, acromegaly, Cushing syndrome (e.g., endogenous, exogenous, and ectopic), and neuroleptic malignant syndrome)

- Certain medications (glucocorticoids, beta-blockers, thiazide diuretics, calcium channel blockers, and phenytoin)
- Patients on total parenteral nutrition (TPN) solutions and intravenous (IV) fluid that contain dextrose are also at risk for HHS.

PATHOPHYSIOLOGY

The syndrome is characterized by severe hyperglycemia, a marked increase in serum osmolality and clinical evidence of dehydration without the accumulation of β-hydroxybutyric or acetoacetic ketoacids which makes it different from DKA. Both conditions are due to deficiency of insulin. As a consequence of deficiency of this key hormone, there is decrease glucose utilization by the peripheral tissue causing hyperglycemia. The peripheral tissues enter a state of "starvation". The release of counterregulatory hormones glucagon, growth hormone, cortisol, and catecholamine stimulate gluconeogenesis and glycogenosis (**Table 1**). The main defect is that there is enough insulin to prevent lipolysis and ketogenesis but not enough to cause glucose utilization (as it takes 1/10 as much insulin to suppress lipolysis as it does to stimulate glucose utilization) possibly smaller incrase in counter regulatory hormones (**Flowchart 1**).

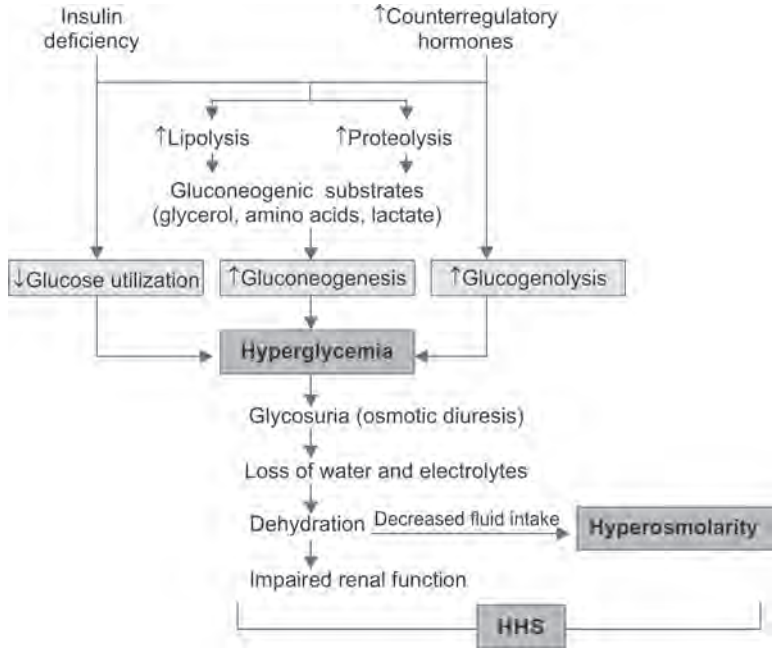
As there is rise in osmolality in the extracellular fluid it causes a shift of water from the intracellular to the extracellular space resulting in intracellular dehydration. Once the blood glucose exceeds the renal threshold (normal range 180–250 mg/dL) glycosuria and osmotic diuresis occurs. In the initial phase, glycosuria temporarily protects the patients from becoming the hyperglycemic. But persistent osmotic diuresis, significant depletion of intravascular volume, decreasing renal perfusion and the ability of the kidneys to excrete large quantities of glucose, profound hyperglycemia, and a further increase in plasma osmolality occur.

The stress of profound hyperglycemia and resultant hyperosmolarity and dehydration, as well as the precipitating illness, contributes to increased production of counter regulatory hormones which accentuates the degree of hyperglycemia. This creates a system of vicious cycle where there is increase level of glucose in the serum, but decreases uptake by the peripheral tissues for tissue metabolism.

In addition to glucose, electrolytes such as sodium, potassium, phosphate, and magnesium are also lost during the osmotic diuresis. Sodium depletion leads to further decrease in intravascular volume, but urinary losses of water always exceeds that of sodium leading to development of hypertonic dehydration.

TABLE 1: The effect of different hormones on glucose metabolism and regulation of ketogenesis.

	Ketogenesis	*Gluconeogenesis*	*Glycogenolysis*	*Glycolysis*	*Glycogen synthesis*
Insulin	Decreased	Decreased	Decreased	Increased	Increased
Glucagon	Increased	Increased	Increased	Decreased	Decreased
Cortisol	Increased	Increased	Increased	Decreased	Decreased
Growth hormone	Increased	Increased	Increased	Decreased	Decreased
Catecholamines	Increased	Increased	Increased	Decreased	Decreased



FLOWCHART 1: The diagrammatic representation of pathogenesis of hyperosmolar hyperglycemic syndrome (HHS).

The effect of hypertonic dehydration on the brain can be very profound. The brain produces idiogenic osmoles (osmotically active substance) to preserve the intracellular volume. The main functions of the idiogenic osmoles are to prevent movement of the fluid from the intracellular space into extracellular space and maintain a balanced equilibrium. The risk of developing cerebral edema is mostly related to how fast the serum osmolarity is decreasing. If the decline is too rapid, then the chances of fluid moving into the brain cell and causing swelling are higher. Hence, in the treatment of HHS, the goal of treatment is a slow correction of the hyperglycemia.

DIAGNOSIS

History and Physical Examination

The history and physical examination are very crucial in the diagnosis of HSS due to significant overlap in the signs and symptoms seen in HHS and DKA. The important points should be noted during the history taking and the initial assessment are insulin regimen, missed doses of the oral hypoglycemic agent, over consumption of carbohydrate-rich diet, and simultaneous use of medications that can trigger hyperglycemia or cause dehydration.

Clinical Features

The patient presents typically with increased urination (polyuria) and increase water intake (polydipsia) due to stimulation of the thirst centre in the brain from severe dehydration and increased serum osmolality (**Table 2**). Weakness, malaise, and lethargy can also be part of the complaint. The most important differentiating feature in HHS is the presence of neurological signs. Decreased cerebral blood flow from severe dehydration can cause focal neurological deficit, disturbance in visual acuity, delirium, and coma.

A system-based approach is necessary for the physical assessment. Patient with HSS are generally ill appearing with altered mental status. Cardiovascular features include tachycardia, orthostatic hypotension, weak and thready pulses, respiratory rate can be normal, tachypnea might be present if acidosis is profound, delayed capillary refill, poor skin turgor, and decreased urine output. Focal neurological deficit and lethargy with low Glasgow Coma Score are the prominent clinical features. In severe cases of HSS, patients might be comatose.

TABLE 2: Depicts sign and symptoms of the patients in the following conditions.

Precipitating factor	*Sign and symptoms*
An infectious process precedes hyperosmolar hyperglycemic syndrome	Fever, malaise, general weakness, tachypnea, and tachycardia
Cardiac or vascular conditions	Chest pain, chest tightness, headache, dizziness, and palpitation
Poor glycemic control	Acanthosis nigricans, oral thrush, vulvovaginitis, and multiple pustular skin lesion

Evaluation

Hyperosmolar hyperglycemic syndrome is a medical emergency that require urgent recognition and treatment. The initial approach to these patients should include a rapid but thorough history and physical examination with special focus on patency of airways, mental status, state of hydration, cardiovascular and renal integrity, and potential sources of infection. Initial laboratory evaluation for HHS is presented in **Table 3**.

Diagnostic features of HSS according to the American Diabetes Association (ADA) include:

- Plasma glucose level >30 mmol/L (>600 mg/dL)
- Serum osmolality >320 mOsm/kg
- Severe dehydration, average of 9 L fluid deficit, and thirst
- Serum pH > 7.30
- Bicarbonate > 15 mEq/L
- Small ketonuria (~+ on dipstick) and absent-to-low ketonemia (<3 mmol/L)
- Some alteration in consciousness
- Blood urea nitrogen (BUN) > 30 mg/dL (increased)
- Creatinine > 1.5 mg/dL (increase)

DIFFERENTIAL DIAGNOSIS

The following are some examples of condition that can cause an alteration in mental status:

- Hypoglycemia
- Hyponatremia
- Hypernatremia
- Hyperammonemia
- Severe intoxication with drugs or alcohol
- Uremic encephalopathy
- Diabetic ketoacidosis

TABLE 3: Initial laboratory evaluation for HHS.

Metabolic evaluation	• Glucose • Serum ketones • Electrolytes (Na, K, Cl, HCO_3, Ca, PO_4, and Mg) • Serum osmolality • BUN and creatinine • Arterial blood gases • Liver function test • Amylase Lipase • HbA1c • Urine analysis
Infectious disease evaluation	• CBC with differential • Urine culture • Blood culture • Viral nasal swab
Others	• ECG • Urine toxicology panel • Urine pregnancy test

(BUN: blood urea nitrogen; CBC: complete blood count; ECG: electrocardiogram; HbA1c: glycated hemoglobin; HSS: hyperosmolar hyperglycemic syndrome)

- Diabetic insipidus
- Central nervous system (CNS) infection
- Severe dehydration
- Myocardial infarction (MI)
- Pulmonary embolism
- Arrhythmia
- Hypotension
- Other causes of dehydration
- Acute blood loss (gastrointestinal or other)
- Excessive diuretic use

TREATMENT APPROACH

Hyperosmolar hyperglycemic syndrome treatment requires a multidisciplinary approach. It is recommended to consult an endocrinologist and intensive care specialist. The main goals in the treatment of HHS are as follows:

- To rehydrate the patient vigorously while maintaining electrolyte homeostasis
- Correction of hyperglycemia
- To treat underlying diseases
- To assist and monitor cardiovascular, renal, pulmonary, and CNS function

Airway Management

Patient of HHS presents with mental status changes, obtundation, or unconsciousness so maintenance of airway is mandatory and secure the airway if the Glasgow Coma Score is <8. Mechanical ventilation is necessary in patients with respiratory failure and circulatory collapse. If patients present with metabolic acidosis, hyperventilation is instituted as it generates respiratory alkalosis, which compensates for the metabolic acidosis and also decreases the risk of cerebral edema.

Intravenous Access

Intravenous access with large bore needle or central venous access is useful. Fluid deficit is large in HHS and in view of profound dehydration peripheral IV access is generally difficult so centrally placed catheter offers an opportunity for vigorous rehydration.

Fluid Resuscitation

To avoid cardiovascular collapse and to perfuse vital organs, aggressive fluid resuscitation is the key in the treatment of HHS. Fluid deficits in adults are large in HHS, being about 9 L on average. According to the ADA guidelines, to expand the extracellular volume fluid, resuscitation with 0.9% saline at the rate of 15–20 mL/kg/h or greater is indicated in the first hour. This amount to about 1–1.5 L in an average sized person. Slower rates are indicated in patients with cardiac or renal disease. Patients with HHS severe volume depletion state, a greater rate of fluid resuscitation is needed but should not exceed 50 mL/kg in the first 4 hours.

Patient's hydration status, serum electrolytes, and urinary output determine the choice of fluids after initial resuscitation. 0.45% normal saline may be used at a rate of 10 mL/kg/h if the patient's sodium level is normal or elevated. 0.9% normal saline may be used if the patient is hyponatremic. First half of the patient's fluid deficit should be corrected in the first 18–24 hours. The plasma osmolality should not change over 3 mmol/kg/h during fluid resuscitation. When the blood glucose concentration reaches 250 mg/dL, change the infusion to 5% dextrose in 0.45–0.7% normal saline. This is to prevent a quick fall in glucose, which may be associated with cerebral edema. In pediatric patients with suspected HHS, to reduce the risk of cerebral edema, correcting fluid deficits over a longer period (48 hours) may help. Potassium replacement initiated when the serum potassium is between 4 mmol/L and 4.5 mmol/L. 20–40 mEq/L of potassium chloride should also be included in the IV fluids to treat hypokalemia. Patients may require pressor support with persistent hypotension in the intensive care unit (ICU) while rehydration is being accomplished. An important endpoint of fluid therapy is to restore urinary output to 50 mL/h or more.

Insulin

Dose of insulin required to reduce the hyperglycemia may be less in HHS patients as compared to those with DKA. Correcting hypovolemia can reduce hyperglycemia considerably by fluid replacement alone, which then increases both glomerular filtration and renal excretion of glucose. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (beta-hydroxybutyrate >1 mmol/L). Start the insulin infusion rate at 0.05 unit/kg/h (bolus is not needed) and titrate to lower blood glucose levels by 50–70 mg/dL/h (2.8–3.9 mmol/L/h). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously. A too-quick reduction in osmolality can lead to cerebral edema.

Phosphate

If severe hypophosphatemia [serum phosphate <1 mg/dL (0.32 mmol/L)] develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

Monitoring during Treatment

Mortality associated with HHS remains high. Cardiorespiratory monitoring is warranted because of profound electrolyte and metabolic abnormalities present during treatment. Endotracheal intubation and mechanical ventilation are indicated when gas exchange has been compromised. Neurologic monitoring is indicated in all patients with HHS who present with altered mental status. Many neurologic syndromes may trigger by hyperosmolarity. If a patient has seizures, phenytoin is not used, because endogenous insulin secretion is inhibited and in general it is ineffective in persons with HHS. Appropriate decrease is osmolality and volume resuscitation and will decrease the chance of seizures. Patients with HHS may also require telemetry monitoring if cardiac workup suggests a cardiac etiology, such as MI, for HHS.

PROGNOSIS

Fluid replacement remains the primary approach to the prevention of complications. MI, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation can develop as a result of severe dehydration and low output state. Prophylactic low-dose heparin can be added.

The overall mortality rate of HHS is more than ten times that of DKA, because of its higher incidence in older patients with multiple comorbid conditions and excessive dehydration. Older patient may have compromised cardiovascular systems also. Other contributory factors for poor prognosis are delay in recognition and treatment. The mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders when prompt therapy is instituted. Insulin treatment should be continued for few weeks, but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. Education of the diabetic patient and caregivers should be instituted.

SUMMARY

The HHS is the most serious acute hyperglycemic emergency in patients with T2DM. Current diagnostic HHS criteria include a plasma glucose level >600 mg/dL and increased effective plasma osmolality >320 mOsm/kg in the absence of ketoacidosis. The reported mortality is between 10 and 20%, which is about 10 times higher than the mortality rate in patients with DKA. Treatment of HHS is includes replacing volume deficit and correcting hyperosmolality, hyperglycemia, and electrolyte disturbances, as well as management of the underlying illness that precipitated the metabolic decompensation.

130 CHAPTER

Hypothyroidism and Myxedema Coma

Ajay Agarwal, Danendra Sahu, Rupak Wadhwa

INTRODUCTION

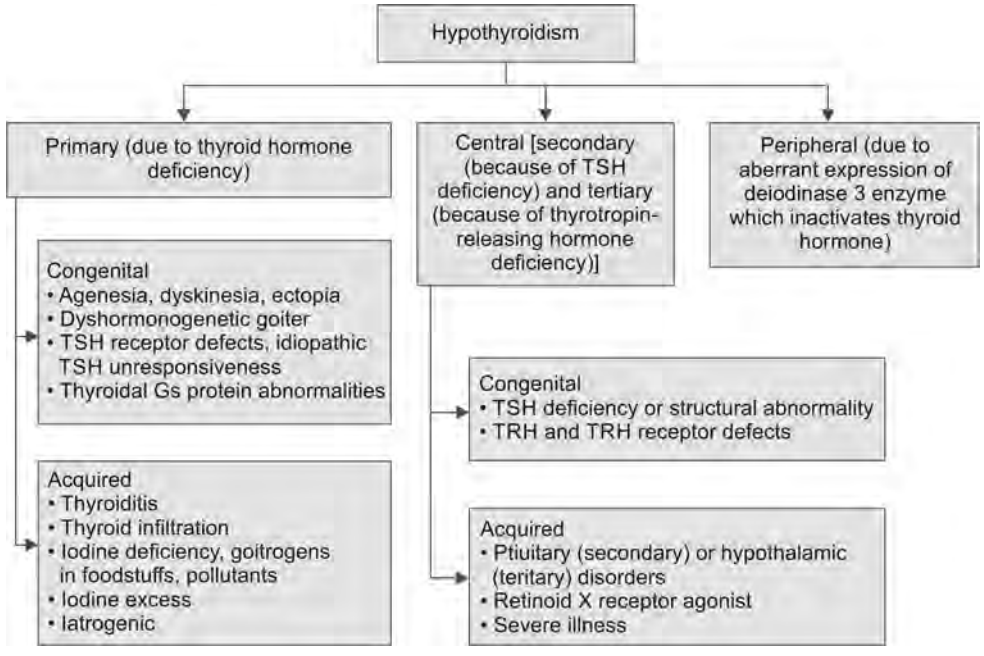
Hypothyroidism, a common metabolic disorder, occurs due to undersecretion of the thyroid hormones, thyroxine (T4), and triiodothyronine (T3). It leads to low serum T4 and T3 and high thyroid-stimulating hormone (TSH) due to compensatory rise. It occurs more commonly in females and elderly population.

CLASSIFICATION AND ETIOPATHOGENESIS

Hypothyroidism can be classified into primary, central, and peripheral types (**Flowchart 1**). Primary hypothyroidism is the most common type (~99%). Iodine deficiency is the most common cause of congenital and primary hypothyroidism globally, whereas chronic immune thyroiditis (Hashimoto's thyroiditis) is the most common cause of acquired hypothyroidism. Other causes include thyroidectomy (total or subtotal), radioactive iodine (RAI) therapy, radiotherapy to head and neck for cancer treatment, thyroid inflammatory diseases, pituitary or hypothalamic disorders, and several drugs (methimazole, propylthiouracil, amiodarone, lithium, and interferon-α) that affect the thyroid hormone availability. Under secretion of thyroid hormones (T4 and T3) from the thyroid gland is the most common cause of primary hypothyroidism whereas pituitary and hypothalamic causes may also affect thyroid gland functioning.

CLINICAL PRESENTATION

The clinical presentation of hypothyroidism includes a wide variety of symptoms, which may differ with age, gender, and disease duration. The most common symptoms are lethargy, hoarseness of voice, constipation, cold intolerance, dry skin, fatigue, menstrual disturbances, and weight gain (**Fig. 1**).



Hypothyroidism
Primary (due to thyroid hormone deficiency)
Central [secondary (because of TSH deficiency) and tertiary (because of thyrotropin-releasing hormone deficiency)]
Peripheral (due to aberrant expression of deiodinase 3 enzyme which inactivates thyroid hormone)
Congenital
• Agenesia, dyskinesia, ectopia
• Dyshormonogenetic goiter
• TSH receptor defects, idiopathic TSH unresponsiveness
• Thyroidal Gs protein abnormalities
Acquired
• Thyroiditis
• Thyroid infiltration
• Iodine deficiency, goitrogens in foodstuffs, pollutants
• Iodine excess
• Iatrogenic
Congenital
• TSH deficiency or structural abnormality
• TRH and TRH receptor defects
Acquired
• Ptiuitary (secondary) or hypothalamic (teritary) disorders
• Retinoid X receptor agonist
• Severe illness

(TRH: thyrotropin-releasing hormone; TSH: thyroid-stimulating hormone)

FLOWCHART 1: Classification and etiopathogenesis of hypothyroidism.

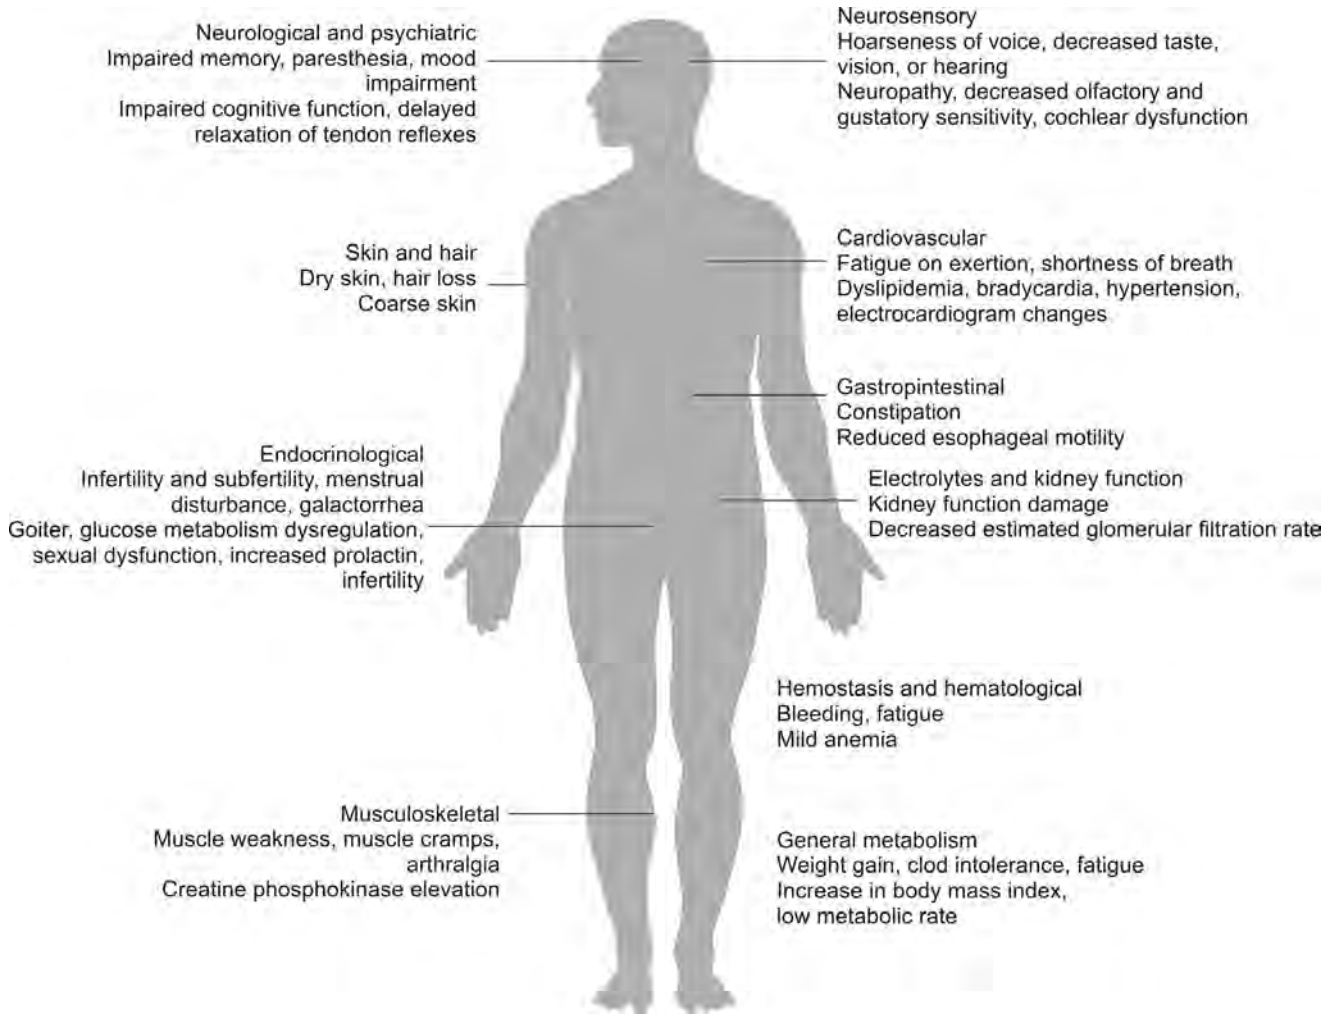


FIG. 1: Clinical manifestations of hypothyroidism.

DIAGNOSIS

The clinical signs and symptoms of hypothyroidism alone are not sufficient for the diagnosis as these are common and can be observed with other diseases or in the healthy state too. Measurement of serum T4 and TSH remains the only validated method for testing thyroid function. However, the standard reference ranges for these assays are still debated as these differ with age, gender, and race. These reference ranges do not consider the symptoms, risk of the disease, and adverse events. The algorithm for the diagnosis of suspected hypothyroidism is shown in **Flowchart 2**.

MYXEDEMA COMA

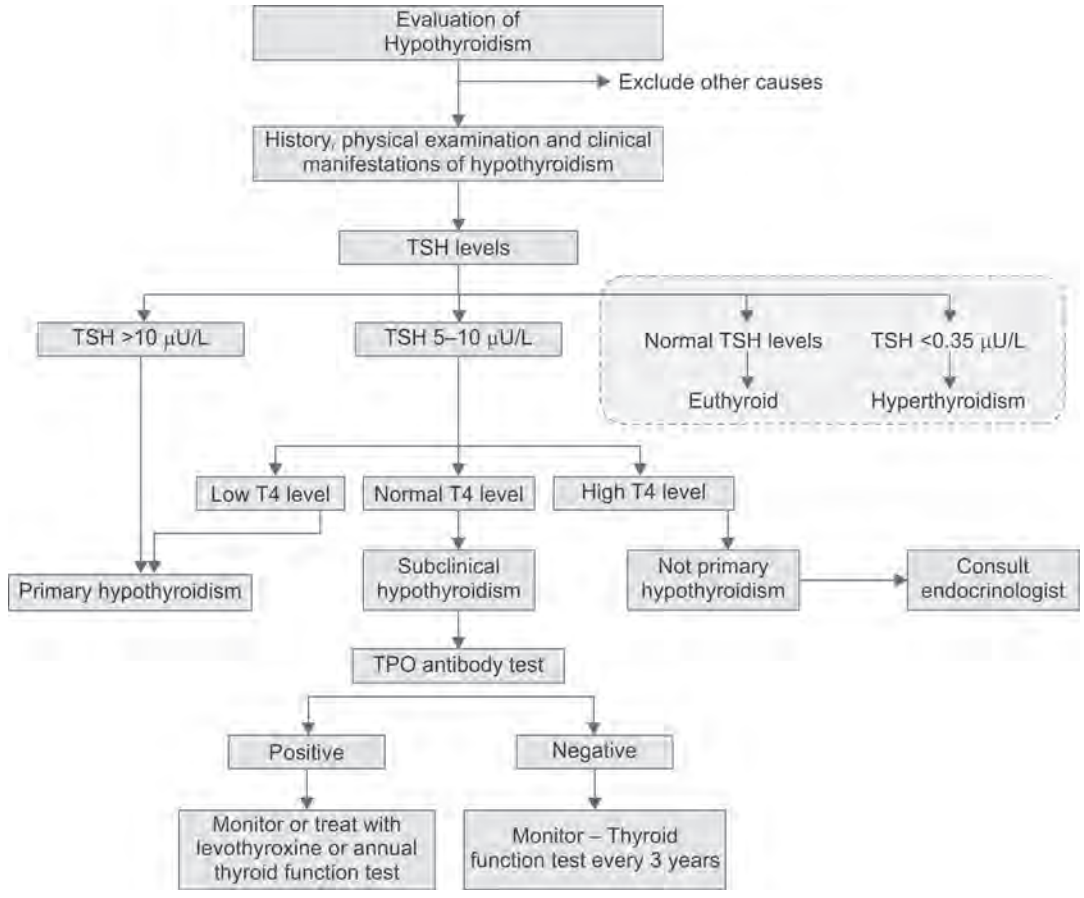
Severe hypothyroidism untreated for a prolonged duration may lead to a rare fatal disease, myxedema coma, in which the body's homeostasis goes haywire due to precipitating factors. These factors include infection, certain medications (amiodarone, anesthesia, barbiturates, β-blockers, diuretics, lithium, narcotics, phenothiazines, phenytoin, rifampin, and tranquilizers), and failure to reinstate thyroid replacement therapy during hospitalization, stroke, surgery, burns, hypoglycemia, hypothermia, gastrointestinal hemorrhage, or trauma among others. Most (95%) of the myxedema coma cases occur due to primary hypothyroidism while hypothalamic or pituitary causes account for the remaining (5%) cases.

Clinical Presentation and Pathogenesis of Myxedema Coma

Patients with myxedema coma generally present with altered sensorium, lethargy, confusion, and possibly obtundation rather than coma. Other characteristics include hypoglycemia, bradycardia, hypoventilation, hypotension, hypothermia, (usually <95.9°F), hyponatremia, increased levels of serum creatinine, and creatinine kinase. The clinical presentation of myxedema coma is shown in **Table 1**. **Flowchart 3** outlines the pathogenesis of the myxedema coma.

Diagnosis

The suspected diagnosis of myxedema coma includes clinical presentation of any patient with coma or compromised mental status with hypercapnia, hypothermia, and/or hyponatremia, and with decreased T3 and T4 concentrations. Measurement of serum cortisol is required to rule out coexisting adrenal insufficiency. However, there is a nonspecific presentation of clinical features in several instances such as altered mental status without coma, which makes it difficult to diagnose



(TPO: thyroid peroxidase; TSH: thyroid-stimulating hormone)

FLOWCHART 2: Diagnosis of suspected hypothyroidism.

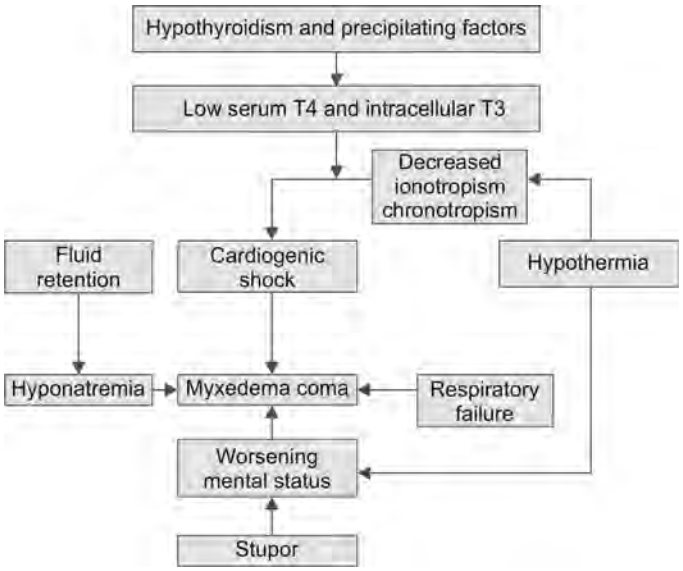
TABLE 1: Clinical presentation of myxedema coma.

System	*Clinical presentation*
Central nervous system (CNS)	• Decreased mental status—may be due to decreased cerebral blood flow and cerebral glucose metabolism • Confusion, apathy, lethargy, obtundation, and coma • Cognitive impairment and psychiatric disorders can also be seen • Hyponatremia • Hypoglycemia (~25% patients)
Respiratory system	• Respiratory depression • Fluid accumulation—pleural effusion • Obstructive sleep apnea—obesity and weight gain • Myxedematous infiltration of the pharynx and tongue requiring mechanical ventilation
Cardiovascular system (CVS)	• Bradycardia, low cardiac output, and decreased blood volume • Increased systemic peripheral resistance and pericardial effusion
Renal system	• Severe renal impairment—reduced blood flow and low glomerular filtration rate (GFR) • Elevated creatinine • Decreased sodium reabsorption leading to hyponatremia
Gastrointestinal tract (GIT)	Decreased intestinal mobility—constipation, anorexia, nausea, abdominal pain, and distension
Skin and hair	• Myxedematous facies—generalized puffiness, ptosis, macroglossia, coarse and sparse hair, and periorbital edema • Dry, pale, and thickened skin with nonpitting edema (myxedema) • Dry and brittle hair • Hoarseness in voice

Continued

Continued

System	Clinical presentation
Metabolic	Hypothermia (up to 75°F)
Laboratory and others	• Reduced T4 and T3 • Elevated thyroid-stimulating hormone (TSH)—primary hypothyroidism; normal/low TSH—central/secondary hypothyroidism • Respiratory acidosis • Electrocardiogram (ECG)—bradycardia, decreased voltage, prolonged QT interval, nonspecific ST-T changes and Osborn waves in cases of hypothermia • Chest radiograph—pleural effusions and cardiomegaly



FLOWCHART 3: Pathogenesis of myxedema coma.

myxedema coma. Overall, altered mental status, hypothermia, and the presence of precipitating events are the three key features for differential diagnosis of myxedema coma. *Chiong and Mariash* developed a tool as diagnostic criteria for myxedema coma based on six common parameters of the disease, which is used by intensive care units (ICUs) of several hospitals (**Table 2**).

TREATMENT

Treatment of Hypothyroidism

Life-long hormone therapy is required in most patients with hypothyroidism. The American Thyroid Association (ATA) recommends levothyroxine monotherapy as the standard of care for hypothyroidism. Levothyroxine should be started at 1.6 μg/kg/day in young and healthy adults for complete replacement. The detailed treatment algorithm for hypothyroidism is presented in **Flowchart 4**.

Treatment of Myxedema Coma

Myxedema coma is a metabolic thyroid emergency condition, and the suspected patients should be administrated intensive care therapy for vital pulmonary, respiratory, and cardiovascular support. The mortality rate could be from 25 to 60% in myxedema coma patients despite the best treatment. Hence, the treatment for suspected myxedema coma should be initiated immediately rather than waiting for laboratory confirmation. Due to lack of studies comparing the efficacy of different treatment regimens, deciding the optimal treatment is challenging. Successful treatment depends upon the timely diagnosis, prompt treatment with thyroid hormones (intravenous levothyroxine is preferred over oral), supportive therapy (appropriate fluid management and correction of hypotension and dyselectrolytemia), and administration of steroid supplement (hydrocortisone) until coexisting adrenal insufficiency is ruled out, along with the aggressive treatment of precipitating factors. The treatment of myxedema coma is detailed in **Flowchart 5**.

A push syringe should be used for the administration of intravenous levothyroxine in myxedema coma cases instead of the infusion tubes due to the risk of drug adherence to the polypropylene tubes resulting in ~40% decreased initial drug concentration. Thyroid function testing (T4 and T3) should be done every 1–2 days to check that T3 levels are not too high and therapy is working. Serum T3 and T4 levels can be improved prior to TSH normalization. Improvements can be observed in pulmonary, cardiovascular, renal and metabolic parameters within a week, and later the patient can be managed with oral T4 therapy alone.

SUMMARY

Hypothyroidism, if not treated for prolonged duration, may lead to a potentially fatal disease condition myxedema coma, which is a rare but serious medical emergency. It is characterized by decreased mental status, hypothermia, hypotension, bradycardia, hyponatremia, hypoglycemia, and hypoventilation. In the case of suspected myxedema coma, serum thyroxine (T4) levels are generally low; TSH may be high for primary hypothyroidism or may be low, normal, or slightly high for central/secondary hypothyroidism. Determination of serum T4, TSH, and cortisol levels is recommended, however, the treatment of myxedema coma should be aggressively initiated in the ICU irrespective of the laboratory confirmation on thyroid levels. The treatment of myxedema coma comprises thyroid hormone therapy, supportive measures (mechanical ventilation, appropriate fluid replacement, correction of hypocortisolemia, hyponatremia, and hypothermia), and treatment of precipitating events (such as infections and gastrointestinal bleeding, etc.).

TABLE 2: Diagnostic criteria for myxedema coma.

Parameter	1. Glasgow Coma Scale score				2. Thyroid-stimulating hormone (TSH) (mU/L)		3. Free T4 levels <0.6 ng/dL	4. Body temperature <95°F	5. Heart rate <60 beats/min	6. Precipitating event*

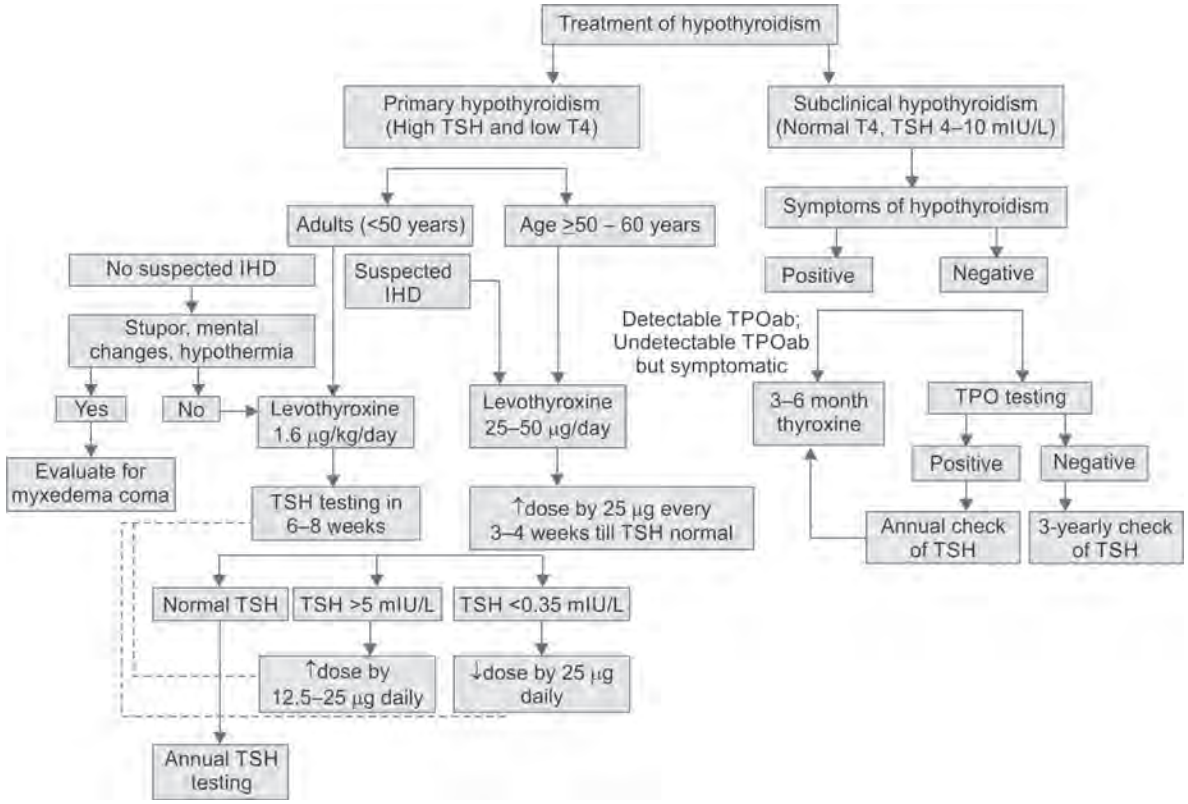
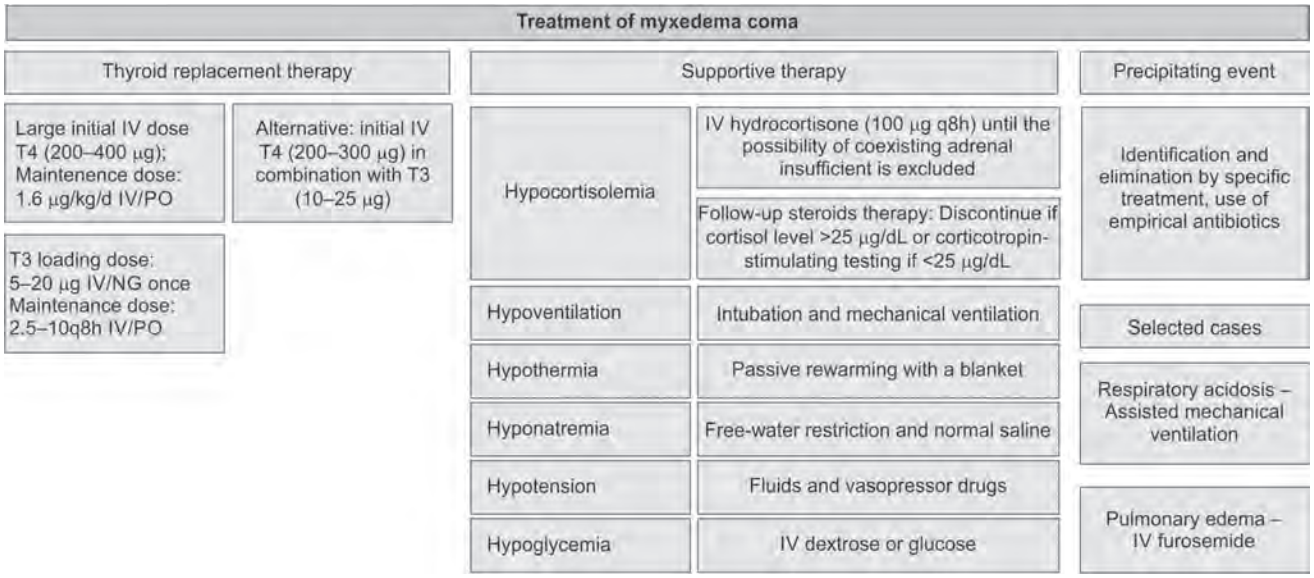
*Burns, carbon monoxide retention, gastrointestinal hemorrhage, infection, sepsis, medications, stroke, surgery, trauma, etc.



(IHD: ischemic heart disease; TSH: thyroid-stimulating hormone; TPO: thyroid peroxidase; T4: thyroxine)

FLOWCHART 4: Treatment algorithm for hypothyroidism.



Treatment of myxedema coma
Thyroid replacement therapy
Supportive therapy
Precipitating event
Large initial IV dose T4 (200–400 µg); Maintenence dose: 1.6 µg/kg/d IV/PO
Alternative: initial IV T4 (200–300 µg) in combination with T3 (10–25 µg)
T3 loading dose: 5–20 µg IV/NG once Maintenance dose: 2.5–10q8h IV/PO
Hypocortisolemia
IV hydrocortisone (100 µg q8h) until the possibility of coexisting adrenal insufficient is excluded
Follow-up steroids therapy: Discontinue if cortisol level >25 µg/dL or corticotropin-stimulating testing if <25 µg/dL
Identification and elimination by specific treatment, use of empirical antibiotics
Hypoventilation
Intubation and mechanical ventilation
Selected cases
Hypothermia
Passive rewarming with a blanket
Hyponatremia
Free-water restriction and normal saline
Respiratory acidosis – Assisted mechanical ventilation
Hypotension
Fluids and vasopressor drugs
Hypoglycemia
IV dextrose or glucose
Pulmonary edema – IV furosemide

(IV: intravenous; PO: enteral)

FLOWCHART 5: Treatment of myxedema coma.

131 CHAPTER

Hyperthyroidism—Graves' Disease and Thyroid Storm

Dheeraj Kapoor, Abhishek Goyal

INTRODUCTION

Graves' disease (the most common form of hyperthyroidism) is an autoimmune disorder of the thyroid gland leading to an overproduction of thyroid hormones. As a result of elevated levels of thyroid hormones T3 and T4, spectrum of disease varies from subclinical hyperthyroidism to thyrotoxicosis (hypermetabolic and life-threatening condition). Graves' disease was initially called "exophthalmic goiter", but later renamed after an Irish doctor Sir Robert Graves' who first described this condition in 1835. The autoimmune nature of the disease depends upon the complex interplay of both, the environmental and the genetic factors. Graves' disease has significant somatic and psychiatric symptoms which affect the overall quality of life with a significant increase in morbidity and mortality. The myriad of attributes of Graves' disease is an outcome of raised thyroid hormone levels. Thyrotropin receptors are activated by thyrotropin-stimulating immunoglobulins (TSIs) which leads to an over production of thyroid hormones and thus the symptoms. Treatment comprises of mitigation of symptom and amelioration of thyrotoxicosis.

EPIDEMIOLOGY

This is the most common cause of hyperthyroidism over the world with a peak incidence in the 3rd to 5th decade of life and a higher risk in women as compared to men. Annual incidence of Graves' ophthalmopathy is also more common in women as compared to men with a higher predominance in whites as compared to Asians. Associated morbidity advances with age. Graves'-associated ophthalmopathy typically occurs within a year of development of hyperthyroidism, but can occur even after a decade of the diagnosis of hyperthyroidism.

CLINICAL PRESENTATION

Since Graves' disease is an autoimmune disorder, signs and symptoms depend upon the prevailing autoimmunity and the degree of thyrotoxicosis. Presentation of Graves' disease rests mainly on the age at the onset of hyperthyroidism along with the severity and duration of thyrotoxicosis (**Table 1**). Generalized weakness, fatigue, listlessness, weight loss, intolerance to heat, and palpitations are the most common symptoms occurring in the majority of subjects. Cardiac symptoms occur more common in the elderly, who present with tachycardia and atrial fibrillation. Goiter can develop at any age but is more common in patients below the age of 60 years. Orbital signs indicate the presence of an active autoimmunity. Ophthalmopathy is disfiguring and may also endanger vision. Its clinical course follows a typical pattern from an active phase lasting up to 3 years to an inactive phase in which the symptoms stabilize. The combination of activity score and the severity of symptoms direct the treatment protocol.

Dermopathy occurs in only a small subset of patients with Graves' disease and is typically seen in those with orbitopathy. It is localized mainly to the pretibial area, but may also occur in areas with repeated trauma. Thyroid acropachy almost always occurs in patients with dermopathy and resembles clubbing of fingers and toes.

PATHOGENESIS

Secretion of thyroid hormones is a complex interplay of various stimulatory and inhibitory factors. thyrotropin-releasing hormone (TRH) produced by the hypothalamus stimulates the pituitary to release thyroid-stimulating hormone (TSH). This TSH then acts upon the thyroid follicles to secrete thyroxine (T4) and to some extent triiodothyronine (T3). Both T4 and T3 have an inhibitory effect on hypothalamus and pituitary. Synthesis of thyroid hormones is dependent upon dietary inorganic iodide absorbed by the intestine. This iodide is transported into the thyroid gland by iodine transporter where it is converted to iodine and gets bound to thyroglobulin by the enzyme thyroid peroxidase (TPO). This process results in the formation of monoiodotyrosine and diiodotyrosine which are coupled to form T3 and T4. These are stored along with thyroglobulin in thyroid follicles. Any process that leads to an increase in peripheral secretion of unbound thyroid hormone leads to signs and symptoms of thyrotoxicosis. Disturbance of this normal homeostatic mechanism can occur at the level of hypothalamus, pituitary, or the thyroid gland itself. TSIs stimulate the thyrotropin receptors leading to an

TABLE 1: Clinical features of hyperthyroidism (Graves' disease).

Signs of Graves' disease	*Symptoms of Graves' disease*	*Extrathyroidal physical signs*
• Loss of weight • Tachycardia and atrial fibrillation • Isolated systolic hypertension and wide pulse pressure • Heart failure • Moist warm skin, palmar erythema, and onycholysis • Loss of hair • Muscle weakness • Fine tremors, hyperreflexia, and hyperkinesia • Palpable goiter and thyroid bruit • Mood disorders (mania or depression)	• *General*: Fatigue, generalized weakness, weight loss, heat intolerance, and neck fullness • *Cardiovascular*: Palpitations and dyspnea • *Respiratory*: Dyspnea • *Neuromuscular*: Tremor, tiredness, fatigue, and muscle weakness • *Skeletal*: Pain in back • *Dermatological*: Warm moist skin, increased sweating, and pruritus • *Gastrointestinal*: Increased bowel frequency • *Eye*: Tearing, gritty eyes, pain, redness, and double vision • *Renal*: Increased thirst and polyuria • *Reproductive*: Menstrual irregularities in women and loss of libido • *Psychiatric*: Anxiety, nervousness, hyperactivity, irritability, and insomnia	• Ophthalmopathy: ○ Lid lag and lid retraction ○ Exophthalmos ○ Double vision ○ Periorbital chemosis, edema, and infection ○ Exposure keratitis ○ Orbital neuropathy • Localized dermopathy acropachy

overproduction of thyroid hormones, thereby abolishing the natural regulatory pathway of thyrotropin. To add to this insult immune cells such as T and B cells and antigen presenting cells produce interferon γ, interleukin (IL)-1β, 6, and 12, tumor necrosis factor-α (TNF-α), CD40 ligand, and other cytokines. Antithyroid drugs mitigate the effect of thyroid hormones thereby reducing the cytokine effect and thus attenuating the autoimmune process.

During the active phase of ophthalmopathy the orbit is impregnated with T and B cells along with CD34 + fibrocytes. These fibrocytes further transform into fibroblasts which in turn produce cytokines. These include IL-1β, 6, 8, and 16, TNF-α, regulated on activation, normal T-cell expressed and secreted (RANTES), and CD40 ligand; which consecutively activate orbital fibroblasts. TSI stimulate thyrotropin and insulin-like growth factor-1 (IGF-1) receptor complex, thereby presenting the inflammatory molecules and promoting glycosaminoglycan synthesis. Cytokine-activated fibroblast manufactures hyaluronan and other glycosaminoglycans, which augment the orbital tissue leading to proptosis and orbital nerve compression. In addition to this, the orbital fat also expands as an after effect of adipogenesis.

DIAGNOSIS

Serum TSH is usually the test of choice and when suppressed to unmeasurable levels (<0.05 μIU/mL) is a sensitive marker for the suspicion of thyrotoxicosis. Thorough history and clinical examination often provide valuable clues for the diagnosis of thyrotoxicosis which can be further confirmed by FT3 and FT4 levels. Diagnosis can be confirmed by the presence of TSH receptor antibodies, measured by enzyme-linked immunosorbent assay (ELISA), which has a high sensitivity and specificity of 98% and 99%, respectively as compared to anti-TPO antibodies, which are present in only 75% cases of Graves' disease. If antibody levels are inconclusive, radioactive iodine uptake (RAIU) can be helpful in differentiating various causes of thyrotoxicosis (**Flowchart 1**). In cases of subacute thyroiditis measurement of C-reactive protein (CRP) and erythrocyte sedimentation rate ESR are helpful. These are usually elevated. Electrocardiogram (ECG) is usually recommended to rule out arrhythmias. Interpretation of thyroid function test is given in **Table 2**.

Thyroid-associated Ophthalmopathy

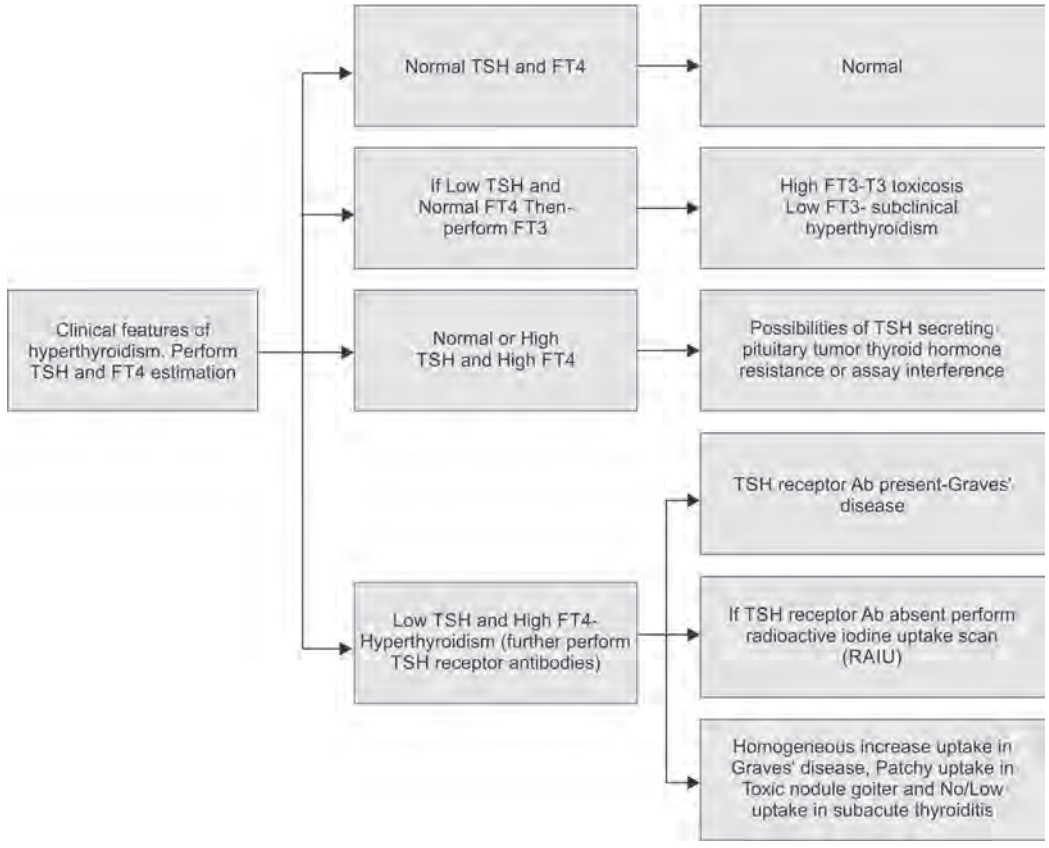
Imaging studies help in differentiating extraocular muscle enlargement from fat enlargement. CT and MRI imaging of orbit is advised when the cause of ocular presentation remains ambiguous. Orbital ultrasound, thermal imaging, scintigraphy with radiolabeled octreotide, and gallium scan may be a practical approach in accurately delineating the disease. Notably in cases of asymmetrical proptosis, excluding an orbital tumor or an artery venous malformation is critical. Estimation of activity and severity of ophthalmopathy by clinical evaluation is the corner stone in guiding treatment.

TREATMENT

Spontaneous remission has been reported in a small subset of patients. About 10–20% patients of Graves' disease develop auto immune hypothyroidism. Antithyroid drugs remain the therapies of choice in uncomplicated cases. Ablative therapy by way of radioiodine use or postsurgical thyroidectomy leads to hypothyroidism and which needs lifelong thyroxine replacement. Thus, each treatment approach has its own advantages and disadvantages which should be discussed in detail with the patient and the therapy be started only after proper counseling.

Symptomatic Relief

Beta-adrenergic blockers are advocated in most patients with symptomatic thyrotoxicosis, especially the elderly and those with a resting heart rate of >90 beats per minute or with another coexistent cardiovascular compromise. These drugs should preferably be avoided in patients with asthma. Alternatively, calcium channel blockers (e.g., verapamil and



Clinical features of hyperthyroidism. Perform TSH and FT4 estimation
Normal TSH and FT4
Normal
If Low TSH and Normal FT4 Then- perform FT3
High FT3-T3 toxicosis
Low FT3- subclinical hyperthyroidism
Normal or High TSH and High FT4
Possibilities of TSH secreting pituitary tumor thyroid hormone resistance or assay interference
Low TSH and High FT4- Hyperthyroidism (further perform TSH receptor antibodies)
TSH receptor Ab present-Graves' disease
If TSH receptor Ab absent perform radioactive iodine uptake scan (RAIU)
Homogeneous increase uptake in Graves' disease, Patchy uptake in Toxic nodule goiter and No/Low uptake in subacute thyroiditis

(FT3: free triiodothyronine; FT4: free thyroxine; TSH: thyroid-stimulating hormone)

TABLE 3: Thyroid inhibitors.

Inhibit hormone synthesis (antithyroid drugs)	Propylthiouracil, carbimazole, and methimazole
Inhibit iodide trapping (ionic inhibitors)	Thiocyanates (–SCN), perchlorates ($–ClO_4$), and nitrates ($–NO_3$)
Inhibit hormone release	Iodine, iodides of Na and K, and organic iodide
Destroy thyroid tissue	Radioactive iodine (I131, I125, and I123)

diltiazem) can also be used in such cases. Anticoagulation is also recommended in patients with thyrotoxicosis presenting with atrial fibrillation.

Therapy

Antithyroid drugs (**Table 3**), surgery, and radioactive iodine have been used over the world by endocrinologists as per their preference and local guidelines while suiting their patient's profile.

Carbimazole and its active metabolite methimazole are the most preferred antithyroid drugs due to ease of once daily usage and a long half-life which leads to a rapid control of symptoms. These drugs act by inhibiting the synthesis of thyroid hormone by blocking oxidation of iodine in the thyroid gland. They are metabolized by the liver and excreted in urine. These are category D drugs and hence not recommended for use in pregnancy; because of secretion in breast milk it is advisable to use these with caution while nursing.

However the American Academy of Pediatrics and the American Academy of Family Physicians consider it to be safe. Methimazole is usually started at 5–15 mg twice daily, going up to 30 mg BID in patients who are toxic and has a maintenance dose of 5–10 mg daily as per the requirement.

Propylthiouracil also inhibits the synthesis of thyroid hormones by blocking oxidation, and when given in high doses, also blocks the 5' deiodinase enzyme which converts

thyroxine to triiodothyronine. It is metabolized by the liver and excreted in urine (35%) and is to be administered 8–12 hourly. It is marked Category D in pregnancy and distributed in breast milk; hence is believed to be contraindicated by some authorities. It is the treatment of choice just before and during the first trimester of pregnancy because methimazole administration during first trimester has been associated with congenital malformations.

This drug is usually initiated at doses of 100–150 mg every 8 hourly which can later be reduced to 50 mg twice or thrice daily as per clinical and biochemical response.

Most patients with Graves' disease achieve euthyroid status within 6–8 weeks of treatment. But some patients with a large goiter, severe hyperthyroidism or with a recent exposure with radioiodine may need to be treated for longer with higher doses. Once euthyroid is achieved, either of the two regimens may be followed. The first is the "block and replace" regimen in which the dose of thionamide is kept constant and later levothyroxine is added to maintain euthyroid. In the second, "titration" regimen, the dose of thionamide is progressively lowered till euthyroid is achieved. Approximately 50% patients treated for 6–18 months go into remission, after which these drugs can be safely stopped with a close monitoring of thyroid function at 4–6 weeks to detect early relapse. In case of relapse where surgery or radioiodine is not an acceptable option, a long-term small dose of thioamide should be considered.

The most common side effect encountered with thionamide use is a pruritic rash which is usually transient. Another rare but important side effect is agranulocytosis which presents with fever, cough, sore throat, or mouth ulcers. All patients being started on these medications should be explained in detail by both written and oral communication that in case of these symptoms they should immediately report to their physician.

Radioactive Iodine Treatment

Radioiodine is administered in a capsule or liquid form which is quickly absorbed by the thyroid gland resulting in thyroid-specific inflammatory response resulting in fibrosis and destruction of the gland over a period of 6 sweeks to 6 months. Iodine 131 is used in doses of 370–550 MBq; now the trend is towards giving a fixed dose which is effective in rendering 70–90% patients euthyroid or hypothyroid rather than individualizing each patient. It is the treatment of choice in patients with toxic multinodular goiter, solitary toxic nodule, Graves' disease, or side effects of antithyroid medication. Pregnancy and breastfeeding are absolute contraindications and it is advisable not to use it in patients with thyroid ophthalmopathy because of the risk of worsening. Post treatment patients are warned not to conceive for at least 6 months after radio ablation and avoid close contact with pregnant females and young children for at least 3 weeks.

Thyroid Surgery

Total or near total thyroidectomy is the treatment of choice in patients who have relapsed after medical management, having large goiter (for cosmetic reasons), women who want to conceive shortly after completion of treatment, and in patients who want to avoid antithyroid drugs or radiation exposure. Women who undergo surgery should wait for stabilization of TSH levels and replacement thyroxine therapy should be started before they attempt conception.

Treatment of ophthalmopathy depends upon the phase and severity of the disease. Most patients require only conservative measures for maintenance of ocular surface moisture and enhancement of tear film. But a small subset who has a symptomatic eye-threatening disease benefit from intravenous pulse glucocorticoid therapy. External beam radiotherapy in combination with intravenous pulse glucocorticoid therapy has better effects than when used alone. Orbital decompression is reserved for patients who have developed optic nerve neuropathy.

THYROID STORM

Thyroid storm is unrecognized, undertreated, and life-threatening form of severe thyrotoxicosis. Thyroid storm is rare and mostly acute reaction to thyroid and nonthyroid surgery, trauma infections, contrast media, amiodarone, and after delivery in preexisting hyperthyroidism. Other risk factors are acute coronary syndrome, pulmonary embolism, and diabetic ketoacidosis. Prompt recognitions and treatment is warranted as mortality is almost 100%. Causes of mortality in patient of thyroid storm are sepsis, multiorgan failure, congestive heart failure, arrhythmias, and disseminated intravascular coagulation. Clinical features of thyroid storm are typical and include hyperpyrexia, out of proportion tachycardia, altered mental status (agitation and delirium coma) along with clinical picture of hyperthyroidism. Management of thyroid storm is summarized in **Table 4**.

TABLE 4: Management of thyroid storm.

Beta-adrenergic blockers	• Propranolol 60–80 mg orally every 4 h [intravenous (IV) 0.5–1.0 mg as test dose then repeat 1–2 mg every 15 min till desired effect then 1–2 mg every 3 h] or • Metoprolol 25–50 mg orally every 6 h or • Esmolol 50–100 µg/kg/min infusion
Inhibition of thyroid hormone synthesis	Propylthiouracil 500–1,000 mg loading then 250 mg every 4 h or methimazole 60–80 mg/day
Inhibition of thyroid hormone release	• Saturated potassium iodide solution (50 mg/drops) 1–2 drops orally or per rectally or • Lugol's solution (8 mg iodide/drops) 5–7 drops
Corticosteroid	Hydrocortisone 300 mg IV then 100 mg every 8 h
Treatment of underlying precipitant	Empirical antibiotics
Supportive measures	Volume resuscitation cooling blankets and fan ice packs/lavage
Others	Lorazepam and diazepam

SUMMARY

In Graves' disease, timely recognition of signs and symptoms followed by adequate supportive care and thyroid-specific therapy is necessary to alleviate the associated risk along with morbidity and mortality. This being the most common cause of hyperthyroidism and remains to be a hot topic for research and evidence-based recommendations. With the advent of newer diagnostic and genomic tools which help in understanding the pathophysiology better, scientists are now more focused on developing agents that block the thyrotropin and IGF-1 receptors, thereby improving the quality of life and at the same time improving the longevity as well. With the knowledge of the dominant antigen of Graves' disease, there stands a chance for antigen-specific therapy. Establishing better immune resilience against thyrotropin receptor is the eventual intention. Evaluation of patient with hyperthyroid features is summarized in **Flowchart 1**.

132 CHAPTER

Acute Adrenal Crisis

Dheeraj Kapoor, Abhishek Goyal

INTRODUCTION

Acute adrenal crisis is a life-threatening medical emergency which responds to supra physiologic glucocorticoid doses. Its initial presentation can be in form of nausea, vomiting, and abdominal pain with unexplained refractory shock not responding to fluid and pressor support. This is a clinical presentation of glucocorticoid deficiency with or without deficiency of mineralocorticoid and adrenal androgens.

Adrenal crisis is the most accepted representation of adrenal insufficiency (AI) with infections being the major precipitating cause. Primary AI is most commonly caused by autoimmune adrenalitis whereas hypothalamic–pituitary tumors most commonly present as secondary AI.

In this chapter we discuss in detail about various aspects of acute adrenal crisis with emphasis on diagnosis and management of this disorder.

Thomas Addison in 1855 described the classical symptoms of AI as fatigue, anorexia, generalized weakness, weight loss, orthostatic hypotension, and salt craving with hyperpigmentation as the primary symptoms. It was considered fatal till 1949 when cortisone was found and glucocorticoid replacement started. Still so many years passed by but this disorder has always been a challenge in diagnosis and treatment. Acute adrenal crisis mimics to several emergencies due to its nonspecific presentation so emergency physician should consider this entity as important differential diagnosis if high index of suspicion on the basis of history, physical examination, and laboratory findings. For effective management of acute adrenal crisis understanding about basic physiology of adrenal gland, pathophysiology, etiology, and therapy are described in this chapter.

BASIC ANATOMY AND PHYSIOLOGY OF THE ADRENAL GLAND

Adrenal gland is capsulated retroperitoneal organ divided *into two zones; (i) outer part known as adrenal cortex, and (ii) outer adrenal medulla.* Adrenal cortex further subdivided in to three zones: (1) *Zona fasciculata* which secretes glucocorticoid (cortisol), (2) *Zona reticularis* secretes the dehydroepiandrosterone acetate (DHEA) which is the intermediate metabolite for sex steroids androgen and estrogen. *Zona glomerulosa* secretes mineralocorticoids (aldosterone), and (3) *Adrenal medulla* secretes catecholamines, epinephrine, and norepinephrine. Important functions of adrenal hormone are summarized in **Table 1**.

Glucocorticoid (Cortisol)

Cortisol is important for normal functioning of all tissues. Cortisol gives cardiovascular stability by maintaining adequate circulatory volume, cardiac contractility, and vascular tone thus stimulate cardiac function. Cortisol enhances the action of catecholamines, epinephrine, and norepinephrine. Release of vasodilators from endothelium is also reduced by cortisol. Thus, cortisol deficient patient present with circulatory collapse/shock which is the hallmark of acute adrenal crisis. Glucocorticoid are important for glucose lipid and protein metabolism and regulate energy storage and utilization. Thus, in glucocorticoid deficient patient loss of appetite weight loss and cachexia are present. Glucocorticoid also facilitate healing of damaged tissue due to its anti-inflammatory action and its absence or deficiency results

TABLE 1: Important functions of adrenal hormone.

System	*Physiological response*
Cardiovascular	Maintain cardiac contractility cardiac function and vascular tone thus provide cardiovascular stability
Endocrine	Inhibit insulin secretion and epinephrine synthesis
Inflammatory	Maintain inflammatory homeostasis, anti-inflammatory action of cortisol, reduce circulating leukocyte and cytokines response, eosinophils, and lymphocytes
Metabolic	Gluconeogenesis lipolysis, muscle protein catabolism, and raise plasma glucose during stress
Renal	Increase in glomerular filtration rate (GFR)

in increase in inflammation and patient present with fever, arthralgia, myalgia, and lethargy. Cortisol release is controlled by hypothalamic–pituitary–adrenal axis (HPA axis) and released during trauma, infection, and stress (**Fig. 1**).

Mineralocorticoid (Aldosterone)

Main function of aldosterone is sodium reabsorption in exchange of potassium at the level of distal convoluted tubule and maintain sodium, potassium, and water balance. Thus, aldosterone deficiency cause sodium loss and potassium retention and rapid loss of salt and water during vomiting and diarrhea leads to coma or death. Aldosterone release is regulated by renin–angiotensin–aldosterone system. Hypotension, hemorrhage, low perfusion pressure, volume depletion, and sodium loss are the trigger factors for renin release (**Fig. 2**).

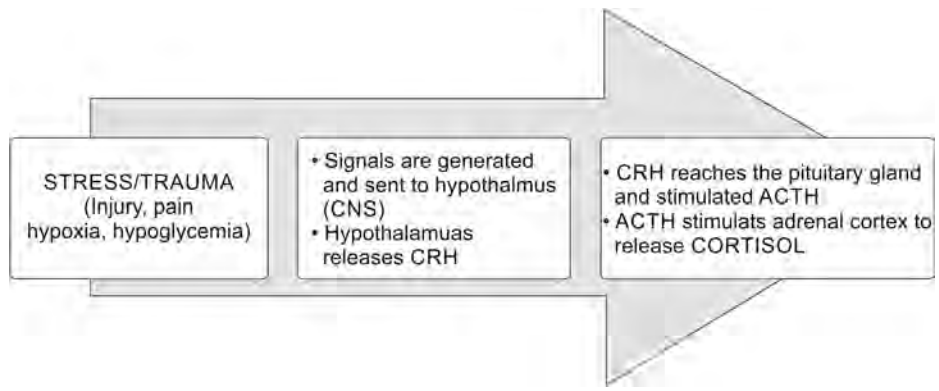
CLASSIFICATION

After understanding the basics about anatomy, physiology, and function of adrenal gland, the one point is clear that adrenocortical hormone deficiency results in reversal of these hormonal effect and produce acute adrenal crisis. Hormone of importance in acute adrenal crisis is cortisol. *AI can be classified on the basis of mechanism into primary, secondary, and tertiary*. Primary AI results from disease inherent to adrenal cortex. Central AI being the collective name for secondary and tertiary resulting due to defective production or action of corticotropin. Secondary AI is a result of pituitary disease that affect the release of corticotropin or prevent its action on adrenal cortex. Tertiary AI is a result of defective synthesis or action of corticotropin-releasing hormone (CRH) and/or vasopressin from hypothalamus which in turn affects the synthesis of corticotropin.

PATHOPHYSIOLOGY

Adrenal cortex is divided into three distinct zones which secrete hormones under the direct feedback control of pituitary and hypothalamus. Zona glomerulosa, the outermost zone secretes aldosterone which is primarily regulated by renin–angiotensin system and extracellular potassium concentration. Hence, the secretion of aldosterone is not affected in secondary and tertiary AI. Zona fasciculata secretes cortisol under the feedback control of anterior pituitary, which produces corticotropin, which in turn is regulated by hypothalamic CRH and vasopressin. The innermost zone, zone reticularis produces androgens, dehydroepiandrosterone, and androstenedione.

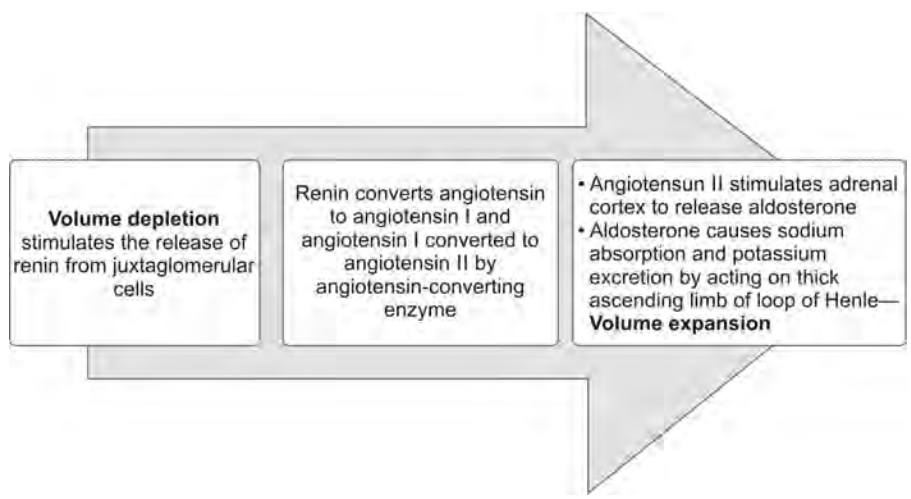
The pathophysiology of adrenal crisis has till now only been deciphered to a limited extent. Development of hypotension can be elucidated to lack of permissive action of glucocorticoid on adrenergic receptors and by volume



STRESS/TRAUMA
(Injury, pain
hypoxia, hypoglycemia)
• Signals are generated and sent to hypothalmus (CNS)
• Hypothalamuas releases CRH
• CRH reaches the pituitary gland and stimulated ACTH
• ACTH stimulats adrenal cortex to release CORTISOL

(ACTH: adrenocorticotropic hormone; CNS: central nervous system; CRH: corticotropin-releasing hormone)

FIG. 1: Response of hypothalamic–pituitary–adrenal axis to stress and trauma.



Volume depletion
stimulates the release of renin from juxtaglomerular cells
Renin converts angiotensin to angiotensin I and angiotensin I converted to angiotensin II by angiotensin-converting enzyme
• Angiotensun II stimulates adrenal cortex to release aldosterone
• Aldosterone causes sodium absorption and potassium excretion by acting on thick ascending limb of loop of Henle—**Volume expansion**

FIG. 2: Response of renin–angiotensin–aldosterone system to volume depletion.

loss due to paucity of sodium and water retention because of missing mineralocorticoid activity. Vomiting and diarrhea aggravate the situation further. Reduced cortisol surge during infection leads to a mismatch between the permissive and suppressive action of glucocorticoids, thereby enhancing the release of proinflammatory cytokines and increased sensitivity to harmful outcome of cytokines [e.g., tumor necrosis factor (TNF) alpha]. Moreover, glucocorticoid receptor function is impaired by proinflammatory cytokines thereby aggravating glucocorticoid deficiency. In cases of adrenal crisis precipitated by surgery or emotion stress, the basic process of execution remains same with the release of cytokines and TNF alpha and glucocorticoid resistance.

CAUSES

After understanding the basics about anatomy, physiology, and function of adrenal gland the one point is clear that adrenocortical hormone deficiency results in reversal of normal physiologic hormonal effect and which in response produces acute adrenal crisis. Hormone of importance in acute adrenal crisis is cortisol. Causes of AI are summarized in **Box 1**.

BOX 1: Causes of adrenal insufficiency.

Causes of primary adrenal insufficiency

- Autoimmune adrenalitis: Isolated or associated with autoimmune polyendocrinopathy syndrome type 1, 2, and 4
- Infections (tuberculosis, human immunodeficiency virus, syphilis, and histoplasmosis)
- Bilateral adrenal hemorrhage/metastasis/infiltration
- Bilateral adrenalectomy
- Drug induced (anticoagulants, ketoconazole, phenytoin, rifampicin, and phenobarbital)
- Genetic disorders: Adrenoleukodystrophy, congenital adrenal hyperplasia, and adrenal hypoplasia congenita
- Familial glucocorticoid deficiency

Causes of secondary adrenal insufficiency

- Pituitary tumor or trauma (adenomas, cysts, meningiomas, and rarely carcinomas)
- Pituitary surgery or irradiation
- Pituitary infiltration or infection (tuberculosis, meningitis, sarcoidosis, and actinomycosis)
- Pituitary apoplexy
- Genetic disorders: Congenital proopiomelanocortin deficiency and Prader–Willi syndrome

Causes of tertiary adrenal insufficiency

- Hypothalamic tumor (craniopharyngiomas or metastasis from breast or lung cancer)
- Hypothalamic surgery or irradiation
- Infection or infiltration (tuberculosis, meningitis, sarcoidosis, and actinomycosis)
- Trauma and injury (skull base fracture)
- Chronic endogenous glucocorticoid hypersecretion (Cushing's syndrome)
- Drugs (glucocorticoids, mifepristone, antipsychotics, and antidepressants)

Tuberculosis

Tuberculosis had been the leading cause of primary AI during the early part of 20th century, but now for past 50 years and more it is autoimmune AI which has become more common. Primary AI can affect all age groups with 30–50 years being most commonly affected and a predisposition for female gender. Secondary AI being more common than primary also has a predisposition for women with the peak age of diagnosis in sixth decade of life. Tertiary AI is a result of long-term exposure to glucocorticoids which leads to sustained suppression of hypothalamic secretion of CRH. Various studies in patients of AI on chronic replacement therapy have reported an incidence of 5–10 adrenal crisis/100 patient years with a proposed mortality from adrenal crisis to an extent of 0.5/100 patient years. Strikingly it has been observed that there is a huge variation in the occurrence of crisis, as some do not experience it for decades while other patients have reported recurrent adrenal crisis, the reason for same is still unknown.

Adrenal Hemorrhage and Infarction

Adrenal glands do not have direct arterial blood supply so they are more prone for infarction and damage during systemic hypotension. Adrenal cortex receives the blood supply from subcapsular arteriolar plexus. Bilateral massive adrenal hemorrhage (BMAH) occurs under severe stressful conditions such as myocardial infarction, severe sepsis with shock, trauma, burn, surgery, and complicated pregnancy. Coagulopathy, thrombocytopenia, and anticoagulants are also responsible for adrenal hemorrhage. Adrenal infarction is common in sepsis by meningococcemia, *Pseudomonas*, *Escherichia coli*, and *Staphylococcus* infections.

Sudden Discontinuation of Long-term Glucocorticoid Therapy

Risk of acute adrenal crisis is more in patient who is on long-term glucocorticoid therapy due to underlying adrenal atrophy and adrenocorticotropic hormone (ACTH) suppression. Adrenal crisis can occur with single use, topical preparation, and even with inhaled steroid.

CLINICAL PRESENTATION

The clinical features in AI depend on the rate of outset and severity of adrenal deficiency, with the preclinical course sometimes ranging up to years even in presence of metabolic derangements, high antibody titers, and raised corticotropin. In patients with undiagnosed AI, there is a typical history of declining health over weeks to months with increasing exhaustion in day-to-day activities, anorexia, and weight loss.

Symptoms in patients with primary AI is due to deficiency of all adrenocortical hormones (glucocorticoid, mineralocorticoid, and androgens), this being in contrast to those with secondary AI who have an intact renin–angiotensin–aldosterone system. This explains the difference in clinical presentation of these conditions due difference in salt and water balance. A specific sign of primary AI, seen in chronic cases, not acute which differentiates it from secondary AI is the presence of hyperpigmentation on pressure points (elbows and knuckles), palmar creases, axillae, nipples, and mucous membranes (buccal, vaginal, and anal). This is caused due

to increase stimulation of melanocortin 2 receptor by ACTH itself. Sign and symptoms of secondary and tertiary AI is due to deficiency of glucocorticoids only along with the underlying primary disorder causing it. Hyponatremia and volume expansion is usually secondary to disproportionate increase in vasopressin release. Clinical manifestation of other anterior pituitary hormones may also persist.

Acute adrenal crisis is usually triggered by a stressful episode (e.g., infection, physiological stress, surgery, or trauma). Customarily a patient presents with nausea, vomiting, abdominal pain, severe hypotension, and hypovolemic shock. They are exhausted, lack on energy and are depressed, these symptoms being frequently misdiagnosed as gastroenteritis. Fever is usual as most of the cases are triggered by an infection. This being a life-threatening medical emergency requires immediate management, and in cases of undiagnosed crisis treatment comes first rather than going for biochemical confirmation of disease. It is imperative to differentiate between Addison's disease and acute adrenal crisis in which the latter presents as vomiting, abdominal pain, and hypovolemic shock. This is a rare disease but can be life-threatening when overlooked. Clinical and laboratory features of the AI and acute adrenal crisis are summarized in **Table 2**.

DIAGNOSIS

Adrenal crisis is endocrine emergency and should be considered in acutely unwell patient with profound unexplained circulatory shock. Severity is depend on level of defect, primary or secondary etiology (HPA axis). Initial diagnosis is completely based on clinical evaluation. Detailed history, physical examination, and investigation are helpful in evaluating the patient (subacute and chronic symptoms) in outpatient department, but not very helpful in emergency department. High index of suspicious is important for diagnosis of adrenal crisis in emergency department. Emergency physician should start the empiric treatment immediately even before receiving the confirmatory laboratory results. One may not get classic laboratory results in acute adrenal failure like adrenal hemorrhage.

CONFIRMATORY DIAGNOSTIC TESTING

Patient with all form of adrenal deficiency have low cortisol level. Low serum cortisol level and inadequate response to stimulation test confirm the diagnosis.

- First step is early morning serum cortisol <3 μg/dL confirm the adrenal deficiency while diagnosis is doubtful when cortisol level >15 μg/dL.
- Second step is to find out if cortisol deficiency is due to ACTH or CRH deficiency, give 250 μg of synthetic ACTH (cosyntropin) and measure the serum cortisol if serum cortisol >8 μg within 30 minutes, considered normal response, and exclude primary adrenal deficiency, but basal corticotropin level are required to differentiate between primary and secondary adrenal deficiency. Corticotropin level are high in primary and low or normal in secondary adrenal deficiency. Insulin tolerance test is test of choice for suspected secondary adrenal failure.
- But in emergency department and in crisis situation both above method of diagnosis, early morning cortisol level and stimulation test are not practical, random serum cortisol level >34 μg/dL exclude the adrenal deficiency while random cortisol level below 15 μg/dL in patient with severe sepsis or shock suggestive of acute adrenal crisis.

Other Investigations

Few more laboratory test, radiology is required to identify the treatable cause (sepsis) of acute adrenal failure. CT abdomen can be done to find out tuberculosis-associated calcification, adrenal hemorrhage, and infiltration while CT head may give clue to destruction of pituitary gland (empty sells syndrome).

TABLE 2: Clinical and laboratory features of adrenal insufficiency.

	Primary adrenal insufficiency	***Secondary adrenal insufficiency***
Clinical features	• Hyperpigmentation, vitiligo, weight loss, hypotension, postural dizziness, and syncope shock • Weakness, fatigue, myalgia, arthralgia, anorexia, vomiting, constipation, abdominal pain, and diarrhea • Amenorrhea infertility salt craving • Depression psychosis	• Weight gain, thin axillary and pubic hair, decreased libido, infertility, and amenorrhea • Weakness fatigue • Headache visual disturbances, anorexia, vomiting, constipation, abdominal pain, diarrhea, myalgia, arthralgia • Depression and psychosis
Laboratory features	Hyponatremia, hyperkalemia, hypochloremia, and acidosis mildly elevated BUN, mild hypoglycemia, anemia, B12 deficiency, and type 1 diabetes mellitus	Hypernatremia or hyponatremia, hypokalemia or normal potassium, normal serum chloride, normal BUN, and marked hypoglycemia
Risk of acute adrenal crisis	Very high	Low
• Clinical features of acute adrenal crisis • Circulatory shock is the hallmark of acute adrenal crisis (hypotension shock tachycardia) • Fever, fatigue, dehydration, arthralgia, myalgia, nausea, anorexia, vomiting, poor concentration, depression, disorientation, abdominal pain (rebound tenderness and rigidity), flank pain, back pain, and lower chest pain		

(BUN: blood urea nitrogen)

EVALUATION AND MANAGEMENT IN EMERGENCY DEPARTMENT

Upon presentation of a patient in emergency room with a suspicion of having adrenal crisis, collecting a comprehensive history is the first step towards assessments of the condition. A brief analysis of his previous medical and surgical history with an emphasis on present medication and steroid use with sudden withdrawal is indispensable. Determining any triggering factors and gathering history about other autoimmune disease is imperative. Classical laboratory abnormalities may affirm the diagnosis to some extent. The findings reveal hyponatremia, hyperkalemia, and hypoglycemia. An electrocardiogram may have abnormalities with an indication of cardiomyopathy. At this point of time empiric treatment for adrenal crisis can be started consists of following points.

Empiric Treatment for Adrenal Crisis before Confirm Laboratory Results

- Hydrocortisone is drug of choice, it has both glucocorticoid and mineralocorticoid properties
- Empiric antibiotics can be started depending on underlying conditions
- Fresh frozen plasm to reverse coagulopathy
- Hyperkalemia should be corrected
- Thyroxine supplementation requirement in primary HPA axis failure (clinical hypothyroidism)
- Correction of dehydration and hypoglycemia
- Vasopressors

Treatment of adrenal crisis condition is straight forward with parenteral administration of 100 mg of hydrocortisone intravenously as bolus along with correction of hypovolemia with 1,000 mL of isotonic saline within first 1 hour, followed by 50–100 mg hydrocortisone in 5% dextrose every 6 hourly intravenously or intramuscularly depending on age and body surface area. In case hydrocortisone is not at disposal, then any other synthetic glucocorticoid like prednisolone can be used in proportionate doses. Baseline blood samples such as cortisol, ACTH, and blood cultures should be drawn before initiation of therapy. In addition to this, aggressive fluid and vasopressor support should be started under continuous cardiac monitoring. Basis the intercurrent condition which triggered the crisis antibiotics and antithrombotic are initiated. Depending upon severity of condition patient should be admitted then to intensive care setting for further workup and management. Serum electrolytes and blood glucose levels should be watchfully checked every 4–6 hours until stabilized. Once patient is stable intravenous glucocorticoid can be tapered and oral maintenance dose started.

Long-term hormone replacement therapy should be initiated once patient is recovered from crisis, intravenous steroid should be changed to oral preparation and prednisolone with longer half-life is required only once daily. Fludrocortisone (mineralocorticoid) is usually given in patient with primary adrenal failure. Androgen transdermal DHEA 25–50 mg is also added for primary adrenal failure.

This treatment regimen to treat hypotension with correction of electrolyte and cortisol imbalance is essentially constant leading to improvement in symptoms within 24 hours. In case recovery in not as progressive as anticipated then other causes of illness (severe sepsis with shock) should be reconsidered. Treatment guidelines for acute adrenal crisis are summarized in **Table 3**.

PREVENTION AND PATIENT EDUCATION

A sizeable morbidity and mortality associated with adrenal crisis can be averted by befitting physician and patient education. As most clinicians rarely see adrenal crisis, they fail to act satisfactorily. Education should emphasize on the endogenous cortisol rhythm and its swift acclimatization to unforeseen demands, limitations of parenteral cortisol administration and its constraint in imitating the natural response. Though it is difficult to predict the oncoming episode of crisis every time still it is wise to be prepared in stressful medical conditions events such as illnesses and elective surgeries with adequate dose adjustments. Suggested dose modifications intent to have a ceiling effect as should happen during a natural deviation in case of a euadrenal patient during the similar episode. This approach to cortisol overload is momentary and does not carry major adverse effects. Corticosteroid dose adjustment guidelines in nonsurgical and surgical situation are summarized in **Tables 4** and **5**.

TABLE 3: Treatment guidelines for acute adrenal crisis.

Fluid resuscitation	At least 2–3 L of normal saline to restore volume and normal sodium balance
Intravenous steroids	Intravenous hydrocortisone 100 mg bolus followed by 100 mg two or three times per day (300–400 mg daily is initial regimen)
Antibiotics	Broad-spectrum antibiotics for febrile patients
Vasopressors	In case of refractory shock
Glucose	50% dextrose may be used, if required
In stabilized patient	• Oral prednisolone fludrocortisone and androgen replacement • Patient education regarding steroid management during acute febrile illness (double the dose of steroid for 3 days) and regular follow-up with physician

TABLE 4: Dose adjustment during nonsurgical procedures in patients of adrenal insufficient for prevention of crisis.

Episode	*Dose adjustment*
Acute febrile illness	Double or triple the daily oral glucocorticoid dose basis the temperature surge, higher the temperature higher the dose adjustment
Significant emotional stress (e.g., major examination)	Add 10–20 mg hydrocortisone or steroid equivalent to regular replacement dosage
Significant physical stress (e.g., intense exercise)	Add 10–20 mg hydrocortisone 30 min before exercise
Acute gastroenteritis/ serious infection (e.g., pneumonia)	Early parenteral hydrocortisone 100 mg then repeat every 6–12 hourly until recovery

TABLE 5: Dose adjustment during surgical procedures in patients of adrenal insufficient for prevention of crisis.

Episode	*Dose adjustment*
Minor outpatient department (OPD) procedure	No adjustment needed, can add extra 20 mg of oral hydrocortisone postprocedure if symptoms suspected
Dental procedure under local anesthesia	Repeat morning dose 1 h before procedure, then continue with double the oral dose for 24 h, thereafter return to normal dose
Minor surgery or major dental surgery under general anesthesia	100 mg hydrocortisone administered parenterally before anesthesia or as infusion during the surgery, postoperatively then continue with double the oral dose for 24 h, thereafter return to normal dose
Major surgery	Start with infusion of hydrocortisone (100 mg over 12 h) just before anesthesia and continue till nil per os, postoperatively then continue with double the oral dose for 48 h, thereafter return to normal dose
Labor and vaginal delivery	Start with infusion of hydrocortisone (100 mg over 12 h) just at the onset of labor and continue till delivery of child, postoperatively then continue with double the oral dose for 48 h, thereafter return to normal dose
Invasive bowel procedure requiring bowel preparation with laxatives	Admit in hospital overnight and start hydrocortisone 100 mg parenterally at the time of bowel preparation along with intravenous fluids, repeat hydrocortisone just before the procedure. Postprocedure continue with double the oral dose for 24 h, thereafter return to normal dose

Every patient should be educated for compliance to hydrocortisone therapy and to carry an emergency card with an emergency set containing 100 mg of hydrocortisone injection for parenteral administration. Patient and their relatives should be well trained about the use of injection in case of emergency. The treating physician should emphasize that in case of crisis sometimes the physical and cognitive impairment can act as a barrier for self-intramuscular injection hence a subcutaneous route can be preferred then. Though it has been observed in clinical practice that most patients prefer a subcutaneous route considering the ease. This change of conventional route is backed by literature which clearly states that even though there is a lag of 11 minutes in case of subcutaneous injection as compared to intramuscular in reaching therapeutic levels, but still this can be a life savior in case of crisis than reaching out to an emergency and getting the injection done. Looking towards future the need of hour is development of a subcutaneous pen device for hydrocortisone injection which will ease the administration and avert a crisis episode.

SUMMARY

Adrenal crisis is a life-threatening medical emergency which requires immediate medical attention. High suspicion for the condition should be reserved for patients presenting with undiagnosed and refractory shock not responding to fluid and vasopressors. Though it can affect all age groups, but elderly and patients with altered mental status at presentation along with concomitant endocrine disorders have higher morbidity and mortality. Hyponatremia, hyperkalemia, and hypoglycemia are usually the presenting symptoms along with hypovolemia. Treatment is unequivocal with parenteral administration of 100 mg hydrocortisone at presentation. Every patient of AI should be educated about the possible crisis and technique of self-administration of hydrocortisone to prevent any uneventful episode.

10. Personal Protective Equipment **68**

TV Ramakrishnan, Akilan Elangovan

• Standard Precautions *68* • Personal Protective Equipment *68* • Hand Hygiene *68* • Types of Personal Protective Equipment Used in Healthcare Settings *68* • Donning and Doffing Personal Protective Equipment *70* • Selecting the Appropriate Personal Protective Equipment for Healthcare Workers *74* • Transmission-based Precautions *74* • Levels of Personal Protective Equipment and Types of Precautions for Infection Control *75* • Optimizing Personal Protective Equipment Usage during Crisis *75* • Decontamination of Personal Protective Equipment for Reuse *75* • Limitations of Personal Protective Equipment *76* • Regulations and Efficiency of Personal Protective Equipment Usage *76*

SECTION 2: RECENT CONCEPTS IN EMERGENCY MEDICINE

11. Research Methodology **80**

Padam Singh, Pooja Sharma, Manish K Singh

• Literature Review *80* • Formulating a Research Question *80* • Essentials of Biostatistics *80* • Research Designs *82* • Sample Size *84* • Statistical Analysis *86* • Test of Significance for Population Mean (μ) *86* • Test for Proportions *88* • Other Commonly used Tests *88* • Statistical Software *88* • How to Read a Scientific Paper *88*

12. Transforming Emergency Department with Digital Technology **91**

Rajesh Kumar Gupta

• Ambulance Management *91* • Check-in at Emergency Room *93* • Triage *93* • Clinical Documentation *93* • Initiating a Care Protocol *95* • Discharge Home or Transfer to Inpatient Department *96* • Emergency Room Admin Dashboard *96* • Technology Hand in Hand with Emergency Room *97*

13. Advanced and Future Technology in the Emergency Department 99

Devendra Richhariya

• Online Check-in *99* • Patient Flow Software *99* • Real-time Locating System *99* • Miniaturization of Imaging and Diagnostic Equipment *99* • Telemedicine *101* • Barcode Scanner *101* • Computers on Wheels *101* • Medical Drones *102* • Driverless Ambulance *103* • Apps Simplifying Communication Administration and In-flight Emergencies *103* • Video Games for Practicing Real Situations *103* • Future of Emergency Medicine *103*

14. Artificial Intelligence in Healthcare 105

Sandhya Shankar Pandey, Devendra Richhariya

• Mapping Mind and Machine Through Brain–computer Interfaces *105* • Artificial Intelligence in Developing the Next Generation of Radiology Tools *105* • Artificial Intelligence in Expanding Healthcare in Developing Regions *106* • Artificial Intelligence in Reducing the Burdens of Electronic Health Record *106* • Artificial Intelligence and Antibiotic Resistance *106* • Artificial Intelligence in Analysis of Pathology Images *106* • Artificial Intelligence in Medical Devices and Machines *106* • Advancing the Use of Immunotherapy for Cancer Treatment *106* • Electronic Health Record as a Reliable Risk Predictor *106* • Artificial Intelligence in Monitoring Health Through Wearables and Personal Devices *107* • Making Smartphone Selfies into Powerful Diagnostic Tools *107* • Bedside Clinical Decision-making with Artificial Intelligence *107* • Administrative Applications of Artificial Intelligence *107*

15. Use of Simulation-based Education in Emergency Medicine 108

Asit Misra, Brad Gable

• History of Simulation *108* • Educational Theory *108* • Simulation Types and Methods *110* • Planning a Simulation Case *110* • Use of Simulation in Emergency Medicine *111* • How to Integrate Simulation Education into an Emergency Medicine Curriculum *111*

SECTION 3: SPECIAL SITUATIONS IN EMERGENCY MEDICINE

16. Overcrowding Management in Emergency Department 114

MI Nizami, Ashima Sharma

• Definition of Overcrowding *114* • Causes of Overcrowding *117* • Interventions *117*

17. Difficult Patient and Situations 119

AN Venkatesh

• Difficult Situations *119* • Types of Difficult Patient *120* • Clinicians as Causative Factors *120* • How to Deal with Difficult Situations? *120* • Role of Emergency Physician to Resolve Difficult Situations *121*

18. Medicolegal Cases and Writing Medicolegal Reports 123

Amit Nabar, Devendra Richhariya, Vivekanshu Verma

• Medicolegal Cases *123* • Medicolegal Reports *123* • Medicolegal Classification of Injuries *127* • How Does the Law Protect the Victim in Medicolegal Cases? *128* • Practical Tips for Medicolegal Case Writing *128* • Do's and Don'ts in Medicolegal Case Writing to Avoid Legal Punishment *129*

19. Medicolegal Issues in the Emergency Department 131

Adarsh Kumar, Vivekanshu Verma, Devendra Richhariya

• What is Duty of Care Toward a Patient? *131* • What is Breach in Duty to Care? *132* • What is Doctrine of RES IPSA Loquitur? *132* • Why Medical Services were Included Under the Consumer Protection Act, 1986? *132* • What Kind of Medicolegal Issues are Faced in Dealing with International Patients? *133* • Medicolegal Guidelines for Managing a

Terminally Ill Patient in the Emergency Department *133* • Patients with Weak Financial Background in a Private Hospital *133* • Medical Negligence *133* • Medical Malpractice Stress Syndrome *134* • Medical Indemnity Insurance *134* • Do not Attempt Resuscitation Guidelines *134* • Euthanasia *135* • Discharge Against the Medical Advice from the Emergency Department *135* • Medicolegal Implications of a Prisoner Absconding from the Emergency Department *136* • How to Declare a Patient Brought Dead? *136* • Grief Counseling *136*

20. Examination of Sexual Abuse Victim **138**

Nikhil D Datar, Meghna Shedge

• Definition of Rape *138* • Presentation in an Emergency Department *138* • Examination *139* • Quick Assessment *139* • General Examination and Injuries *139* • Documentation *141* • Treatment *141* • Emergency Contraception *141*

21. End-of-life and Palliative Care in the Emergency Department **143**

Naeem Toosy

• Trajectory of Dying and End-of-life Decision-making *143* • Palliative Care and Bioethics *144* • Communication at the End of life *144* • End-of-life Symptoms Management *145*

22. Death Declaration **147**

Rammohan Radhakrishnan, Sahanya Ramesh Shetty

• Possible Circumstances of Death *147* • Effect of Death on Survivors *147* • Effect on Emergency Department Physicians *147* • Communication Strategies *148* • Viewing of the Body *149* • Medical Examination: Autopsy *149* • Organ Donation *149* • Organ Donation: Death of a Child *149*

23. Brain Death **151**

Bhawana Sharma, Devendra Richhariya

• Pathophysiology of Brain Death *151* • Recommendation *151* • Definition *152* • Prerequisites *152* • Documentation of Coma *152* • Documentation of Absence of Brainstem Reflexes *152* • Documentation of Apnea *153* • Additional Tests *154* • Other Tests *154* • Brain Death Mimic *154* • Movement Observable after Brain Death *155* • Brain Death Declaration and Organ Donation *155* • Care of the Potential Organ Donor *155*

24. Organ Donation and Transplantation **159**

Devendra Richhariya, Bhawana Sharma

• History of Organ Transplant: Worldwide and in India *159* • Evolution of Law: Transplantation of Human Organ Act *160* • Challenges *160* • How to Curb the Problems *161*

SECTION 4: PREHOSPITAL AND DISASTER MANAGEMENT

25. Ground Medical Transfer **163**

GV Ramana Rao

• What is Ground Medical Transfer? *163* • Salient Historical Milestones *163* • Current Context *163* • Key Principles Guiding the Ground Medical Transfers *163* • Models of Ground Medical Transfers *164* • Basic Tasks and Tenants *164* • Types of Road Ambulances *165* • Planning and Coordination *165* • Training Schedule for Emergency Medical Technician *166* • Quality Assurance *166*

26. Air Medical Transfer **168**

Saleh Fares, Michael J Nolan

• Decision for Air Medical Transfer *168* • Flight Physiology *168* • Standards of Care: Air Medical Transfer *169* • Special Considerations *170* • Recent Advances *170*

27. Basic Concepts of Disaster Management **172**

Venkat Changavalli, Devendra Richhariya

• Definitions *172* • Classification of Disasters *172* • Disaster Management Cycle *173* • Disaster Response Management *174* • Incident Command System *174* • Multiagency Coordination during Response *174* • Early Warning System for Disaster *175* • Role of Technology as Decision Support Tools *176* • Humanitarian Consideration in Disaster Response *176* • Conducting Exercise for Disaster Management *176* • Preparing the Emergency Department for Mass Casualties *177* • Mass Casualty Management *178*

28. Mass Casualty Management **180**

Saurabh Dalal

• Background *180* • Case Studies *181* • Innovation and Best Practices *181* • Bridging the Gap *182* • Incident Response System *182* • National Emergency Operational and Preparedness Structure *182* • Way Forward *182*

29. Preparedness for Chemical, Biological, Radiological, and Nuclear/Energetics Disasters **185**

Shaza Karrar, Mohammad Anzal Rehman, Saleh Fares

• CBRN Preparedness among Emergency Providers *185* • Approach to a Cbrne Incident *185* • Mitigation *186* • Preparedness *186* • Response *186* • CBRN Scene Management Zones *187* • Recovery *188* • Chemical Agents *188* • Biologic Agents *188* • Radiation/Energetics *191* • Mass Casualty Training *192*

30. Military Medicine **195**

Ahmed Humaid, Saleh Fares, Abdulla Alhmoudi

• Tactical Combat Casualty Care Principles *195* • Field Triage *196* • Approach to the Injured Soldier *196* • Medical Evacuation *199* • Challenges and Innovations *199*

SECTION 5: RESUSCITATION

31. Basic and Nondefinitive Airways **201**

Advait Thakor

• How to Recognize Airway Obstruction in an Emergency Department? *201* • Airway Positioning Maneuvers *201* • Airway Adjuncts *202* • Suctioning *203* • Bag-valve-mask Ventilation *203* • Supraglottic Airway Devices *205*

32. Advanced Airway Management **208**

Venugopalan Poovathumparambil

• Applied Anatomy *208* • Advanced Airway Management *209* • Airway Assessment *210* • Laryngoscopic Grading for Difficult Intubation *211* • Position for Intubation *211* • Technique of Intubation *212* • Rapid Sequence Intubation *212* • Delayed Sequence Intubation *215* • Intubation without Pharmacologic Agents *215* • Difficult Airway *215* • Failed Airway *215* • Protected Intubation in Highly Infected Patient—In View of Covid-19 *216* • Capnography *216*

33. Cardiopulmonary Resuscitation **219**

Mabel Vasnaik

• Steps of Resuscitation *219* • Postcardiac Arrest Care *222* • Cardiopulmonary Resuscitation in Children–how is it Different? *222* • Special Situations *223* • Defibrillation *224* • Cardioversion *226* • Recent Advances *227* • Recent Updates on Cardiopulmonary Resuscitation *227*

34. Cardiopulmonary Resuscitation in Special Situation **230**

Jesús Daniel López Tapia, Andrea Pechir Cerrillo

• Hypoxia *230* • Electrolyte Imbalances *230* • Hypothermia *230* • Hypovolemia *231* • Cardiac Tamponade *231* • Tension Pneumothorax *231* • Thrombosis (Coronary and Pulmonary) *231* • Toxins (Poisoning and Intoxications) *231* • Special Patients *231*

35. Postcardiac Arrest Syndrome **234**

Devendra Richhariya, Bhawana Sharma

• Postcardiac Arrest Syndrome—pathophysiology *234* • Airway and Breathing *234* • Circulation *236* • Disability-optimizing Neurologic Recovery *236* • Targeted Temperature Management *237* • Prognostication *238* • Rehabilitation *240* • Organ Donation *240*

SECTION 6: MANAGING CRITICALLY III PATIENT IN EMERGENCY DEPARTMENT

36. Oxygen Therapy and Oxygen Delivery System **241**

Bhawana Sharma, Devendra Richhariya

• Indications *241* • Classification of Oxygen Delivery System *242* • Low-flow System *242* • High-flow System *244* • Selection of Oxygen Delivery System *244* • Initiation of Oxygen Therapy in Emergency Department *244* • Long-term Oxygen Therapy *245* • Oxygen Toxicity *245* • High-flow Nasal Cannula Oxygen Therapy *245* • Medical Oxygen Cylinders: Types Capacity and Estimation of Running Time *246*

37. Hyperbaric Oxygen Therapy **249**

Amit Gupta

• History *249* • Physiology *249* • Rationale of use of Hyperbaric Oxygen Therapy/Mechanism of Action *249* • Equipment and Procedure *250* • Indications *250* • Contraindications *251* • Clinical Application *251* • Potential Harm, Safety, and Precautions *252*

38. Noninvasive Ventilation **254**

Kishalay Datta

• Modes of Noninvasive Ventilation *254* • Physiologic Changes with NIV: How does NIPPV Works? *255* • Selection Criteria for NIPPV *255* • Interface or Mask for NIPPV *255* • How to Initiate NIPPV in Patients? *256* • Monitoring of Patients on NIPPV *256* • Predictors of Success of NIPPV *256* • What Type of Ventilators can be used for NIPPV? *257* • What Modes of Ventilator can be used for Noninvasive Ventilation? *257* • How to Set the Ventilator for NIPPV? *257* • Weaning *257* • Complications of NIPPV *257* • High-flow Nasal Cannula *258*

39. Mechanical Ventilation **259**

Mrinal Sircar, Saurabh Mehra, Devendra Richhariya

• Physiology of Breathing *259* • Mechanical Determinants of "Patient–Ventilator" Interactions *259* • Indications of Mechanical Ventilation *260* • Types of Mechanical Ventilation *260* • Modes of Ventilation *261* • Initiation of Ventilation *263* • Monitoring after Initiating Ventilation *264* • Complications of Intubation and Ventilation *265* • Airway Pressures, Alarms, and Troubleshooting *265* • Mechanical Ventilation in Special Conditions *266*

40. Sedation and Analgesics for Mechanically Ventilated Patients **270**

Manish Garg, Devendra Richhariya

• Goals and Principles *270* • Medications *270* • Assessment *272* • Special Situations *273*

41. Extubation in Emergency Department **275**

Joanne Hng Mei Hwa, Ahmad Zulkarnain Ahmad Zahedi

• Patient Selection and the "ABC" Procedural Consideration *275* • Postextubation Complications and Management *277* • Palliative Extubation in Emergency Department *278*

42. Vascular Access **280**

Eric Revue

• Basic Knowledge of Pathophysiology *280* • How to Choose Appropriate Vascular Device? *281* • Peripheral Access *281* • Central Venous Catheters *283* • Midline Catheters *285* • Peripherally Inserted Central Catheters *285* • Use of Ultrasound for Central Venous Catheter Insertion *286* • Removal of Catheter *286* • Arterial Access *286* • Arterial Blood Pressure *287* • Emergency Conditions Where Femoral Artery Access is Recommended *287* • Intraosseous Device *288* • Complications *289*

43. Intravenous Fluids **291**

Ripenmeet Salhotra, Supradip Ghosh

• Crystalloids *291* • Balanced Salt Solutions *292* • Colloids *293* • Maintenance Fluids *293*

44. Assessment of Volume Status and Hemodynamic Monitoring **296**

Sangeeta Chakraborty, Debashish Dhar, Devendra Richhariya

• Static Methods of Volume Assessment and its Limitations *296* • Dynamic Methods of Volume Assessment and its Limitations *298* • Devices for Hemodynamic Monitoring *300* • Invasive Hemodynamic Monitors *300* • Noninvasive Hemodynamic Monitors *301*

45. Arterial Blood Gas Analysis **303**

Devendra Richhariya, Bhawana Sharma

• Basics of Pulmonary Gas Exchange *303* • Disorders of Gas Exchange *304* • Basics of Acid-base Balance *304* • Disturbance of Acid-base Balance *305* • Concepts in Acid-base Disorders and Formulas *305* • Steps in the Interpretation of Arterial Blood Gas *305* • Strong Ion Difference Approach versus Traditional Approach *305* • Arterial Blood Gas Sampling Technique *309*

46. Electrolyte Imbalances **311**

Ayşegül Bayır

• Hypernatremia *311* • Hyponatremia *312* • Hyperkalemia *314* • Hypokalemia *315* • Hypocalcemia *316* • Hypermagnesemia *317* • Hypomagnesemia *317*

47. Sepsis **319**

Ravi Jain, Yash Javeri

• Definition *319* • Epidemiology *319* • Pathophysiology *319* • Differentials *320* • Screening and Diagnosis of Sepsis *320* • Management *321* • Other Supportive Therapies *326* • Disposition *326* • Code Sepsis *326*

48. Overview of Shock **328**

Khusrav Bajan, Devendra Richhariya

• Clinical Presentation *329* • Use of Ultrasound in Evaluation and Diagnosis of Shock *329* • Management of Shock *330* • Specific Measures *333*

49. Vasopressors and Inotropes in Resuscitation **335**

Manish Mehta

• Physiology: Receptors and Mechanisms of Action *335* • Common Pharmacological Agents *336* • Clinical Application of Vasopressors and Inotropes in Shock Resuscitation *338* • Fundamental Concepts for use and Practical Issues *338* • Complications *339* • Summary and Recommendations *340*

50. Perfusion Endpoint in Resuscitation of Shock **341**
Nisreen Hamza Maghraby, Zainab Musa Al Alawi
• Macrocirculatory Endpoint *341* • Microcirculatory Endpoint *342*
• Clinical Assessment of Perfusion *343*

51. Extracorporeal Membrane Oxygenation **345**
Basar Cander
• Historical Development of Extracorporeal Membrane Oxygenation *345* • Extracorporeal Membrane Oxygenation Techniques *345* • Extracorporeal Membrane Oxygenation Components *346* • Weaning *346* • Indications *347* • Contraindications *347*
• Complications *347* • Extracorporeal Membrane Oxygenation in Special Patient Groups *348*
• Future Projections *349*

52. Procedural Sedation and Analgesia **350**
Devendra Richhariya, Bhawana Sharma
• Sedation Policy and Guidelines *351* • Indications in Emergency Department *351* • Presedation Patient Evaluation *351* • Preparation *351* • Technique for Procedural Sedation and Analgesia *352*

53. Pain Management in Emergency Department **355**
Radhika Rani Chandra, Devendra Richhariya
• Pathophysiology *355* • Assessment of Pain in Emergency Department *356*
• Assessment Tools for Pain *356* • Pharmacologic Therapy for Pain *357* • Anesthetic Agents in Pain Management *361* • Regional Anesthesia (Peripheral Nerve Block) *362* • Nonpharmacologic Intervention for Pain *362*

54. Point-of-care Ultrasound in Resuscitation **364**
Won-Jun Kuk, Mohamed Moheb El Abd, Tiffany Fong
• Step 1: Pump *364* • Step 2: Tank *366* • Step 3: Pipes *369*

55. Ultrasound-guided Procedures **374**
Richa Manglorkar, Mohaned Moheb El Abd, Tiffany Fong
• Physics of Ultrasound *374* • Transducers *375* • Knobology *375* • Technique Overview *375* • Peripheral Venous Catheter Placement with Ultrasound Guidance *375*
• Central Venous Catheter Placement with Ultrasound Guidance *376* • Ultrasound-guided Pericardiocentesis *384* • Ultrasound-guided Peripheral Nerve Blocks *386*

56. Cricothyrotomy **394**
Sanjay Shah
• Applied Anatomy *394* • Indications *394* • Position of the Patient *395*
• Needle Cricothyrotomy *395* • Percutaneous Cricothyroidotomy (Seldinger Technique) *395*
• Surgical Cricothyroidotomy *396* • Complications *397*

57. Tracheostomy Related Emergencies **398**
Devendra Richhariya, Bhawana Sharma
• Emergent Life-threatening Complications *398* • Urgent Complications *400*
• Myiasis (Maggots) of Tracheostomy Wound *401*

SECTION 7: CARDIOVASCULAR EMERGENCIES

58. Chest Pain Evaluation in Emergency Department **403**

Devendra Richhariya

• Causes of Chest Pain *403* • Evaluation *405* • Diagnostic Approach *405*
• Electrocardiogram *407* • Other Studies *408*

59. Palpitation **409**

Roberta Petrino, Aldo Tua

• Etiology *409* • Pathophysiology *409* • Clinical Presentation *412* • Red Flags *412*
• Evaluation *412* • Investigations *413* • Treatment *413*

60. Syncope **415**

Brajesh Kumar Mishra

• Epidemiology *415* • Pathophysiology *415* • Classification *415* • Life-threatening Causes of Syncope *415* • Common Causes of Syncope *416* • Other Causes of Syncope *416*
• Objectives for Evaluation *417* • Investigation *418* • Treatment *419* • Risk Stratification for Syncope in Emergency Department *420* • Future Perspective *420*

61. Interpretation of ECG **421**

Kartikeya Bhargava

• Cardiac Arrhythmias *421* • Tachyarrhythmias *421* • Bradyarrhythmia *425*
• ST-T Changes *426* • QRS Morphology Amplitude Duration and Axis Pattern *430*
• Miscellaneous ECG Findings in Emergency *432*

62. Cardiac Biomarkers **434**

Omar Ghazanfar, Israa M Salih, Saleh Fares

• Ideal Cardiac Biomarker *434* • Troponin *434* • Creatinine Kinase-MB *435* • Myoglobin *435*
• Natriuretic Peptide *435* • Other Markers *435* • Multiple Marker Approach *435*
• Future Perspective *437*

63. Echocardiography in Emergency Department **438**

Manish Bansal

• Echo in Assessment of Acute Chest Pain *438* • Echo in Assessment of Dyspnea/Shortness of Breath *441* • Echo in Assessment of Hypotension and Hemodynamic Instability *444*
• Echo in Assessment of Stroke Patients *446* • Echo in Assessment of Syncope *447*
• Echo in Assessment of Pyrexia of Unknown Origin *448*

64. Coronary Computed Tomography in Chest Pain Evaluation **449**

Devendra Richhariya

• Indications of Coronary CT Angiography *449* • Contraindications for Coronary CT *450*
• Factors Affecting the Quality of Coronary CT Images *450* • Preparation and Instructions for Coronary CT *450* • Triple Rule-out Protocol *450* • Interpretation of Coronary CT *451*
• Coronary CT as Decision Making Tool *451*

65. Acute Coronary Syndrome **453**

Naveen Bhamri, Devendra Kumar Agarwal, Sudhanshu Sekhar Parida

• Etiopathogenesis and Risk Factors *453* • Management of Acute Coronary Syndrome *453*
• Common Strategies for Stemi and Nstemi Management *457* • Non-ST Elevation—ACS Management *457* • Stemi Management *457* • Special Consideration in Stemi/Nstemi Management *457* • Disposition *459*

66. Cardiogenic Shock **460**

Devendra Richhariya

• Definition *460* • Etiology *460* • Pathophysiology *460* • Diagnosis *461*
• Management *462* • Critical Care Support *462* • Revascularization Support *463*
• Mechanical Support *464* • Special Situation *466* • Reversible Myocardial Dysfunction (Myocarditis, Sepsis-induced Myocardial Dysfunction) *467*

67. Acute Heart Failure **468**

Devendra Richhariya

• Pathophysiology *468* • Precipitating Factors *468* • Classification *468*
• Clinical Features *469* • Diagnosis *469* • Emergency Department Treatment *469*
• Pharmacologic Therapy *469* • Mechanical Assistance *471* • Disposition *472*

68. Cardiac Arrhythmias: Identification and Management **473**

Ives Hubloue, Jamal Yusuf

• Bradyarrhythmias *473* • Tachyarrhythmias *476* • Supraventricular Tachycardias *476*
• Ventricular Tachycardias *478*

69. Cardiomyopathies **481**

Jamal Yusuf, Saurabh Sharma, Bhushan Shah

• Pathophysiology *481* • Clinical Presentation *482* • Diagnostic Evaluation *482*
• Treatment *483* • Mechanical Circulatory Support *483*

70. Valvular Emergencies **486**

Rahul Mehrotra, Mayank Gupta

• General Concepts of a Cardiac Murmur *486* • Acute Mitral Regurgitation *487* • Acute Aortic Regurgitation *488* • Prosthetic Heart Valve Thrombosis *488* • Acute Rheumatic Fever *490*

71. Cardiac Tamponade and Pericardiocentesis **492**

Laila Ali Hussein, Ayesha Almemari, Devendra Richhariya

• Overview of Cardiac Tamponade *492* • Etiology *492* • Clinical Features *492*
• Diagnostic Testing *492* • Management *494* • Pericardiocentesis *494*
• Methods for Removal of Pericardial Fluids *494*

72. Cardiac Temporary Pacing **497**

Kartikeya Bhargava

• Types of Temporary Pacing *497* • Indications of Temporary Pacing *498* • Temporary Pacing Procedure *498* • Complications of Temporary Pacing *499* • Postprocedure Care *499*

73. Postcardiac Surgery Emergencies **501**

Yatin Mehta, Devendra Richhariya

• Paravalvular Aortic/Mitral Regurgitation *501* • Bleeding *501* • Arrhythmias *502*
• Tension Pneumothorax *503* • Cardiac Tamponade *503* • Acute Coronary Syndrome Following Cardiac Surgery *505* • Intractable Hypotension *505* • Gastrointestinal Emergencies *505* • Stroke and Other Neurosurgical/Neurological Complications *506*
• Cardiac Surgery Associated Acute Kidney Injury *506* • Acute Decompensated Heart Failure *507*
• Perioperative Respiratory Failure *508* • Prevention of Postcardiac Surgery Complications *508*

74. Systemic Hypertension **510**

Au Kin Heng Constantine, Quintin Kwok

• Definition Classification Grading *510* • Etiology and Pathophysiology *510*
• Clinical Presentation *511* • Evaluation of Hypertension *512* • Stepwise Approach to Systemic Hypertension *512* • Therapeutic Approach to Hypertensive Emergencies and Urgencies *514*

75. Pulmonary Hypertension **517**

Asaad S Shujaa, Marah Alatrash, Noor Bamohammed

• Classification *517* • Pathophysiology of Pulmonary Hypertension *518*
• Clinical Presentation *518* • Evaluation *519* • Investigations and Interpretation *519*
• Treatments for Pulmonary Hypertension *519* • Disposition *520*

76. Pulmonary Embolism **521**

Ashima Sharma

• Risk Factors *522* • Clinical Presentation *522* • Pretest Probability, Scoring System and PERC *522*
• Diagnostic Workup *523* • Treatment *526*

77. Acute Aortic Dissection **530**

Devendra Richhariya

• Epidemiology *530* • Pathogenesis and Risk Factors of Aortic Dissection *530* • Classification of Acute Aortic Dissection *531* • Clinical Presentation of Acute Aortic Dissection *531* • Diagnostic Strategies for Acute Aortic Dissection in the Emergency Department *532* • Treatment *532*
• Acute Aortic Dissection in Pregnancy *535*

78. Antithrombotic Therapy **536**

Santosh Pandey

• Overview of Hemostasis *536* • Oral Anticoagulants *536* • Heparin *538*
• Antiplatelet Agents *538* • Fibrinolytic Drugs *538* • Adverse Effects *540*

79. Antithrombotic Reversal Agents **541**

Devendra Richhariya

• The Clotting/Coagulation Cascade *541* • Reversal of Warfarin *542* • Reversal of Direct Oral Anticoagulants *543* • Reversal of Heparin and Low-molecular-weight Heparins *545*
• Reversal of Antiplatelet Therapy *545*

80. Peripheral Arteriovascular Disease **547**

Prasad Rajhans, Ujwal Prakash Dhundi

• Etiology/Causes *547* • Pathophysiology *547* • Clinical Presentation *547*
• Diagnostic Strategies *548* • Management *549* • Disposition *549*

SECTION 8: RESPIRATORY EMERGENCIES

81. Cough **551**

Bhawana Sharma

• Acute, Subacute, and Chronic Cough *551* • Mechanism of Cough *551* • Etiology of Cough *551*
• Characteristics of Cough *551* • Associated Features of Concern (Red Flags) *552* • Complications of Cough *552* • Investigations *552* • Treatment *553*

82. Hemoptysis **556**

Veerottam Tomer

• Pulmonary Circulation *556* • Etiology of Hemoptysis *557* • Evaluation of Patient with Hemoptysis *557* • Management of Patient with Hemoptysis *558*

83. Clubbing and Cyanosis **563**

Vivek Chauhan, Suman Thakur

• Clubbing *563* • Cyanosis *566*

84. Acute Respiratory Failure **570**

Chitra Mehta

• Definition *570* • Classification *570* • Pathophysiology *570*
• Clinical Presentation *572* • Diagnostic Approach *572* • Management *572*

85. Acute Severe Asthma **575**

Bhawana Sharma, Devendra Richhariya

• Acute Asthma *575* • Pathophysiology *575* • Clinical Evaluation *576* • Investigations *577*
• Treatment *578* • Status Asthmaticus *579* • Pulmonary Function Test *580*
• Spirometry *580* • Interpretation of the Pulmonary Function Test *581*

86. Chronic Obstructive Pulmonary Disease **583**

Sudha Kansal

• Risk Factors *583* • Pathophysiology *583* • Initial Assessment *584*
• Diagnosis *584* • Treatment *585* • Acute Exacerbation of Chronic Obstructive Pulmonary Disease *587* • Management of Exacerbation *588* • Triage to Home or Hospital *589*
• Noninvasive Ventilation *589* • Mechanical Ventilation *589* • Criteria for Discharge and Advice *590* • Follow-up Assessment *590* • Prevention *590* • Prognosis *591*

87. Pneumonia **592**

Ashish Kumar Prakash, Reena Verma, Anand Jaiswal

• Classification of Pneumonia *592* • Pathophysiology *593* • Clinical Evaluation *593*
• Diagnostic Approach *594* • Hospital Admission Decisions *596* • Treatment of Pneumonia *597*
• Special Treatment Considerations *600* • Prevention *600*

88. Pneumothorax **602**

Bhawana Sharma, Devendra Richhariya

• Pathophysiology *602* • Clinical Features *603* • Primary Spontaneous Pneumothorax *603*
• Secondary Spontaneous Pneumothorax *603* • Catamenial Pneumothorax *603*
• Tension Pneumothorax *603* • Radiological Evaluation of Pneumothorax *604* • Management of Pneumothorax *604* • Intercostal Chest Drain Insertion *605* • Pneumomediastinum (Mediastinal Emphysema) *611* • Subcutaneous Emphysema *612*

89. Pleural Effusion, Lung Empyema, and Cavitary Lung Lesions **614**

Laxman Bhusal, Rabin Bom

• Pleural Effusion *614* • Lung Empyema *617* • Cavitary Lung Lesions *618*

90. Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) **621**

Devendra Richhariya, Bhawana Sharma

• Definition of Cases and Clinical Features *621* • Clinical Features *621* • Severity Classification of SARS-CoV-2, Investigations and Suggested Treatment *622* • CT Chest in SARS-CoV-2—Correlation with Disease Severity *622* • Remdesivir *623* • Favipiravir *624* • Tocilizumab *627*
• Convalescent Plasma Therapy in Patients with COVID-19 *627* • Vaccines for SARS-CoV-2 *628*
• SARS-CoV-2 Vaccines in India *629* • OMICRON—New Variant of SARS-CoV-2 *630*

SECTION 9: GASTROINTESTINAL EMERGENCIES

91. Abdominal Pain **633**

Roberta Petrino, Aldo Tua

• Etiology *633* • Pathophysiology *633* • Clinical Presentation *633*
• Evaluation *636* • Investigations *637* • Treatment *638*

92. Nausea, Vomiting, Hiccups, Constipation **640**

Devendra Richhariya

• Nausea and Vomiting *640* • Hiccups *643* • Constipation *646*

93. Diarrhea-associated Diseases **649**

Sanjay Kumar

• Pathophysiology *649* • Approach to Acute Diarrhea *649* • Traveler's Diarrhea *651*
• Persistent and Chronic Diarrhea *651* • *Clostridium Difficile*-induced Diarrhea *651*
• Inflammatory Bowel Disease *653* • Celiac Disease *653*

94. Gastrointestinal Bleeding **656**

Anukalp Prakash, Anshu Nagpal

• Epidemiology *656* • Causes *656* • Initial Assessment and Prognostication *657*
• History and Physical Examination *657* • Laboratory Investigations *658*
• Treatment *658* • Endoscopy Therapy *659*

95. Esophageal Emergencies **662**

Purushottam Vashistha

• Atypical Chest Pain *662* • Acute Dysphagia or Odynophagia *662* • Pill Injury *663*
• Esophageal Foreign Body *663* • Caustic Injury to Esophagus *664*
• Esophageal Injury and Perforations *664* • Mallory–Weiss Syndrome *665*
• Boerhaave's Syndrome *665*

96. Dyspepsia and Peptic Ulcer Disease **666**

Ravindra Kale

• Etiology *666* • Pathophysiology *666* • Clinical Presentation *666*
• Evaluation *667* • Treatment *667* • Prognosis *668*

97. Acute Pancreatitis and Cholecystitis **669**

Sanjay Kumar

• Acute Pancreatitis *669* • Acute Cholecystitis *672*

98. Acute Hepatitis **674**

Amit Mittal, Akanksha Rastogi

• Etiology *674* • Pathophysiology *674* • Clinical Presentation *675*
• Evaluation *675* • Investigations *675* • Treatment *676*

99. Chronic Liver Disease and Complications **677**

Ravindra Kale

• Malnutrition *677* • Infections *677* • Gastrointestinal Bleeding *678*
• Ascites *678* • Pulmonary Complications *678* • Hepatorenal Syndrome *679*
• Hepatocellular Carcinoma *679* • Hepatic Encephalopathy *679*

100. End-stage Liver Disease **682**

Uday Sanglodkar, Neeraj Mangla

• Definitions *682* • Management of Hepatic Encephalopathy *683* • Management of Gastrointestinal Bleed *683* • Management of Acute Kidney Injury *684* • Management of Sepsis *686* • Management of Ascites *687* • Management of Hepatic Hydrothorax *688*
• Liver Transplantation in Critically Ill ESLD Patients *688*

101. Liver Transplant and Related Complications **690**

Amit Ganguly

• Indications *690* • Contraindications *691* • Brain Dead Donor and Optimization *691* • Liver Transplant Procedure *691* • Complications of Liver Transplant *691* • Immunosuppression and Rejection *692* • Outcome *692*

102. Bowel Obstruction **694**

Jesús Daniel López Tapia, Aldo Emigdio Bartolini Salinas

• Etiology *694* • Pathophysiology *695* • Clinical Presentation *695* • Evaluation: History and Physical Examination *695* • Investigations *696* • Treatment *697*

103. Acute Appendicitis **699**

Mukund Khetan

• Anatomy *699* • History *699* • Etiopathogenesis *699* • Presentation *700* • Evaluation *700* • Investigations *701* • Appendicitis in Special Population *702* • Treatment *702* • Special Considerations during Appendectomy *703* • Recent Advances *704*

104. Anorectal Diseases **706**

Ashok Kumar Puranik, Devendra Richhariya

• Hemorrhoids *706* • Anal Fissure *708* • Anorectal Abscess *709* • Anal Fistula *711* • Pilonidal Disease *712* • Rectal Prolapse *714* • Rectal Trauma/Foreign Body *714* • Proctitis *715* • Pruritus Ani *715* • Proctalgia Fugax *715*

105. Vascular Abdominal Emergencies **717**

Devendra Richhariya

• Vascular Abdominal Anatomy *717* • Abdominal Vascular Thromboses *718* • Ischemic Bowel *719* • Aneurysm *720* • Visceral Artery Aneurysms *722*

SECTION 10: RENAL AND GENITOURINARY EMERGENCIES

106. Imaging Modalities in Genitourinary Disease **723**

Aman Gupta

• Conventional Plain Film Radiography *723* • Intravenous Urography *723* • Retrograde Urography *724* • Cystography *725* • Retrograde Urethrography and Voiding Cystourethrogram *725* • Percutaneous Nephrostomy and Antegrade Pyelography *725* • Ultrasound *726* • Doppler Sonography *727* • Computed Tomography *727* • Magnetic Resonance Imaging *728* • Nuclear Medicine *729*

107. Hematuria **731**

Puneet Ahluwalia

• Classification of Hematuria *731* • Etiology *731* • History and Initial Evaluation *731* • Stepwise Approach for Evaluation *733* • Unexplained Hematuria *734* • Follow-up after Initial Negative Evaluation *734* • Treatment *734*

108. Acute Urinary Retention **738**

Puneet Ahluwalia

• Epidemiology *738* • Etiopathogenesis *738* • Categories of Urinary Retention *740* • Clinical Presentation *740* • Evaluation *740* • Initial Management of Acute Urinary Retention *741*

109. Acute Kidney Injury and Rhabdomyolysis **743**

Ankit Purohit, Devendra Richhariya

• Pathophysiology *743* • Acute Kidney Injury *744* • Definition *744* • Risk Factors and Causes for Acute Kidney Injury *744* • Clinical Evaluation *747* • Diagnostic Testing *747*
• Management of Acute Kidney Injury in the Emergency Department *747*
• Acid-base Derangement in the Critically Ill Acute Kidney Injury *749*
• Renal Replacement Therapy *750* • Rhabdomyolysis *750* • Disposition *751*

110. End-stage Renal Disease **753**

Devendra Richhariya

• Chronic Kidney Disease *753* • End-stage Renal Disease *754* • Pathophysiology *754* • Clinical Features of Uremia *754* • Hemodialysis *756* • Peritoneal Dialysis *758* • Renal Transplant *759*

111. Kidney and Ureteral Stones **761**

Devendra Richhariya

• Risk Factors *761* • Cause *762* • Clinical Presentation *762* • Emergency Department Evaluation *762* • Imaging Modalities *763* • Management and Treatment *764*
• Prognosis *764* • Complications *764* • Special Concerns *765*

112. Urinary Tract Infection **766**

Krunal Desai

• Definitions and Classification *766* • Pathophysiology *766* • Risk Factors and Uropathogens *766* • Clinical Features *767* • Differential Diagnosis *767* • Diagnostic Evaluation *767* • Treatment *768* • Disposition *771*

113. Penile Emergencies **773**

Puneet Ahluwalia, Devendra Richhariya

• Anatomy *773* • Priapism *773* • Zipper Injury and Penile Entrapment *775*
• Balanitis and Posthitis *775* • Peyronie's Disease *776* • Penile Calciphylaxis *776*
• Phimosis *776* • Paraphimosis *779* • Penile Fracture *781*

114. Acute Scrotal Emergencies **784**

Devendra Richhariya

• Anatomy *784* • Etiology of Acute Scrotum *784* • Painful Scrotum *785*
• Painless Swollen Scrotum *787* • Erythematous Scrotum *787* • Traumatic Scrotum *787*
• Diagnosis *787* • Treatment *788*

115. Renal Transplant Related Complications **791**

Vishal Saxena, Yogeshman Anand

• Hypertension Following Kidney Transplant *791* • Surgical and Urologic Complication *791*
• Infection after Kidney Transplantation *793* • Cytomegalovirus Infection *793* • BK Polyomavirus Infection *793* • Fungal Infections Post-transplant *793* • Allograft Rejection *793* • New-onset Diabetes after Transplant *794* • Post-transplant Malignancy *794*

SECTION 11: NEUROLOGICAL EMERGENCIES

116. Headache **796**

Devendra Richhariya

• Etiology *796* • Pathophysiology *796* • Clinical Presentation *797*
• Evaluation *797* • Investigations *797* • Treatment *798*

117. Acute Dizziness and Vertigo **801**

Ramyajit Lahiri, Subhra Choudhury

• Definition *801* • Etiology *801* • Physiology *802* • Pathophysiology *803*
• Concerning Clinical Features *804* • Evaluation-history and Physical Examination *804*
• Other Test *808* • Investigations *809* • Management *809*

118. Altered Mental Status: Delirium **814**

Devendra Richhariya

• Definition *814* • Subtype of Delirium *815* • Recognizing the Delirum *815* • Pathophysiology of Delirium *815* • Etiology *815* • Evaluation *816* • Management *817* • Disposition *818*

119. Acute Ischemic Stroke **820**

Chandril Chugh

• Epidemiology and Risk Factors *820* • Ischemic Stroke Classification *820*
• Clinical Presentation *821* • Radiological Investigations in Acute Stroke *821*
• Management of Acute Stroke *823* • Intravenous Thrombolysis *824*
• Endovascular Treatment for Stroke *825* • Cryptogenic Stroke *826*

120. Subarachnoid and Intracerebral Hemorrhage **828**

Alireza Baratloo, Arash Safaie

• Etiology/Causes *828* • Pathophysiology of the Condition *828*
• Clinical Presentation and Red Flags *829* • Evaluation and Interpretation of Findings *829*
• Investigations *829* • Treatment *829* • Disposition *831*

121. Seizures and Status Epilepticus **833**

Gouri A Ranade, Priyanka G Mahale

• Common Causes of Status Epilepticus *833* • Classification and Stages of Status Epilepticus *833*
• Initial Evaluation and Management *834* • Phase Wise Management of Status Epilepticus *834*
• Special Situations in Status Epilepticus *835* • Systemic Complications of Status Epilepticus *836*

122. Acute Flaccid Paralysis **838**

Priyanka G Mahale, Rahul Kulkarni, Devendra Richhariya

• Guillain–Barré Syndrome *838* • Myasthenia Gravis *839* • Transverse Myelitis *839*
• Botulism *840* • Inflammatory Myopathy *840* • Systemic or Metabolic Disorders Causing Acute Flaccid Paralysis *840* • Weakness Associated with Critical Illness *841* • Trauma Induced Acute Flaccid Paralysis *841* • Evaluation of Acute Flaccid Paralysis *842* • Lathyrism *842*

123. Meningitis Encephalitis and Brain Abscess **844**

Atul Tungikar, Priyanka G Mahale, Devendra Richhariya

• Evaluation of Meningitis *844* • Management of Meningitis *845* • Encephalitis *846*
• Brain Abscess *848*

124. Coma: Evaluation and Management **849**

Noel Fernando

• Pathophysiology *849* • Differential Diagnosis *849* • Clinical Finding *849* • Clinical Examination *849* • Grading of Coma *851* • Investigations *851* • Treatment *851*

SECTION 12: ENDOCRINAL EMERGENCIES

125. Type 1 Diabetes Mellitus and Insulins **855**
Amit Gupta, Vinod Kumar
• Type 1 Diabetes Mellitus *855* • Diagnosis *855* • Insulin *856*

126. Type 2 Diabetes Mellitus: Management **859**
Ashok K Taneja
• Epidemiology: Prevalence in World and India *859* • Risk Factors *859*
• Etiology and Pathogenesis *859* • Diagnosis and Screening *860* • Management *860*
• Stepwise Approach of Managing Type 2 Diabetes Mellitus *865*

127. Hypoglycemia **867**
Jugal Kishor Sharma, Dinesh Sharma
• Etiology *867* • Pathophysiology *868* • Clinical Features *868* • Diagnosis *868*
• Classification of Hypoglycemic Events *868* • Treatment *869* • Prevention *869*

128. Diabetic Ketoacidosis **871**
Rajeev Chawla, Shalini Jaggi, Sidhant Trehan
• Epidemiological Aspect *871* • Pathogenesis of Diabetic Ketoacidosis *871* • Precipitating Factors for Diabetic Ketoacidosis *871* • Presenting Features for Diabetic Ketoacidosis *871*
• Ketosis Prone Type 2 Diabetes Mellitus *871* • Evaluation of Patient for Diabetes Ketoacidosis *872*
• Diagnostic Criteria for Diabetic Ketoacidosis *872* • Treatment Goals for Diabetic Ketoacidosis *873*
• Complications of Diabetic Ketoacidosis *875* • Preventive Measures for Diabetic Ketoacidosis *875*

129. Hyperosmolar Hyperglycemic Syndrome **877**
Dheeraj Kapoor
• Diabetes Overview *877* • Etiology *877* • Pathophysiology *878* • Diagnosis *879*
• Differential Diagnosis *879* • Treatment Approach *880* • Prognosis *880*

130. Hypothyroidism and Myxedema Coma **882**
Ajay Agarwal, Danendra Sahu, Rupak Wadhwa
• Classification and Etiopathogenesis *882* • Clinical Presentation *882*
• Diagnosis *883* • Myxedema Coma *883* • Treatment *885*

131. Hyperthyroidism—Graves' Disease and Thyroid Storm **888**
Dheeraj Kapoor, Abhishek Goyal
• Epidemiology *888* • Clinical Presentation *888* • Pathogenesis *888* • Diagnosis *889*
• Treatment *889* • Thyroid Storm *891*

132. Acute Adrenal Crisis **893**
Dheeraj Kapoor, Abhishek Goyal
• Basic Anatomy and Physiology of the Adrenal Gland *893* • Classification *894*
• Pathophysiology *894* • Causes *895* • Clinical Presentation *895* • Diagnosis *896*
• Confirmatory Diagnostic Testing *896* • Evaluation and Management in Emergency Department *897* • Prevention and Patient Education *897*

Volume 2

SECTION 13: EYE, EAR, NOSE, THROAT, AND ORAL EMERGENCIES

133. Eye Emergencies **899**

Carreen Pakrasi, Sudipto Pakrasi

• Anatomy *899* • Penetrating Ocular Injuries *900* • Nonpenetrating Ocular Injuries *901*
• Chemical Injuries *903* • Contact Lens-related Emergencies *903* • Conjunctivitis *903*
• Corneal Ulcers *903* • Uveitis *904* • Glaucoma Emergencies *904*
• Neuro-ophthalmology Emergencies *904* • Optic Neuritis *904* • Papilledema *904*
• Vascular Emergencies *904* • Vitreous Hemorrhage *905*

134. Ear Emergencies **907**

Shaarang Sachdev, Salil Malik

• Anatomy of Ear *907* • Common Symptoms of Ear Problems *908* • Outer Ear Infections *909*
• Middle Ear Infection *910* • Inner Ear Infections *911* • Trauma to Ear *911*
• Procedures Related to Ear *912*

135. Nasal Emergencies **915**

Harshil Mehta

• Epistaxis *915* • Nasal Fracture *918* • Nasal Septal Hematoma *919*

136. Face and Jaw Emergencies **921**

Devendra Richhariya, Harshil Mehta

• Facial Swelling *921* • Localized Facial Swelling *921* • Generalized Facial Swelling *922*
• Facial Cellulitis *923* • Jaw Dislocation *924*

137. Neck, Throat, Oral, and Dental Emergencies **928**

Aman Sharma, Devendra Richhariya

• Pharyngitis *928* • Epiglottitis *929* • Peritonsillar Abscess *930* • Ludwig's Angina *931*
• Retropharyngeal Abscess *932* • Infectious Mononucleosis *933* • Oral Candidiasis *934*
• Oral Herpes Simplex *935* • Dental Pain *936* • Gingivitis *936* • Dental Abscess *940*
• Bleeding after Dental Surgery *940* • Dental Trauma *941*

138. Management of Foreign Bodies of Ear, Nose and Throat **944**

Mohammad Anzal Rehman, Neha Hudlikar, El Rasheed Salih

• History Taking and Presentation 944 • Approach and Management 944 • Foreign Bodies of the Ear 945
• Foreign Bodies of the Nose 947 • Foreign Bodies of the Throat 948

SECTION 14: HEMATOLOGY AND ONCOLOGY

139. Anemia **952**

Akanksha Rastogi, Amit Mittal

• Pathophysiology *952* • Types of Anemia *952* • Classifications *952* • Clinical Presentation *952*
• Red Flags *953* • Evaluation of Anemia *953* • Differential Diagnosis *954* • Investigations *954*
• Hemolytic Anemia *956* • Treatment *956*

140. Approach to Pancytopenia **958**

Benita Florence, Dodiy Herman

• Definition *958* • Etiology *958* • Clinical Features *959* • Diagnostic Workup *959*
• Aplastic Anemia *959* • Inherited Aplastic Anemia *960*

141. Approach to Leukemia **962**

Dodiy Herman, Benita Florence

• Epidemiology *962* • Risk Factors *962* • Clinical Presentation *962* • Classification *963* • Clinical Manifestation and Assessment *963* • Investigations *963* • Treatment in the Emergency Department *964* • Other Emergencies *964* • Precautions *965*

142. Oncological Emergencies **967**

Amit K Jain

• Oncological Emergencies Related to Local Tumor Effects *967* • Oncological Emergencies Related to Biochemical Derangements *971* • Oncological Emergencies Related to Hematological Derangements *973* • Oncological Emergencies Related to Therapy *975*

143. Thrombocytopenia, Bleeding, and Coagulopathy **979**

Ragesh Radhakrishnan Nair, Isha Gambhir

• Primary Hemostasis *979* • Coagulation Cascade *980* • Approach to Thrombocytopenia *981* • Disorders of Coagulation *983*

144. Blood Transfusion Therapy and Related Complication **986**

Aseem Kumar Tiwari, Geet Aggarwal

• Responsibility of Emergency and Blood Bank Team *986* • Transfusion Approach and Massive Transfusion Protocol *987* • Role of Specific Blood Components *988* • Adverse Effect of Blood Transfusion *990* • Hemovigilance (Hemovigilance Program of India) *991*

145. Therapeutic Plasmapheresis **993**

Rahul Solanki, Devendra Richhariya

• History *993* • Indications *993* • Techniques *994* • Complications *995*

146. Sickle Cell Disease **997**

Devendra Naik

• Pathophysiology *997* • Clinical Features *997* • Approach to Sickle Cell Disease Patient in Emergency Department *999* • Management *999*

147. Thrombotic Microangiopathies **1002**

Sirisha Kadali, Devendra Richhariya

• Thrombotic Thrombocytopenic Purpura *1002* • Hemolytic Uremic Syndrome *1005* • Immune Thrombocytopenic Purpura *1005* • Hellp Syndrome *1006* • Disseminated Intravascular Coagulation *1007* • Heparin-induced Thrombocytopenia *1009*

SECTION 15: DERMATOLOGY, RHEUMATOLOGY AND PSYCHIATRY

148. Approach to Skin Diseases in Emergency **1013**

Ramanjit Singh, Nidhi R Sharma

• History Taking *1013* • Examination of the Patient *1013* • Diagnostic Tests *1013* • Bedside Tests in Dermatology *1018* • Evaluation of the Nature of Diseases *1021* • Vesiculobullous Disorders *1021* • Drug Rash with Eosinophilia and Systemic Symptoms/Drug-induced Delayed Multiorgan Hypersensitivity *1021* • Infectious Diseases *1021* • Noninfectious Causes of Hemorrhagic Lesions *1022* • Necrotizing Fasciitis *1022* • Urticaria and Angioedema *1022* • Erythroderma *1022* • Inflammatory Cutaneous Disorders *1023* • Environmental Disorders *1023* • Acute Skin Failure *1023*

149. Generalized Dermatologic Emergencies **1025**

Tejas D Patel

• Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis *1025* • Pyoderma Gangrenosum *1026* • Staphylococcal Scalded Skin Syndrome *1027* • Necrotizing Fasciitis *1027* • Urticaria (Hives), Angioedema, and Anaphylaxis *1027* • Pemphigus Group of Diseases *1029* • Vasculitis *1030* • Lepra Reaction *1030* • Psoriasis (Erythrodermic Psoriasis) *1030* • Acute Skin Failure *1030*

150. Approach to Joint Pain **1033**

Sourabh Malviya

• Evaluation of Joint Pain *1033* • Laboratory Tests *1035* • Synovial Fluid Analysis *1035* • Imaging *1035* • Treatment *1037*

151. Overview of Rheumatological Disorders **1039**

Neeraj Jain, Amit Dua

• Classification and Definition *1039* • Etiology *1039* • Evaluation *1039* • Diagnosis *1042* • Treatment *1044*

152. Evaluation of Mental Health and Common Psychiatric Emergencies **1047**

Mohammad Anzal Rehman, Mansoor Masarrat Husain

• Evaluation of Mental Health *1047* • Investigations *1049* • High-risk Psychiatric Presentations in the Emergency Department *1050* • Overview of Psychiatric Illness *1051* • Thought Disorders, Psychosis, and Schizophrenia *1054*

SECTION 16: OBSTETRICS AND GYNECOLOGICAL EMERGENCIES

153. Acute Pelvic Pain **1056**

Dolly C Yadav

• Anatomy, Pathophysiology, and Etiology *1056* • Emergency Department Evaluation *1056* • Treatment *1059* • Disposition and Follow-up *1059* • Specific Conditions in Nonpregnant Females *1060*

154. Abnormal Uterine Bleeding **1066**

Sanjukta Dutta, Mainak Majumdar

• Basic Physiology *1066* • Etiology *1066* • Evaluation of Abnormal Uterine Bleeding *1067* • Investigations *1069* • Management *1069* • Disposition *1070*

155. Ectopic Pregnancy **1072**

Sonal Parihar

• Causes *1072* • Types of Ectopic Pregnancy *1072* • Clinical Presentation *1073* • Evaluation *1074* • Investigations *1074* • Treatment *1075*

156. Emergencies during Pregnancy **1078**

Devyani Misra, Mariyum Faruqi

• Nausea and Vomiting of Pregnancy and Hyperemesis Gravidarum *1079* • Spontaneous Abortion *1081* • Septic Abortion *1083* • Hypertension in Pregnancy *1086* • Hellp Syndrome *1095* • Placenta Previa *1095* • Prelabor Rupture of Membranes *1098* • Preterm Labor *1099*

157. Comorbid Conditions and Pregnancy **1104**

Laxman Bhusal, Rabin Bom

• Diabetes *1104* • Thyroid Diseases *1105* • Cardiovascular Diseases *1105*
• Asthma *1106* • Epilepsy *1106*

158. Emergency Delivery **1108**

Sangeeta Kaushik Sharma

• Prehospital Care *1108* • Emergency Department Care *1108* • Complicated Delivery *1110*
• Umbilical Cord Prolapse *1110* • Cesarean Section *1112* • Postpartum Complications *1112*

159. Resuscitation in Pregnant **1114**

Vijaya Banu Mohan, Dodiy Herman, Benita Florence

• Physiological Changes in Pregnancy *1114* • Critically Ill Maternal Patients *1114* • Maternal Collapse *1114* • Maternal Cardiac Arrest *1115* • Approach to Critically Ill Obstetric Patient *1115* • Approach to Maternal Cardiac Arrest *1116* • Management after Resuscitative Hysterotomy *1119* • Amniotic Fluid Embolism *1119*

SECTION 17: PEDIATRIC EMERGENCIES

160. Pediatric and Neonatal Transport **1121**

Trevor L Tredway

• Referring and Receiving Hospital Responsibilities *1121* • Criteria for Transfer *1121* • Mode of Transport *1121* • Transport Team *1122* • Patient Monitoring and Care *1122*

161. Pediatric Resuscitation **1124**

Mohammad Anzal Rehman, Thiagrajan Jaiganesh

• Systematic Approach to the Critically Ill Child *1124* • Primary Survey *1124*
• Secondary Survey *1127* • Pediatric Shock—Identification and Management *1128*
• Cardiopulmonary Arrest *1129* • Overview of Neonatal Resuscitation *1133*

162. Examination of Newborn **1136**

Nilu Sunil, Devendra Richhariya

• General Evaluation *1136* • Vital Signs *1137* • Systemic Examination *1138*

163. Crying Infant **1142**

Prabhat Maheshwari, Upasana Iyer

• What is Cry? *1142* • Normal and Excessive Crying *1142* • Etiology *1142*
• Pathophysiology *1142* • Features of Concern (Red Flag Signs) *1142*
• Prehospital Care *1142* • Evaluation of Crying Infants in Emergency Department *1144*
• Investigations *1145* • Treatment *1145*

164. Immunization in Pregnant Women, Infant and Children **1147**

Ashok Mishra

• Historical Aspects of Vaccination *1147* • Vaccination in Pregnancy *1148*
• Vaccination in Children *1150* • Cold Chain *1154* • Adverse Event Following Immunization *1155*

165. Pediatric Fever and Other Life-threatening Infections **1158**
Faiz Ahmad, Devendra Richhariya
Etiology *1158* • Pathophysiology of Fever *1158* • Clinical Presentation *1159*
• Features of Concern—red Flags *1159* • History and Physical Examination *1160*
• Diagnosis and Management *1160* • Antipyretics *1161* • Urinary Tract Infection *1162*
• Occult Bacteremia *1162* • Pneumonia *1162* • Severe Acute Respiratory Syndrome Coronavirus 2 Infection in Children *1162* • Multisystem Inflammatory Syndrome in Children Related to Covid-19 *1163*

166. Pediatric Abdominal Pain **1169**
Thiagrajan Jaiganesh, Faiz Ahmad
• Evaluation of Acute Abdominal Pain in Children *1169*
• Evaluation of Chronic or Recurrent Abdominal Pain in Children *1172*

167. Vomiting, Diarrhea, Dehydration in Children **1177**
Deepak Goyal
• Etiology *1177* • Assessment of Child with Vomiting and Diarrhea *1177*
• Dehydration in Diarrhea *1178* • Treatment *1178*

168. Pediatric Fluid and Electrolyte Therapy **1181**
Devendra Richhariya
• Physiologic Differences *1181* • Fluid Therapy *1181* • Maintenance Electrolytes *1183*
• Electrolyte Abnormalities *1183* • Monitoring Fluid and Electrolyte Therapy *1183*

169. Respiratory Problems in Infants and Children **1185**
Sandip Kumar
• Etiology *1185* • Pathophysiology *1186* • Clinical Presentation *1187*
• Evaluation *1187* • Investigations *1188* • Treatment *1188*

170. Pediatric Cardiac Emergencies **1190**
Munesh Tomar, Aditi Gupta
• Neonatal Cardiac Emergencies: An Overview *1190* • Presentation *1190*
• Case Scenarios—Cyanosis *1190* • Case Scenario—Cardiovascular Collapse *1192*
• Case Scenario—Acute Congestive Heart Failure *1193* • Pediatric Cardiac Emergencies *1193*
• Drugs Commonly Used in Cardiac Emergencies *1199*

171. Pediatric Diabetic Ketoacidosis **1201**
Devendra Richhariya
• Epidemiology *1201* • Pathophysiology *1201* • Clinical Presentation *1202*
• Diagnosis *1202* • Emergency Department Management *1203* • Complications *1206*
• Disposition *1206*

172. Pediatric Seizure **1208**
Devendra Richhariya
• Causes *1208* • Pathophysiology of the Condition *1208* • Clinical Presentation *1210*
• Febrile Convulsion *1210* • Status Epilepticus *1210* • Evaluation *1211*
• Investigations *1211* • Antiepileptic Drugs *1212* • Treatment *1212*

173. Pediatric Oral and Dental Emergencies **1215**
Trevor L Tredway
• Classification and Management of Traumatic Dental Injuries *1217*
• Classification and Management of Tooth Fractures *1217*

174. Rashes in Newborn and Infant **1220**

Nadeem Uddin Qureshi, Irene Oriaifo, Rekha Gadiparthi, Mohammed Moiz Qureshi

• Terminology of Primary Lesions *1221* • Benign Neonatal Skin Lesions *1221*
• Disorders of Pigmentation *1225* • Vascular Lesions of Infancy *1226*

175. Pediatric Antibiotic Prophylaxis **1228**

Veena Raghunathan, Devendra Richhariya

• Nonpharmacologic Options *1269* • Reassessment *1270*

183. Geriatric Gynecology **1271**

Laxman Bhusal, Rabin Bom

• Osteoporosis *1271* • Vulvovaginitis *1271* • Urogynecologic Issues *1271* • Breast Cancer *1271* • Vaginal Bleeding in the Postmenopausal Patient *1272* • Ovarian Cancer *1272* • Cervical Cancer *1272* • Benign Causes of Vaginal Bleeding *1272* • Menopausal Symptoms and Hormone Replacement Therapy *1272* • Pelvic Organ Prolapse *1273*

SECTION 19: INFECTIOUS DISEASE EMERGENCIES

184. Emerging and Re-emerging Infections **1275**

Dharmesh Lal

• Important Terms *1275* • Enabling Factors *1276* • Diseases Profile *1276*
• Control Measures *1286* • Elements of an Epidemic Management System *1286*
• Vaccine Development *1288*

185. Immunization and Postexposure Prophylaxis for Infections **1290**

Sara Nooruddin Kazim, Devendra Richhariya

• Influenza *1290* • Pertussis *1291* • Diphtheria *1291* • Tetanus *1291*
• Pneumococcus *1291* • *Meningococcus* *1292* • Herpes Zoster (Varicella) *1292*
• Human Papillomavirus *1292* • Tuberculosis *1292* • Measles/Mumps/Rubella *1292*
• Chickenpox *1293* • Hepatitis A *1293* • Hepatitis B *1293* • Yellow Fever *1293*
• Polio *1293* • Typhoid *1294* • Japanese Encephalitis *1294* • Rabies *1295*
• Smallpox *1295* • Anthrax *1295*

186. Tropical Infections in Travelers **1298**

Ananthakrishnan C, Devendra Richhariya

• Etiology/Causes *1298* • Evaluation: History and Physical Examination *1298*
• Clinical Presentaion *1300* • Tropical Infections Presenting as Undifferentiated Fever *1300*
• Hepatitis A *1302* • Meningococcal Meningitis *1303* • Tropical Diseases Presenting as Diarrhea *1303* • Tropical Infections with a Primarily Dermatologic Presentation *1303*
• Important Tropical Diseases Rarely Occurring in Travelers *1304* • Pediatric Considerations *1304*
• Protection of Contacts and Staff *1305*

187. Zoonotic Infections **1307**

Olita Shilpakar, Devendra Richhariya

• Tick-Borne Infections *1307* • Rocky Mountain Spotted Fever *1307* • Tick Paralysis *1307* • Lyme Disease *1308* • Tick-Borne Relapsing Fever *1309*
• Tularemia *1310* • Babesiosis *1310* • Treatment of Tick-Borne Infection *1310*
• Zoonotic Meningitis and Encephalitis *1310* • Zoonotic Respiratory Infection *1310*
• Zoonotic Dermatologic Infection *1311* • Zoonotic Infections from Pets *1311*
• Emerging Zoonotic Viruses of Bat Origin *1311* • Emerging Zoonotic Viruses from Other Sources *1312* • Prevention and Control of Emerging Zoonotic Diseases *1312*

188. Tetanus **1314**

Sayuri Enriquez Saenz, Devendra Richhariya

• Pathophysiology of Tetanus Toxin *1314* • Symptomatology of Tetanus *1314* • Diagnosis *1315* • Treatment of Tetanus *1315* • The Role of Botulinum Toxin in Tetanus-induced Rigidity and Spasms *1315* • Advantages and Disadvantages of Botulinum Toxin Treatment in Tetanus *1316*

189. Dengue Fever **1317**

Sahanya Ramesh Shetty, Neeraj Mangla

Epidemiology *1317* • Modes of Transmission *1317* • Transmission *1318* • Immunopathogenesis *1318* • Clinical Picture *1318* • Clinical Manifestations *1318* • Severe Dengue *1319* • Step-wise Approach to Treatment *1321* • Diagnosis *1321* • Management *1322* • Complications in Severe Dengue *1323* • Complication: Compensatory Shock *1323* • Complication: Hypotensive Shock *1323* • Hemorrhagic Complications *1325* • Complication: Fluid Overload *1326*

190. Malaria **1328**

Sahanya Ramesh Shetty, Neeraj Mangla, Devendra Richhariya

• Incidence *1328* • Causative Agent, Types, and Life Cycle *1328* • Pathophysiology *1329* • Clinical Features *1329* • Investigation and Diagnosis *1329* • Treatment of Uncomplicated Malaria *1332* • Radical Treatment *1333* • Chemoprophylaxis to Travelers *1333* • Treatment of Severe Malaria *1333* • Chronic Complications of Malaria *1334* • Cerebral Malaria *1334*

191. Tuberculosis **1336**

Suman Thakur, Vivek Chauhan

• Etiology/Causes *1336* • Pathophysiology *1336* • Clinical Presentation *1336* • Evaluation *1337* • Investigations *1337* • Treatment *1338* • Disposition *1339*

192. Rabies **1341**

Ashok Mishra

• Current Scenario *1341* • Pathogenesis *1342* • Clinical Presentation *1343* • Diagnosis *1343* • Management of Human Rabies (Hydrophobia) *1344* • Prevention of Human Rabies *1344* • Modern Antirabies Vaccine *1345* • Rabies Immunoglobulin for Passive Immunization *1346* • Specific Situations *1346* • Control of Rabies *1347*

193. Skin and Soft Tissue Infections **1349**

Javier Saavedra Urbe, Devendra Richhariya

• Microbiology *1349* • Impetigo *1349* • Abscess *1351* • Purulent Cellulitis *1352* • Nonpurulent Cellulitis *1352* • Erysipyelas *1353* • Necrotizing Soft Tissue Infections *1353*

194. Musculoskeletal Infections **1356**

Avdi S Tahiri, Artan Bejta

• Osteomyelitis *1356* • Spondylodiscitis (Vertebral Osteomyelitis) *1358* • Spinal Epidural Abscess *1359* • Septic Arthritis *1359* • Periprosthetic Joint Infection *1360*

195. Management of Sexually Transmitted Infection **1362**

Shahbaz Anees, Durre Aden

• Epidemiology *1362* • Role of the Emergency Department *1362* • Risk Factors *1362* • Evaluation *1362* • Investigations *1362* • *Chlamydia* *1363* • Gonorrhea *1363* • Trichomonas Vaginitis/Bacterial Vaginosis *1363* • Syphilis *1364* • Herpes Simplex Virus *1364* • Pelvic Inflammatory Disease *1365* • Special Scenario *1365*

196. HIV Infections **1367**

Susmeet Mishra, Ushirin Bose

• Etiology *1367* • Pathophysiology *1367* • Clinical Presentation *1368* • Evaluation *1368* • Investigations *1369* • Treatment *1370* • Immune Reconstitution Inflammatory Syndrome *1370* • Postexposure Prophylaxis *1373* • Disposition *1373*

197. Care of Immunocompromised and Transplant Patient **1375**

Charu Malhotra, Brunda RL, Ritin Mohindra

• Neutropenia *1375* • Diabetes *1377* • Alcoholism and Cirrhosis *1377* • Renal Failure *1377* • Functional or Surgical Asplenia *1377* • Corticosteroid *1377* • Transplant Patient Care *1377* • General Approach to Transplant Patient *1377* • Graft-versus-Host Disease *1378* • Transplant-Specific Problems *1378*

SECTION 20: TOXICOLOGY

198. Analytical Toxicology **1381**

VV Pillay

• Biochemical and Hematological Tests Useful in Toxicology *1382* • Analytical Methods used in Toxicology *1383* • Qualitative Assays *1383* • Quantitative Assays *1385*

199. General Management of Poisoning **1392**

VP Chandrasekaran, Balaji Muruga B

• Setting up a Poisoning Center *1392* • Primary Toxicology Survey and Stabilization *1392* • Secondary Toxicology Survey *1394* • Removal of Poisoning *1394*

200. Common Pesticides Poisoning in India **1404**

VV Pillay

• Organophosphorus Poisoning *1404* • Carbamates *1415* • Aluminum Phosphide Poisoning *1417*

201. Anticholinergics **1421**

Shikha Tandon

• History *1421* • Pharmacology *1421* • Etiology of Anticholinergic Toxicity *1422* • History and Evaluation *1422* • Clinical Features *1422* • Differential Diagnosis *1422* • Management *1423* • Disposition *1423*

202. Antidepressant Antipsychotic **1425**

Devendra Richhariya

• Antidepressant *1425* • Overdose and Toxicity *1425* • Treatment *1427* • Serotonin Syndrome *1428* • Antipsychotics *1428* • Extrapyramidal Symptoms *1429* • Drug-induced Heat Stroke *1429* • Neuroleptic Malignant Syndrome *1429*

203. Anticonvulsants Barbiturates and Phenytoin Toxicity **1431**

Vivekanshu Verma

• Barbiturates *1431* • Phenytoin Toxicity *1432*

204. Sedatives Benzodiazepine and Nonbenzodiazepine **1435**

Chidrupi Sharma

• Benzodiazepines *1435* • Nonbenzodiazepines *1437*

205. Opioids **1439**

Olita Shilpakar

• Pathophysiology *1439* • Toxicokinetics *1440* • Clinical Evaluation *1440*
• Differential Diagnosis *1440* • Investigation *1441* • Treatment *1441*
• Disposition *1441* • Opioid Withdrawal *1441*

206. Substance Abuse **1443**

Ramesh K Maharjan, Jukel Shrestha, Rashmisha Maharjan

• History *1443* • Epidemiology *1443* • Hallucinogens *1444* • Lysergamides *1444*
• Marijuana and Synthetic Cannabinoids *1444* • Amphetamines *1445* • Cocaine *1446*

207. Alcohol **1449**

Ajay Singh Thapa, Devendra Richhariya

• Alcohol Intoxication *1449* • Alcohol Withdrawal Syndrome *1451* • Methanol Poisoning *1452*

208. Cardiovascular Drug Overdose **1455**

Rahul Solanki

• β-Adrenergic Antagonists and Calcium Channel Antagonists *1455*
• Cardioactive Steroid Toxicity *1459* • Antihypertensive *1461* • Antiarrhythmics *1463*

209. Salicylates, Acetaminophen, and Nonsteroidal Anti-inflammatory Drugs **1466**

Ajay K Mishra, Jitendra Chandrakar

• Mechanism of Action *1466* • Salicylates *1466* • Acetaminophen *1467* • Nonsteroidal Anti-Inflammatory Drugs *1469*

210. Hydrocarbons and Volatile Substances **1472**

Atanu B Bhattacharya

• Classification and Properties *1472* • Pathophysiology *1472* • Clinical Presentation *1473*
• Red Flags *1474* • Evaluation *1474* • Investigation *1474* • Treatment *1474* • Disposition *1475*

211. Caustic Ingestion **1477**

Narendra Nath Jena, Subbulakshmi Dhanabal

• Pathophysiology *1477* • Etiology *1478* • Clinical Features *1478*
• Evaluation *1478* • Investigations *1479* • Management *1479* • Complications *1479*
• Disposition and Follow-up *1479*

212. Inhaled Toxins **1481**

Subramanian Senthilkumaran, Ponniah Thirumalaikolundusubramanian

• Etiology *1481* • Pathogenesis *1481* • Clinical Features *1482*
• Investigation *1482* • Diagnosis *1482* • Management *1482* • Asphyxiants *1484*
• Carbon Monoxide Poisoning *1484* • Cyanide Poisoning *1485*

213. Iron and Heavy Metals **1487**

Sameer Thapa, Anup Raj Upreti

• Iron *1487* • Lead *1488* • Mercury *1489* • Arsenic *1489* • Investigations *1490*
• Other Metal Poisoning *1490*

214. Dyshemoglobinemias **1492**

Gireesh Kumar KP

• Methemoglobinemia *1492* • Sulfhemoglobinemia *1495*
• Carboxyhemoglobinemia—Carbon Monoxide Poisoning *1496*

215. Toxic Plants **1499**

TV Ramakrishnan, Mona Lisa

• *Thevetia peruviana 1499* • *Nerium odorum 1500* • *Datura metel 1500*
• *Abrus precatorius 1500* • *Myristica fragrans 1501* • *Nicotiana tabacum 1501*
• *Strychnos Nux-vomica 1501* • *Gloriosa superba 1502* • *Ricinus communis 1502*
• *Calotropis 1502* • *Cannabis sativa 1503* • *Cleistanthus collinus 1503*

216. Pediatric Toxicology **1505**

Nisreen Hamza Maghraby, Chafika Lasfer, Mohamad Al Jumaan

• Pharmacokinetic Differences in Pediatric Age *1505* • Emergency Evaluation *1505* • History and Physical Examination *1507* • Investigations *1508* • Management *1508* • Disposition *1508*

217. Obstetrics Toxicology **1511**

Sara Nooruddin Kazim, Mahra Nooruddin Kazim, Lara Abumuaileq, Azza Yousif

• Drug Pharmacokinetics during Pregnancy *1511* • Pharmacology of Drug Transfer Across the Blood–Placental Barrier *1511* • Fetal Toxicology *1511*
• Organogenesis *1512* • Teratogenesis *1512* • General Approach to Poisoning in Pregnant Women *1512* • Acetaminophen *1512* • Antidepressants *1514* • Iron *1514*
• Over-the-Counter Medications *1514* • Substance Misuse *1515* • Anticonvulsants *1515*
• Anticoagulants *1516* • Carbone Monoxide *1516* • Cardiovascular Drugs *1516*

SECTION 21: TRAUMA AND WOUND MANAGEMENT

218. Integrated Trauma System **1518**

Prasad Rajhans, Purushotham Godavarthy

• Introduction and Epidemiology *1518* • Concept of an Integrated Trauma System *1518*
• Prehospital Trauma Care *1518* • Acute Care Facilities *1521* • Rehabilitation *1522*
• Injury Epidemiology and Prevention *1523*

219. Initial Assessment and Management of Polytrauma **1524**

Sanjay Shah

• Trimodal Distribution of Trauma Mortality *1524* • Primary Survey and Initial Resuscitation *1525*
• Secondary Survey *1529*

220. Trauma Resuscitation **1533**

Ankur Verma

• Science Behind Trauma Resuscitation *1533* • Resequenced Approach *1534*
• Airway in Trauma *1534* • Recognition of Shock, Occult Shock, and Bleeding Patient *1535*
• Damage Control Resuscitation *1537*

221. Focused Assessment with Sonography in Trauma **1540**

Devendra Richhariya

• Evolution of Fast *1540* • Accuracy of Fast and Clinical Decision-making *1540*
• Fast Technique and Interpretation *1541* • Newer Protocols and Extended Fast *1542* • Heart *1543* • Hemothorax or Pleural Effusion *1543*
• Pneumothorax *1543* • Inferior Vena Cava *1545* • Serial Fast *1546*
• Solid-Organ Evaluation *1546* • Bowel and Mesenteric Injury *1546* • Pregnant Patients *1546*
• Fast and Pediatric Patients *1546* • Training and Experience *1546* • Future Applications *1547*

222. Facial Trauma **1548**

Syed Ahmed Adil

• Approach and Management *1548* • Major Facial Bones *1550* • Temporomandibular Joint Dislocation *1551* • Eyes/Orbit *1552* • Lacerations *1554* • Imaging Studies *1554*

223. Head Trauma **1557**

Prasad Rajhans, Harshwardhan Singh Pawar, Devendra Richhariya

• Cerebral Blood Flow and Autoregulation *1557* • Pathophysiology of Traumatic Brain Injury *1558* • Mechanism of Injury *1558* • Consequences of Traumatic Brain Injury *1558* • Pattern of Brain Injuries *1559* • Traumatic Brain Injury—According to Severity *1560* • Clinical Features of Traumatic Brain Injury *1561* • Guidelines for Management of Head Injuries *1561* • Resuscitation and Management of Head Trauma in the Emergency Department *1561*

224. Neck Trauma **1565**

Lokendra Gupta, Atul Singh Tomar

• Etiology *1565* • Anatomy *1565* • Pathophysiology *1566* • Clinical Presentation *1566* • Evaluation of Neck Trauma *1567* • Management *1567* • Important Points *1569*

225. Spinal Trauma **1570**

Winston Noronha

• Applied Anatomy of Spine *1570* • Mechanisms of Injury *1571* • Classification of Spinal Injuries *1571* • Clinical Grading *1572* • Specific Injuries *1573* • Radiology in Spinal Trauma *1575* • Initial Assessment and Management *1575* • Management *1577* • Adjunct Therapy *1578* • Emerging Therapies *1578*

226. Cardiothoracic Trauma **1579**

Pushkin Roy, Devendra Richhariya

• Chest Wall Injury *1579* • Rib Fracture *1579* • Flail Chest *1580* • Costochondral Separation *1580* • Nonpenetrating Ballistic Injury *1580* • Sternal Fracture *1580* • Subcutaneous Emphysema *1580* • Pulmonary Contusion *1582* • Pulmonary Laceration *1582* • Pneumothorax *1582* • Hemothorax *1583* • Tracheobronchial Injuries *1584* • Traumatic Asphyxia *1584* • Diaphragmatic Injuries *1584* • Esophageal Injuries *1584* • Blunt Cardiac Injury *1585* • Injuries of the Aorta and Great Vessels *1587* • Critical Decisions in Thoracic Trauma Management *1587* • Imaging to Diagnose or Exclude Thoracic Injury *1587* • Disposition from the Emergency Department *1588*

227. Abdominal Trauma **1589**

Sanjay Shah, Chintan Thanki

• Etiology *1589* • Pathophysiology *1589* • Clinical Presentation *1590* • Evaluation *1590* • Investigations *1591* • Treatment *1592* • Resuscitative Endovascular Balloon Occlusion of the Aorta *1594* • Disposition *1595*

228. Genitourinary Trauma **1597**

Rajashekar Mohan, Lancelot Lobo, Nawin Kumar

• Mechanism of Injury *1597* • Evaluation and Clinical Features *1598* • Investigations *1598* • Treatment Options *1598*

229. Extremity Trauma and Crush Injury **1602**

M Shiva Reddy, Rammohan Radhakrishnan

• Mangled Extremity Care *1602* • Initial Care of the Wound *1603* • Extremity Trauma *1603*

230. Vascular Injury **1612**

Rohan Shah

• Etiology and Incidences *1612* • Pathophysiology *1612* • Clinical Presentation *1612*
• Diagnosis *1613* • Management *1613* • Complications *1614*

231. Management of Orthopedic Injuries **1615**

Sandeep Jain

• Etiology of Orthopedic Injuries *1615* • Classification of Orthopedic Injury *1615*
• Fracture Healing *1615* • Clinical Presentation *1616* • Investigations *1616*
• Initial Management *1617*

232. Common Orthopedic Procedures **1621**

Mihir Dholakia

• Immobilization of Cervical Spine and Application of Cervical Collar *1621* • Helmet Removal *1622*
• Immobilization of Trauma Patient and Log Roll *1622* • Fracture Management: Traction *1622*
• Fracture Management: Splinting and Casting *1624* • Types of Splints *1625* • Upper Extremities Immobilization *1626* • Lower Extremities Immobilization *1629* • Joints Dislocation: Reduction Techniques *1630* • Local Anesthesia and Blocks *1632* • Arthrocentesis *1633*
• External Fixator, Pelvic Binder, External Pelvic Fixator *1634*

233. Geriatric Trauma **1636**

Devendra Richhariya

• Geriatric Anatomy and Physiology *1636* • History: Mechanism of Injury *1637*
• Clinical Workup *1637* • Initial Management and Resuscitation *1638*
• Diagnostic Evaluation *1639* • Special Situations *1639* • Disposition *1640*

234. Approach to Pediatric Trauma **1641**

133
CHAPTER

Eye Emergencies

Carreen Pakrasi, Sudipto Pakrasi

INTRODUCTION

The eye is a small but essential part of the body. It is the one thing that adds quality to life. Hence, care of the eyes is as important as of any other part of the human body. Most often, the emergencies related to the eye will be obvious, with the cause related to either injuries such as trauma and chemicals and presenting with suggestive history and complaints of severe pain and visual loss of varying degrees from 6/6 to no perception of light. Sometimes, pain is the only presenting complaint in potentially debilitating conditions that must be detected early so as to prevent late visual complications, such as optic neuritis, temporal arteritis, and sometimes herpes zoster. A high index of suspicion and an acute clinical sense is important in early diagnosis. Ocular emergencies are those conditions that may or may not present with ocular pain and redness and are potentially blinding. These have to be recognized and treated swiftly so as to preserve the visual functions of the eye.

The World Health Organization (WHO) studies quote the incidence of ocular injuries causing loss of work hours as 55 million. Epidemiological studies by Vats et al. has found the mean age of ocular trauma to be 24.2 years. The prevalence of ocular trauma is reported to 2.4% of the population in an urban setting in India. We are going to try to present the various scenarios in a logical progression so that they are easily identifiable by first responders in an emergency setting. The Ocular Trauma Score has been presented according to various standard systems, of which the Birmingham Eye Trauma Terminology (BETT) is one of the most widely accepted. The terminology and classification is mostly to differentiate between penetrating and nonpenetrating ocular trauma due to mechanical cause.

Causes of Ocular Emergencies

Of the patients presenting in the emergency, the cause of symptoms can be any of the following. Most classifications of ocular emergencies will focus on ocular trauma. However, in a multispecialty hospital, patients walk in with any of the following presentations:

- *Infections*:
  - *Viral conjunctivitis*: Herpes simplex conjunctivitis or epidemic keratoconjunctivitis
  - Mucopurulent conjunctivitis
  - Ocular involvement due to herpes zoster
- *Trauma*: This will be discussed in detail.
- Ocular presentations of systemic diseases
- Diplopia and sudden loss of vision due to vascular or neurological causes

  Culturally, in India, there are a few festivities that have a high incidence of ocular emergencies. These may be infective or there may be chemical injuries to the cornea or emergency as a result from ocular trauma. All emergencies are usually on high alert around these festivities.
- *Holi*: Injury during the festival of Holi can be any of the following:
  - Infections due to contaminated color or water going into the eye
  - Chemical injuries due to reactions to adulterated and artificial colors
  - Closed or open globe injuries due to blunt trauma with balloons willed with water hitting the eye at high velocity
- *Dussehra*: Bow and arrow injuries

ANATOMY

The eye has a unique function, which requires clarity of its surface. It is soft, therefore susceptible to traumatic injuries. However, it also has a unique setting. It is placed inside a bony socket, which is designed to protect the eye, which by its nature of being closed on all sides except the front, serves as a buffer against direct impact. The front of the eye is protected by the eyelids, which are very sensitive to light, wind, and are served by a highly reactive nervous system, which closes the lids whenever there is a threat to them. Any loss of function of the lids will therefore increase the risk of injury to the eye itself.

The entire body is protected by skin, which is tough and capable of protecting the underlying tissue from direct injury. The eye, however, has skin that is soft, transparent, and susceptible to injury. This is because of its function of gathering light rays and transmitting them to the retina, so that an image can be generated. The cornea, the most anterior part of the eye, has to be as clear as any clear glass. Disturbance in this clarity will result in an alteration in the visual acuity.

In the same way, the arrangement of cells in the minutest way is very crucial to the proper functioning of the central part of the eye in the visual axis, which is responsible for good vision. The cornea, lens, the chambers of the eye, the retinal layers, and the optic nerve are all part of this visual pathway which culminate in the visual cortex, in the brain which is ultimately the seat of vision perception. There are conditions, which present as ocular emergencies with loss of vision or doubling of vision, which have nothing to do with the eye, but instead have diseases of the brain and the nerves that originate there, the cranial nerves. With this minimalistic overview of the relevant anatomy, we will approach the various cause of ocular anatomy by first dividing them into three major categories, which are:

1. *Traumatic ocular emergencies*: Those related to injury. Penetrating and nonpenetrating injuries and blunt injuries.
2. *Nontraumatic ocular emergencies*: Causes not arising from injury. Infections, inflammations, vascular, and neurological.
3. Chemical injuries

PENETRATING OCULAR INJURIES

History

The maintenance of the integrity of the globe is the most natural instinct served by vision to protect the eye and it has an inbuilt protective mechanism in the following ways.

The orbit serves to protect the globe from injuries by serving as a physical block against any oncoming projectiles unless they are directly approaching it from the front.

The eyelids also protect the globe with their ability to respond to sudden external insult by shutting the lids to cover the cornea. The lids themselves are soft so it is common for penetrating injuries of severe nature to go through the lid into the globe.

In penetrating injuries, there will be a history of any of the following projectiles entering the eye: stone, bullet, sharp object, finger with great force, pencil, and crackers.

The scenarios in which these injuries happen are school—in the classroom as well as in the playgrounds and laboratories, road traffic injuries, factories, construction sites, Diwali and Dusshera celebrations because of the crackers and swords used for play, and sports, especially those that involve sharp implements and speed. Any situation can result is eye injuries of varying levels if they involve implements that are sharp or pointed, hence, preventive measures are always to be followed as per protocols. The signs/symptoms that indicate an ocular emergency can be any of the following: Sudden and acute pain, sudden drop in vision, bleeding from the eye or around it, swelling, doubling of vision, flashes/floaters, and history of injury/intraocular foreign body.

Examination

The clinical signs will vary according to the severity of the injury, associated injuries, head and neck injuries, facial injuries, orbital fractures, neurological damage, and multiple injuries. The BETT is the most widely accepted classification of ocular trauma (**Box 1**).

The BETT provides a logical key to understanding of all injuries to allow better understanding of the extent and prognosis. It is desirable that it becomes the language for everyday clinical practice. We are further simplifying the signs and symptoms so that all physicians may be able to grade and treat presenting ocular emergencies more efficiently.

A key consideration is the kinetic energy of the bow as it makes impact with the eyeball. $E = ½\ mv^2$ or (Energy) = ½ (mass) × $(\text{velocity})^2$. A sharp object will easily penetrate the eye,on the other hand blunt objects need higher kinetic energy to cause rupture of the globe. They can cause extensive damage to the intraocular structure without globe rupture.

The original classification stressed on mechanical trauma. The following is the adapted terminology of the BETT, which includes nonmechanical injuries, which has been proposed by Shukla et al. (**Table 1**).

The following are the injuries depending on which part of the eye is involved:

- *Lid lacerations*: There can be tears of the eyelids and the skin around the eye. Often, in the presence of a penetrating injury, it would be wise to look for a track, which may point to the site of penetration of the eyeball.

BOX 1: Eye trauma.

- *Closed globe injuries:*
  - Contusion
  - Lamellar laceration
- *Open globe injuries:*
  - Laceration penetrating
  - Intraocular foreign body (IOFB)
  - Perforating

TABLE 1: New classification for ocular trauma (Shukla et al.).

Local	*Associated injuries*	*Cause of injuries*
Mechanical: • Globe • Destructive • Adnexal	• Head injury • Facial injury • Multiple injury	• Industrial • Sports related • Road traffic • Assault • Agricultural • Orbital • Daily activities
Nonmechanical: • Chemical • Thermal • Radiation • Electrical		

- *Conjunctival tears*: These can be accompanied by hemorrhage in the affected area. If any hemorrhage is seen, it is wise to look for an injury in the sclera under the hemorrhage.
- *Penetrating scleral injury* will often be found if there is a local contusion in the conjunctiva.
- *Penetrating corneal injuries:* The extent of the corneal tear will determine the extent of the injury.
- *Closed penetrating corneal injury*: If the injury is small it may be self-sealed or partial and the integrity of the globe will be maintained, this may be still a closed globe injury because the injury is partial thickness or sealed. The iris may seal the wound. If there is a knuckle of the iris in the wound, it is imperative for the iris to be repositioned in order to avoid the dreaded complication of sympathetic ophthalmia in the other eye. There may be blood in the anterior chamber of the eye known as hyphema. In the process of the blood been mobilized out of the anterior chamber, there may be blood cells which block the anterior chamber angle from where drainage from the anterior chamber takes place. This will lead to a rise in the intraocular pressure. It is imperative to look for a retained intraocular foreign body, which may be imbedded in any of the intraocular structures, that is, the cornea, the iris, the lens, or the retina. There can also be blood in the vitreous cavity of the back of the eye, which makes it difficult to see the retina. In these cases, if an iron foreign body causes the penetrating injury, a simple X-ray of the orbit will reveal the embedded foreign body. It is important to remove these foreign bodies because these are toxic to the eye. If there is an accompanying retina injury, the retina may be detached or may have a hemorrhage. Direct optic nerve injuries are rare but penetrating injuries have been known to sever the optic nerve completely causing optic avulsion.
- *Open globe injury*: When there is full thickness corneal wound and open globe.

NONPENETRATING OCULAR INJURIES

Blunt/Closed Globe Injury

The eye is a finely balanced instrument of vision and in order to achieve its perfect functionality, all the anatomical arrangements in the path of the light has to be in perfect alignment. Any injury, which leads to misalignment or alteration of the normal anatomy of these anatomical structures, will cause an aberration in its function, which results in loss of vision to varying extents.

Symptomatic Presentation

The patient may have any of the following complaints following blunt trauma to the eye:

- Watering
- Foreign body sensation
- Inability to keep the eye open
- Photophobia
- Loss of vision
- Pain
- Doubling of vision

Clinical Findings

Again, the approach to localizing the diagnosis must be logical and methodical, examining the eyeball and noting the findings from the outer part of the eye and progressing inward.

Contusions (Nonpenetrating Injury)

In contusion injuries, there may be injury to the eye wall, i.e., the sclera and the cornea. Look for any swelling in the supraorbital margins, the eyebrows or the eyelids. The discoloration of the lids will be evident if there is a localized hemorrhage anywhere on the forehead or eyebrows. Pooling of fluid will follow the gravitational pull and swelling will usually extend downward toward the cheekbones presenting as a *black eye*.

Supraorbital Injuries

Injuries in the area of the eyebrow line with a swelling over the lateral one-third of the eyebrow must be looked at carefully. Very often there will be an indirect optic nerve compression injury. In such cases the pupillary reaction must be closely evaluated to indicate any afferent pupillary defect. These are often overlooked in the face of other seemingly more serious injuries and can result in permanent loos of function of the optic nerve and visual loss. The only indicator will be an afferent pupillary defect in the presence of the supraorbital injury because the optic atrophy will not be apparent in the initial stages. A timely course of systemic steroids can save the optic nerve from damage due to local inflammation and edema and need to be given immediately, on detection.

Subconjuctival Hemorrhage

These are alarming to look at but will be harmless and easily treated by local cold compresses alone with lubricating eye drops to ease any foreign body sensation (**Fig. 1**). The important possible underlying injury to look for is that of a scleral rupture which can be hidden by the hemorrhage. There may also be an involvement of the ocular muscles with accompanying diplopia.

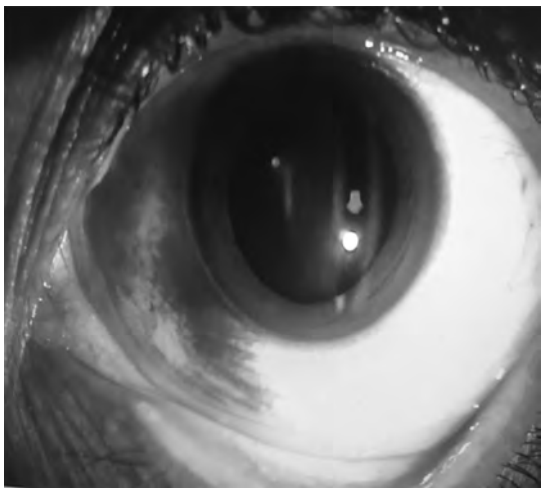

FIG. 1: Subconjunctival hemorrhage. ***(For color version, see plate 14)***

Corneal Abrasions

These are the most common injuries after any impact (**Fig. 2**). The cornea is intact but the continuity of the surface is compromised. The presence of corneal injury will typically give rise to acute and copious watering accompanied by unbearable foreign body sensation. This is a protective response, which help to protect the cornea from drying and infection when the surface is abraded. The eye remains closed and the pain is acute. On staining the cornea with fluorescein dye a tell-tale fluorescence will be clearly detected indicating a breach in the corneal epithelium. These require pad and bandage with an antibiotic ointment to assist resurfacing for as long as the corneal epithelium takes to heal completely. Examination must be done every 24 hours with a repeat pad and bandage every day until the epithelium is resurfaced and the cornea no longer registers staining. Healing can sometimes result in various levels of scarring. Depending on the site of the initial injury, the vision can be variously affected with central scars obviously causing the maximum loss.

Hyphema

It is defined as blood in the anterior chamber. The presence of blood in the anterior chamber of the eye can follow open (penetrating) as well as closed (nonpenetrating) injuries of the eye. Whenever there is a history of significantly severe force, any blunt injury of the eye can cause blood to collect in the anterior chamber. This occurs due to direct force on the iris causing it to bleed.

Associated Injuries

There can be various nonobvious effects that can accompany a bleed into the anterior chamber. These have to be detected early to prevent future vision loss. Angel recession must be ruled out with a good gonioscopic examination of the anterior chamber angle. The incidence of angle recession can be anywhere between 20% and 90% of all ocular trauma and of these 5–20% will develop angle recession glaucoma. Angle recession of the angle of >180° has a high risk of raised intraocular pressure. Raised intraocular pressure will also result due to the hyphema itself, concomitant uveitis or anterior dislocation of the lens. All or any of these can cause blockage of the trabecular meshwork. The patient must be given a pad and bandage to rest the eye and speed the mobilization of heme from the anterior chamber. The patient is also encouraged to lie in a semi-reclined position as the resolving hyphema can result in deposition of heme pigments on the anterior surface of the lens. In case the hyphemia is increasing over the first few days, look for iris injury.

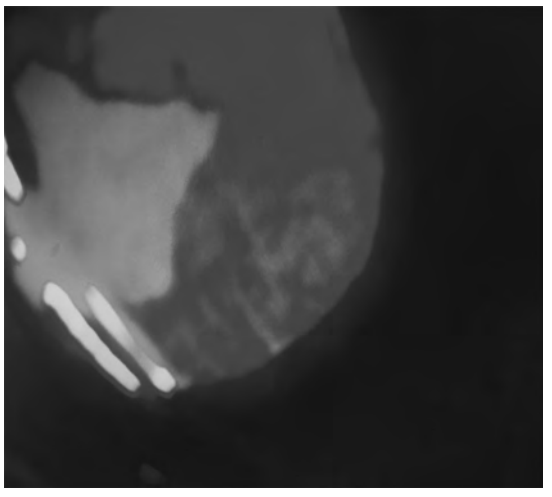

FIG. 2: Corneal abrasion. ***(For color version, see plate 14)***

Iris Injuries

Injuries to the iris will give a good indication of the presence of an angle recession. The iris sphincter damage will result in a dilated nonreacting pupil with no loss of a consensual response to light.

Vitreous Hemorrhage

Retinal hemorrhage, retinal tears, or posterior vitreous avulsion can also result in a bleed into the vitreous cavity. This will result in severe loss of vision. The fundus glow will be lost on distant direct. Ultrasound examination (preferably B-scan) will reveal the extent of the injury and can identify any retinal detachment, which significantly decreases the visual prognosis.

Retinal Injuries

Injuries to the retina may or may not result in immediate loss of vision. If the injury is sparing the macula and is not in the visual axis, the vision may not be affected on primary examination. Floaters are a good indicator of the presence of vitreous liquefaction and maybe a retinal tear. Flashes will most certainly accompany a tear in the peripheral retina. Careful history taking is a must to determine this. In case there are any complaints of floaters or flashes, the peripheral retina must be screened repeatedly over the following weeks to make sure that small tears in the retina is not missed. These are potentially preventive with timely treatment. Retinal hemorrhages can be present without symptoms and can be easily detected by careful examination of the retina with a 90D lens as well as careful indirect ophthalmoscopy. They need no treatment except observation and follow-up.

Berlin Edema

This is caused by countercoup injury to the macular due to impact over the anterior part of the globe. It is also called commotio retinae in keeping with the pathophysiology, where the injury is indirect, due to the transmission of the force across the tissues causing damage across the point of impact. There is retinal swelling, which can cause a significant drop in the visual acuity, which usually resolves spontaneously in a couple of weeks.

Extraocular Muscle Involvement

Any involvement of the extraocular muscles will give rise to diplopia. Any complaint of diplopia demands a thorough evaluation of the surrounding orbital spaces and bony structures for any inflammation or fracture and trapping of any of the ocular muscles within the fracture. The diplopia will usually resolve spontaneously with anti-inflammatory medication and requires observation till healing is complete before contemplating surgical management. Blow out fractures involve fracture of the inferior wall and may sometimes need surgical correction without which the diplopia will not resolve.

CHEMICAL INJURIES

As far as ocular injuries go, chemical injuries are the most dreaded and difficult to contain. It is absolutely essential that they be recognized immediately and managed efficiently as this will determine the visual prognosis. The load of contaminant, the response time, and type of contaminant determines the success of treatment. The goal is to eliminate the causative substance and restore the conjunctival spaces to the normal PH level as soon as possible so as to limit the seepage of the contaminant into the deeper layers of the ocular surface tissues.

Alkali Burns

In this respect, alkali burns continue to be the most challenging situations because of the nature of alkali. They can saponify the cell membrane and penetrate the cornea rapidly into the anterior chamber causing the PH of the aqueous to rise thereby damaging the iris and ciliary body. The vascular supply can be affected causing ischemic damage to the cornea leading to rapid deterioration of the integrity of the ocular surface.

Acid Injuries

On the contrary, the nature of acid burns is to coagulate and fix the ocular tissues so that there is limited penetration to the deeper structures. They may cause expensive immediate damage but will contain themselves after the initial insult.

Management

Immediate and copious irrigation of the affected eye should be carried out and continued until PH testing of the conjunctival sac returns to normal. This helps the offending substance to leech out gradually, thereby limiting the extent of penetration into the deeper tissues.

After sufficient irrigation has been carried out, a detailed history of the type of chemical involved in the injury. In case there is evidence of any solid particles, these must be carefully removed from the conjunctival sac so that there is no risk of continued penetration.

The presence of limbal ischemia is an indicator of the extent of injury and will determine the prognosis. Corneal epithelium integrity has to be determined by fluorescein staining of the cornea. In the presence of alkali burns, 10% potassium ascorbate drops have been seen to be useful in limiting damage to the ocular tissue by scavenging free radicals released by degranulating polymorphs. Further management will best be done by an ophthalmologist and will involve prevention of scarring with the use of antibiotic steroid combinations, ointment, and pad and bandage. Further surgical treatment may be required to treat any scarring that is bound to occur if the injury is extensive.

CONTACT LENS-RELATED EMERGENCIES

Displaced or Broken Contact Lenses

This is a common complaint. The patient may or may not be aware of the contact lens inside the eye. Patient may present with pain, foreign body sensation and red eye. A careful history will determine that the patient is a contact lens user. Detailed examination of the eye must be done to detect the presence of a contact lens in the conjunctival sulcus. Removal of the lens and antibiotic along with lubricating eye drops will suffice as treatment. Sometimes, the patient would have tried unsuccessfully to extract the contact lens and may have abrasion on the cornea. This will require a pad and bandage with antibiotic ointment for 24 hours.

CONJUNCTIVITIS

These will sometimes report to the emergency room and working knowledge is useful even though they are rarely sight-threatening and have very few complications apart from superficial corneal scarring. Allergic or infective inflammation of the conjunctiva can occur suddenly and without warning making it an ocular emergency. Allergic conjunctivitis will most often be accompanied by edema of the surrounding adnexa. The eyelids will be swollen without much inflammation and increased local temperature. The conjunctiva will reveal typical papillary response with causing acute dry eyes and foreign body sensation. The discharge will be watery if there is not accompanying infection. Bacterial conjunctivitis will by typically accompanied by mucopurulent discharge and matting of the lashes. A conjunctival swab from the lower fornix for Giemsa stains and culture sensitivity before treatment would be prudent to allow specific antibiotic therapy according to the sensitivity pattern.

Viral conjunctivitis will be accompanied by decreased corneal sensations and this simple test can prevent unnecessary antibiotic exposure. The symptoms will vary little except for the lack of mucopurulent discharge. Epidemic keratoconjunctivitis must be treated with close follow-up and will usually not require topical antibiotic unless the picture is of a mixed infection with superadded infection. Prevention of transmission of this highly contagious disease is as important as the treatment of the disease itself in order to limit the proportion of the epidemic. Personal hygiene lessons must be given along with other management.

CORNEAL ULCERS

Corneal ulcers are a dreaded condition, which unless treated immediately and well, can lead to nonhealing and chronically debilitating complications that are potentially blinding.

They can be of bacterial or viral infective origin and can also be degenerative. These will all present with similar symptoms of red eye accompanied by extreme pain and photophobia.

Bacterial Corneal Ulcers: Examination will reveal a staining ulcer on the cornea of varying depth and extent depending on the severity of the condition. If caught early, a course of broad-spectrum oral antibiotics along with local fortified antibiotic drops will prevent further deterioration and promote restoration of the normal epithelial integrity. Mydriatic eye drops will alleviate pain and redness and relieve the photophobia.

Viral corneal ulcers can be identified by the classical dendritic pattern on staining. Topical and systemic antiviral medication will be required to promote healing. Mydriatic eye drops will alleviate pain and redness and relieve the photophobia in these conditions as well.

UVEITIS

This potentially debilitating condition can present as an anterior, posterior, or panuveitis, involving both the anterior as well as the posterior chambers of the eye. The patient will present with complaints of a varying degree of pain and photophobia depending on the severity of the inflammation. If caught early, the treatment will prevent deterioration otherwise the inflammation progresses to create keratic precipitates (KPs) on the endothelium with outpouring of cells into the anterior chamber resulting in an increased stickiness of the iris. Unless the ciliary muscles are kept in motion by the prescription of a medium long-acting mydriatic eye drop, the sticky iris will form posterior synechiae with the anterior lens surface.

Management

Immediate management of uveitis aims to decrease the inflammation by the administration of topical and if severe enough, oral corticosteroids to control the inflammatory response. The prescription of mydriatic eye drops is necessary in order to prevent synechiae and also to relax the ciliary muscles thereby decreasing the pain. Long-term management must include all tests for the detection of an underlying cause. Pointers toward possible cause are the type of KPs (fine KPs in nongranulomatous uveitis and thick mutton fat KPs in granulomatous uveitis). These are not in the purview of emergency management.

GLAUCOMA EMERGENCIES

High intraocular pressure in the eye will result in the following: Pain due to stretching of the ocular structures, blurring of the vision, and haloes due to corneal edema. The pupillary reactions will be sluggish. If the patient has angle-closure glaucoma, the anterior chamber will be flat with possible iris bombe, if there is a pupillary block.

Angle-closure Glaucoma

This is a very typical presentation with a patient complaining of headache accompanied by generalized congestion of the conjunctiva with blurring of vision. Bringing the intraocular pressure down is immediately rewarding with alleviation of symptoms. Further management on follow-up will require preventive yttrium aluminum garnet (YAG) laser peripheral iridotomy. Angle-closure glaucoma will cause most glaucoma emergencies but the intraocular pressure can also be high in untreated open angle glaucoma, secondary glaucoma, or steroid induced glaucoma, resulting in similar symptoms without flattening of the anterior chamber.

NEURO-OPHTHALMOLOGY EMERGENCIES

Ocular emergencies of neurology origin will bring the patient into the emergency room with any of the following complaints:

- *Sudden loss of vision*: The most ominous and urgent complaint that can result from optic neuritis, temporal arteritis, and intracranial lesions affecting the optic tract or papilledema.
- *Diplopia*: This is a very debilitating condition that can arise from loss of innervation to any of the muscles groups or isolated muscles.
- *Ptosis*: Usually resulting from under action of the third nerve alone or in conjunction with other nerves.
- *Proptosis or periorbital swelling* in case of thyroid ophthalmopathies and orbital tumors. Management will involve investigation to isolate the cause and treatment of the cause itself if one is found.

OPTIC NEURITIS

Inflammation of the optic nerve will result in swelling of the optic nerve head with loss of vision to varying degrees. The pupil will show afferent pupillary defect in the side involved. Management with intravenous (IV) methylprednisolone or a short course of oral steroids is indicated and visual outcome is dependent on early initiation of treatment. If systemic steroids are not instituted early, they have questionable efficacy in the late stage. Central vision may be maintained with a significant peripheral field loss so a visual field analysis (VFA) test and an optical coherence tomography (OCT) to demonstrate optic nerve abnormality is highly indicated.

PAPILLEDEMA

Routine evaluation of hypertensive patients may reveal the presence of papilledema, which then becomes an emergency. On evaluation, the blood pressure may be found to be dangerously high. Neurological emergency patients may present with papilledema, in which case, the pupils may be sluggish and the visual fields indicative of the pathology.

VASCULAR EMERGENCIES

Sudden loss of vision may be a complaint in patients with vascular abnormalities resulting in hemorrhages in the retina or the vitreous cavity. Dilation of the pupil will reveal the pathology.

Venous Occlusion: Central Retinal Vein Occlusion and Branch Retinal Vein Occlusion: Semi-emergencies

Symptoms

Sudden onset of floaters and varying degrees of visual loss depending on the volume of hemorrhage. Venous occlusions are the most common causes of visual loss in diabetic retinopathy. Central retinal vein occlusion (CRVO) at the optic nerve is one of the causes of sudden visual loss. 90% of these occur in people over 80 years. Branch retinal vein occlusion (BRVO) or branch vein occlusion will also cause visual loss but occurs in the branch veins.

Central Retinal Artery Occlusion

It is an acute emergency. Sudden and complete loss of vision, which may or may not be accompanied by history of acute, transient, pain, or headache. This is one of the most dreaded causes of sudden loss of vision. It involves blockage of the central retinal artery resulting in acute ischemia. The treatment requires quick diagnosis and lowering of the eye pressure with ocular massage and medication. Only one out of four patients will retain good vision on recovery.

VITREOUS HEMORRHAGE

Symptoms

Sudden and painless loss of vision to varying degrees depending on the extent of the hemorrhage. Examination in all these cases will reveal loss of vision with abnormal fundus glow. The eye will be quiet and there is usually no pain unless the intraocular pressure is high. The intraocular pressure must be checked, as it can be associated with abnormal vasculature that can be the cause of both the hemorrhage as well a rise in the intraocular pressure.

Management

Vitreous hemorrhage is not an acute emergency. The symptoms are very mild, apart from the vision loss. The patient needs to be thoroughly examined to rule out the presence of a retinal detachment. Manage any comorbidity like hypertension or cardiac disease, which may be the pathogenesis of the condition. If patient is on any anticoagulants, either stop them or modify them according to INR. The immediate management of central retinal artery occlusion (CRAO) is directed at bringing down the intraocular pressure to facilitate greater perfusion. This is done by undertaking anterior chamber paracentesis and with the help of medical management to bring down the intraocular pressure. Efforts must be then made to isolate possible causes with full blood work and cardiology workup.

SUMMARY

Successful patient outcomes in the setting of ocular emergencies depends on correct recognition and assessment as well as appropriate initial management and referral. Assessment involves a concise history, observation, pupil examination, and ocular movements should be tested in patients with a suspected orbital wall fracture. Documentation of visual acuity or subjective vision is vital. Important conditions to recognize include penetrating injuries, nonpenetrating injuries, chemical burns, acute angle-closure glaucoma, orbital cellulitis, and retinal detachment. Common presenting complaints in emergency department, their evaluation, and interventions are summarized in (**Table 2**).

TABLE 2: Common eye problem presentation in emergency department and their evaluation and treatment.

Presentation	***Possible causes to look for***	***Investigations***	***Treatment***
Acute foreign body sensation accompanied by watering and conjunctival congestion	• Corneal or conjunctival foreign body • Conjunctivitis	Fluorescein staining/evert the upper lid and check the palpebral conjunctiva/check the conjunctival fornices	• Antibiotic eye drops and ointment • Moisturizing eye drops • Removal of foreign body and pad and bandage with antibiotic ointment for 24 h and close follow-up
Acute foreign body sensation accompanied by watering	History of injury: Paper edge/blunt trauma/pointed substances/finger/eye pencil	Fluorescein staining	Pad and bandage with antibiotic ointment for 24 h and repeat if there is residual staining with fluorescein under observation in cobalt blue filter
Acute pain with circumciliary congestion of the conjunctiva	Flare and cells in the anterior chamber/presence of posterior synechiae	CBC with ESR/ACE/ANA/ tubercular antibodies	Topical corticosteroids in high frequency initially depending on the grade of cells and flare in the anterior chamber, in tapering dosage. In the presence of severe or pan uveitis, systemic corticosteroids are advised
Acute pain with congestion, photophobia, and haloes	Flattening/shallowing of the anterior chamber accompanied by high intraocular pressure	Check the intraocular pressure and do a gonioscopy to determine the presence and grade of angle-closure	Antiglaucoma agents, specifically pilocarpine eye drops to induce miosis causing the intraocular pressure to drop. If insufficient, injection mannitol can be given in IV bolus over 20 min after checking the blood pressure
Sudden painless loss of vision	Optic disk edema or hyperemia/ disk hemorrhages/optic disk pallor/retinal ischemia (CRAO, CRVO, and BRVO)	OCT and fluorescein angiography/visual field test/ check pupillary reaction	Refer to ophthalmologist for OCT/VFA and fluorescein angiography before starting any treatment. In case of CRAO, immediate paracentesis and ocular massage is very essential
Sudden painless loss of vision/floaters and flashes	Gray fundus reflex/retinal detachment on indirect ophthalmoscopy	Screening of the peripheral retina to rule out any holes/ tears or retinal detachment	Refer to ophthalmologist for treatment of retinal detachment
Sudden blurring of vision with history of mild pain or painful movements	Afferent pupillary defect/field defect and blurring of the disk margins to suggest optic neuritis	Visual field test/OCT	Systemic steroids have a role if started early otherwise their role is debatable

Continued

Continued

Presentation	*Possible causes to look for*	*Investigations*	*Treatment*
History of injury/dog bite/ RTA/blunt injuries	Look for penetrating injuries or orbital fracture/history of abuse/ look for supraorbital injury	X-ray orbit to rule out retained intraocular foreign body/diplopia charting/ pupillary reaction	Dog bite protocol has to be followed according to guidelines. The face is a very sensitive area. May need repair/ refer to ophthalmologist. Seidel sign test: Put fluorescein in the eye and check for aqueous leak on the slit lamp
History of splash or contact with chemical agents/sprays	Detailed history is required to determine the agent and classify it as an acid or alkali. The treatment is specific and must be instituted immediately		Wash the eye from the medial to the lateral side for at least 30 min with normal saline or water if none is available. Find and remove all crystals. Irrigate till the pH reading returns to 7–7.3. In alkali injuries, 10% potassium ascorbate has been shown to decrease morbidity

(ACE: angiotensin-converting enzyme; ANA: antinuclear antibody; BRVO: branch retinal vein occlusion; CBC: complete blood count; CRAO: central retinal artery occlusion; CRVO: central retinal vein occlusion; ESR: erythrocyte sedimentation rate; OCT: optical coherence tomography; RTA: road traffic accident; VFA: visual field analysis)

134 CHAPTER

Ear Emergencies

Shaarang Sachdev, Salil Malik

INTRODUCTION

A variety of emergency conditions related to ear problems; emergency physician may need to handle in emergency department (ED). Common ear emergencies are related to infections either related to outer middle or inner ear. It is important for the emergency physician to aware about the anatomy of the ear to effectively manage the ear emergencies. Other emergencies like trauma to ear are also needs to manage effectively. This chapter describes infections, trauma, and procedures related to ear.

ANATOMY OF EAR

External Ear

The auricle or the pinna of the external ear is a protruding structure prone to traumatic lacerations. It consists of an elastic cartilage with tightly attached overlying skin, receiving its blood supply from the underlying perichondrium. Exposure of the cartilage after an injury may lead to infections, erosive chondritis, and necrosis. The outer one-third of the external auditory canal (EAC) has an incomplete cartilage whereas the inner two-thirds is composed of bone with a tight overlying skin attachment that easily injured due to a minute trauma.

The blood supply is from the superior temporal vessels in the anterior part and the posterior auricular vessels in its posterior part. The connection of the posterior auricular vein to the sigmoid sinus is a source of the intracranial spread of infections.

The nerve supply is via the auriculotemporal nerve, greater auricular nerve, lesser occipital nerve, and the vagus nerve. The posterior wall of the EAC is supplied by the vagus nerve and so it would not be anesthetized with an auricular nerve block if any repair is required. Anatomy of ear is described in **Figure 1** and normal otoscopic examination shown in **Figure 2**.

Middle Ear

The middle ear is an air-filled cavity in the petrous bone that extends from the tympanic membrane (TM) laterally to the oval

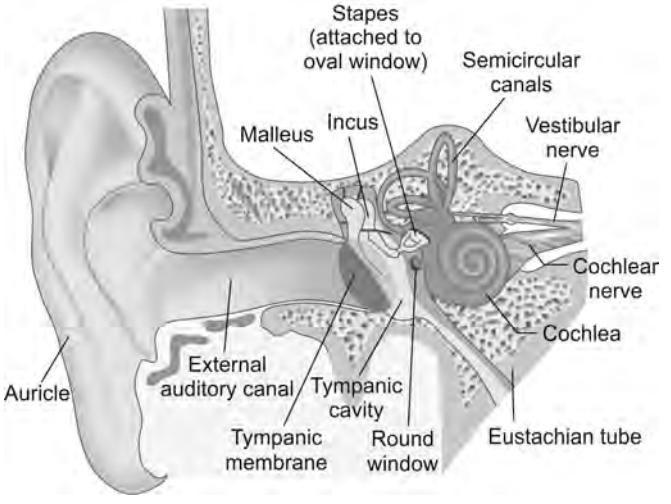

FIG. 1: Anatomy of the ear.

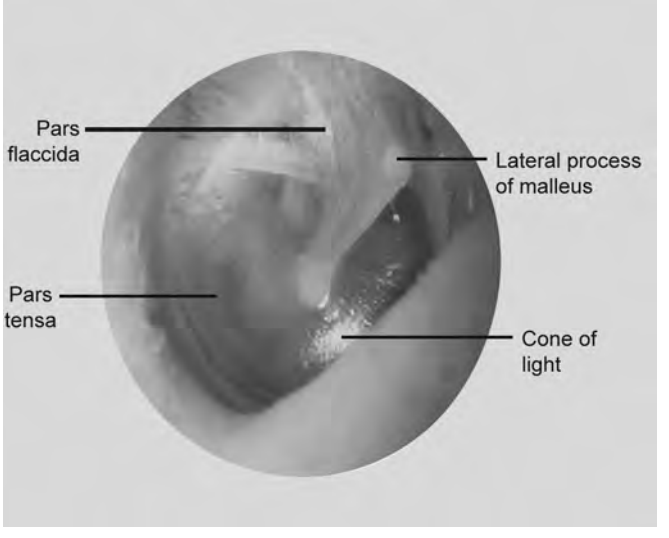

FIG. 2: Normal ear on otoscopic examination. ***(For color version, see plate 14)***

window medially and contains the three auditory ossicles—malleus, incus, and stapes.

Anteriorly, it communicates with the nasopharynx via the eustachian tube, and posteriorly, to the mastoid. Superiorly is the attic or the epitympanum. Most of the infections and barotrauma to the middle ear is due to the dysfunction of the eustachian tube due to inflammation, obstruction, or direct trauma. The relative horizontal and short nature of the eustachian tube in the pediatric population accounts for higher incidence of otitis media (OM) as it hinders its drainage via gravity with increased transmission of infections from the nasopharynx.

The TM is an oblique fibrous membrane attached medially to the malleus at the umbo forming the *cone of light* [as visualized via the otoscope (**Fig. 2**)]. Superiorly, the *pars flaccid* is a thicker part of the TM. The remainder of the membrane is thin, known as the *pars tensa* and is prone to perforation.

The facial nerve transverses through the posterior wall of the middle ear. The innervations of the middle ear are via the tympanic nerve (CN IX), auriculotemporal nerve (CN V), and the auricular nerve (CN X).

Inner Ear

The inner ear consists of the bony and the membranous labyrinth.

- The bony labyrinth is part of the temporal bone and contains the cochlea, the vestibule and the three semicircular canals and is filled with perilymph.
- The membranous labyrinth consists of the cochlear duct (hearing organ), the vestibule (utricle and saccule), and the semicircular ducts (balance organs).

Vestibular afferent nerves passing to the brainstem help modulate body balance, tone, body, and eye movements. Blood supply is from the vertebrobasilar system. Since the anterior vestibular artery supplies the semicircular canals and not the cochlea, its isolated occlusion leads to vestibular syndrome without auditory defects.

COMMON SYMPTOMS OF EAR PROBLEMS

Common symptoms related to ear pathology are otalgia tinnitus and hearing loss and their causes are summarized in **Table 1**.

Otalgia

Otalgia or earache can be classified as primary otalgia and referred otalgia. Primary otalgia is caused by diseases of the auricular and periauricular structures, whereas referred otalgia is caused by diseases originating from distant structures. Causes of *primary otalgia* include infections of the ear (otitis externa, OM, etc.), cerumen impaction, otic foreign bodies, trauma to the ear, and facial neuralgias. Causes of *referred otalgia* include eustachian tube dysfunction, pathology of the temporomandibular joint, dental pathology, infections, and abscesses in and around the pharynx, nasal cavity pathology, foreign body in the throat or neck, and thyroid disorders.

Tinnitus

It is defined as perception of sound without external stimulation. Tinnitus can be divided into *objective* (which can be heard by the examiner) and *subjective. Objective tinnitus* is caused by conditions such as arteriovenous (AV) malformations and arterial bruits. Some of the conditions which cause *subjective tinnitus* include hearing loss (sensorineural or conductive), head trauma, side effects of medications (aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, loop diuretics, and chemotherapeutics), psychiatric disorders (depression and anxiety), hypertension, multiple sclerosis, and Ménière's disease. Consider antidepressants for patients presenting to ED with tinnitus and who have been advised discharge with ear, nose, and throat (ENT) follow-up. It is often difficult to elicit the cause of tinnitus in a busy emergency room. Referral to an otolaryngologist is warranted in such cases.

TABLE 1: Causes of otalgia tinnitus and hearing loss.

Causes of otalgia	*Causes of tinnitus*	*Causes of hearing loss*	*Ototoxic agents (causing tinnitus and hearing loss)*
• *Infections*: Otitis externa, otitis media, mastoiditis, myringitis, labyrinthitis, and perichondritis • Trauma • Foreign bodies of ear • *Neuralgias*: Trigeminal, herpetic, and great auricular neuralgias • *Dental*: Dental caries and abscess • *Retropharyngeal/oropharyngeal problems*: Tonsillitis and abscess • *Nasal problems*: Sinusitis and deviated nasal septum • Cerumen impaction • *Referred pain*: Temporomandibular joint problems	• *Objective causes*: Arteriovascular malformation, arterial bruit, eustachian tube enlargement, and stapedial muscle spasm • *Subjective causes*: Sensorineural hearing loss, conductive hearing loss, head injury, hypertension, depression, anxiety, acoustic neuroma, multiple sclerosis, Ménière's disease, and Cogan's syndrome	• Idiopathic • *Infections*: Mumps, Epstein–Barr virus, herpes simplex virus, and meningitis • *Ear disease*: Ménière's disease and ear surgery • *Trauma*: Head injury, barotrauma, and acoustic trauma • *Systemic disease*: Cardiovascular/ neurovascular disease, and intracranial hemorrhage	• *Antibiotics*: Aminoglycosides, vancomycin, erythromycin, neomycin, and polymyxin B • *Salicylates*: NSAIDs and quinine • *Diuretics*: Furosemide and bumetanide • *Chemotherapeutic drugs*: Carboplatin, cisplatin, vinblastine, and vincristine • *Others*: Ethanol, sildenafil, and tadalafil

(NSAIDs: nonsteroidal anti-inflammatory drugs)

Hearing Loss

Sudden hearing loss can be divided into *sensorineural* (cochlea, auditory nerve, or central auditory processing) and *conductive* (external ear, TM, and ossicles).

Conductive hearing loss generally occurs in reversible conditions such as otitis externa, OM, or cerumen impaction. Causes of sudden hearing loss are varied and may be idiopathic (most common), infectious, vascular, hematologic, metabolic, rheumatologic, or conductive. Evaluate the medication history of the patient for possible toxic side effects.

Prior history of trauma or a pop heard preceding the hearing loss may indicate perforation of the TM or ossicular dislocation. Ménière's disease usually presents with a triad of hearing loss, vertigo, and nystagmus. If the physical examination is unremarkable (perhaps a conductive hearing loss ruled out), consider urgent otolaryngology consultation. Consider glucocorticoids (60 mg of prednisone OD for 7–14 days or dexamethasone 300 mg OD for 3 days) with ENT follow-up for suspected idiopathic sensorineural hearing loss.

Weber Test

Weber test is performed by placing a vibrating tuning fork on the forehead of the patient. Normally, the sound is heard equally on both sides. Lateralization of sound to either side implicates either a conductive hearing loss on that side or a sensorineural hearing loss of the other ear.

Rinne Test

Rinne test is performed by placing the tuning fork over the mastoid bone, and then moving it towards the entrance of the ear canal. The sound is usually heard better though the air conduction than the bone conduction. A conductive hearing loss of the ear can be established if the sound is heard better over the mastoid bone on that side.

OUTER EAR INFECTIONS

Acute Diffuse Otitis Externa

Otitis externa is the infection and inflammation of the EAC. Predisposing factors for the development of otitis externa include disruption of the skin integrity of the EAC, secondary to scratching or overzealous disimpaction of cerumen (**Fig. 3**). It occurs mostly in summers and in tropical climates. It is often referred to as swimmer's ear. Diabetic patients have a higher cerumen pH, therefore, a higher incidence of otitis externa in this population.

Microbiology: Pseudomonas aeruginosa, *Staphylococcus aureus, Staphylococcus epidermidis*, and Enterobacteriaceae are the common microbes involved. Fungal otitis externa (otomycosis) occurs in tropical climates and in the immunocompromised individuals or in individuals who have been previously on long-term antibiotic therapy. Most cases are caused by *Aspergillus* or *Candida.* Topical medications and hearing aids are implicated in causing noninfective otitis externa.

Clinical features are pruritus, otalgia, erythema, and edema of the EAC (**Fig. 4**). Otorrhea, crusting of the ear canal, mastication, or periauricular skin movement triggers the pain and hearing loss in severe cases.

Emergency department treatment includes analgesia, keep the ear dry and advise against inserting anything in the ear, nonototoxic ototopical antimicrobials with or without steroids (aminoglycoside is contraindicated in cases of TM perforation), cleansing of the EAC (irrigation with *hydrogen peroxide* in a 1:1 dilution with warm saline or water or a gentle suction under direct visualization), acidifying agents (acetic acid), aural toilet ± ear wick insertion in case significant canal edema or extensive debris, and ENT specialist review, if needed.

The following are commonly used antibiotic/steroid regimens:

- Ofloxacin otic five drops BD
- Acetic acid/hydrocortisone otic five drops thrice daily (do not use with perforated TM)
- Ciprofloxacin/hydrocortisone otic three drops BD
- The above antibiotics are commonly used for 7 days to treat otitis externa. Oral antibiotics indicated in febrile patients and those with periauricular spread of the disease. If fungal infection is suspected, treat with topical *clotrimazole* 1% solution. Alternatively, systemically treat with an antifungal agent such as *fluconazole.*

Malignant Otitis Externa

Malignant otitis externa is a potentially life-threatening infection of the external ear/canal/soft tissue with possible spread to the skull base. Malignant otitis externa begins as a simple otitis externa which then spreads to the deep tissues of the external ear/canal.

FIG. 3: External ear appearance in otitis externa. ***(For color version, see plate 14)***

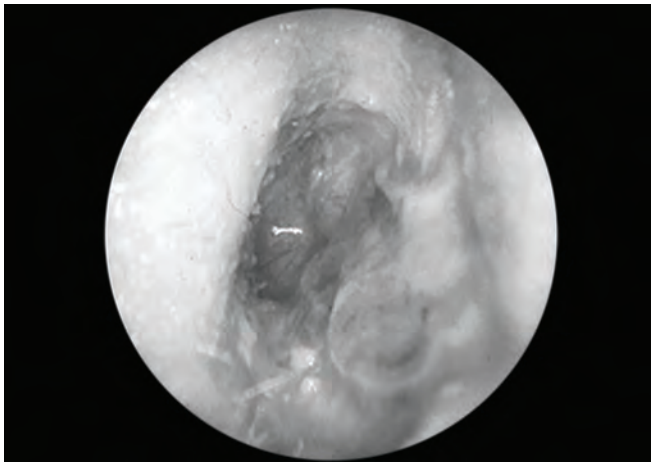

FIG. 4: External auditory canal erythema and edema. ***(For color version, see plate 14)***

Suspect in individuals with persistent otitis externa despite 2–3 weeks of topical antimicrobial therapy. Elderly, diabetic, and immunocompromised patients are most affected.

Microbiology: Pseudomonas aeruginosa and methicillin-resistant *Staphylococcus aureus* (MRSA).

Clinical features: Severe otalgia, otorrhea, edema of the EAC, granulation tissue on the floor of the EAC. Parotitis, trismus, and assess for the seventh cranial nerve function which may be affected secondary to cranial extension.

Complications: Lateral or sigmoid sinus thrombosis and meningitis.

CT or MRI of the head used to diagnose the infection. ED treatment includes analgesia, emergent otolaryngology (ENT) consultation, and admission to hospital for intravenous (IV) antibiotics. Commonly used antibiotic regimens are:

- Tobramycin 2 mg/kg IV and piperacillin 3.375–4.5 g IV
- Ceftriaxone 1 g IV
- Ciprofloxacin 400 mg IV

Perichondritis

Perichondritis is infection of cartilage of outer ear. Ear piercing, ear trauma, and burn skin infection are common risk factors while diabetes and immunodeficiency can aggravate it. Problem stars with pain, redness and swelling around the auricle and later pus develops, and fluctuation can be palpated. Any foreign body like piercing must be removed and pus should be drained to control the infection. Common causative organism is *Pseudomonas aeruginosa*. Antibiotic fluoroquinolones-ciprofloxacin orally should be started. Parenteral antibiotics may be required as SPACE (*Serratia, P. aeruginosa, Acinetobacter Citrobacter, Enterobacter*) organism develops resistance to fluoroquinolones very quickly and reaccumulation of abscess may occur. Single ED visit is not sufficient for complete treatment so patient should be referred to specialist in early stages to avoid reaccumulation of abscess or permanent disfigurement (cartilaginous destruction of auricle of the ear "cauliflower ear").

MIDDLE EAR INFECTION

Otitis Media

Otitis media primarily affects infants and children with incidences peaking in the preschool years (6–18 months of age) and declining with advancing age. Acute OM is much less common in adults than children. The most common bacterial pathogens recovered in adults with *acute OM* are *Streptococcus pneumoniae*, *Haemophilus influenzae*, Methicillin-sensitive *S. aureus*, and *P. aeruginosa*. Young adults remain protected from all *Haemophilus* strains as they have received the *H. influenzae* type b vaccine. The predominant organisms involved in *chronic OM* are *S. aureus, P. aeruginosa*, *Aspergillus*, and anaerobic bacteria (less common). *Viral OM* caused predominantly by respiratory syncytial virus and rhinovirus occur in those under the age of 10.

Clinical features: Otalgia, otorrhea, hearing loss, deafness (older children), nonspecific symptoms such as fever, lethargy, irritability, and poor feeding (younger children), prodrome of an upper respiratory infection (younger children), *and* bulging or retracted TM which may be red in color, with associated loss of light reflex may be present on otoscopic examination (**Fig. 5**). Pneumatic otoscopy almost uniformly demonstrates impaired mobility. Assess facial nerve function in view of its proximity to the middle ear.

Treatment measures include analgesia, oral antibiotics, and urgent specialist consultation for patients appearing septic or for those who present with complications of acute OM. Strongly consider IV antibiotics in such cases. The preferred initial antibiotic treatment includes:

- Amoxicillin 250–500 mg PO three times daily for 7–10 days
- Azithromycin 500 mg PO daily for 1 day then 250 mg PO daily for 4 days
- Cefuroxime 500 mg PO two times daily for 10 days

Complications of OM are TM perforation, hearing loss, acute serous labyrinthitis, facial nerve paralysis, acute mastoiditis, lateral sinus thrombosis, cholesteatoma, and intracranial complications (meningitis and brain abscess).

Acute Mastoiditis

Mastoiditis is an infection of the mastoid process of the temporal bone (**Fig. 6**). *Microbiology: S. pneumonia*e, *S. pyogenes*, and *P. aeruginosa* are common causative organism.

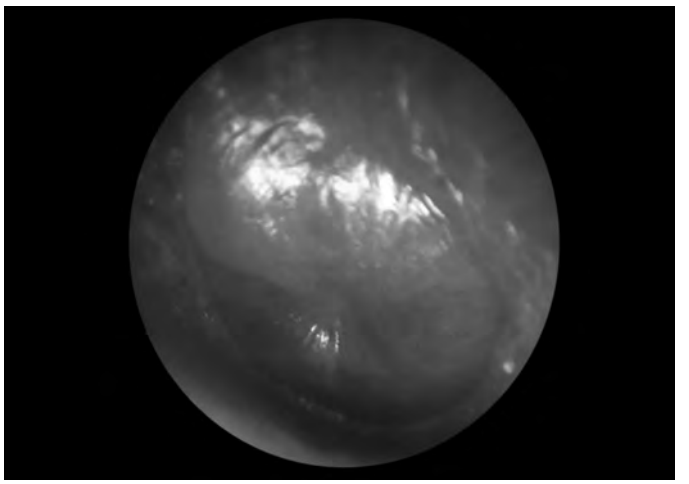

FIG. 5: Otoscopic appearance of external auditory canal and tympanic membrane in otitis media. ***(For color version, see plate 14)***

FIG. 6: Postauricular erythema and swelling in acute mastoiditis. ***(For color version, see plate 15)***

Clinical features of acute mastoiditis are otalgia, fever, otorrhea, postauricular erythema, swelling, and tenderness.

Diagnosis is by history, physical examination, and by contrast CT.

Treatment includes IV antibiotics, ceftriaxone 2 g IV, or levofloxacin 750 mg IV. Refractory cases may require irrigation and debridement with possible mastoidectomy.

Bullous Myringitis

Bullous myringitis is a form of acute OM characterized by painful fluid-filled vesicles on the TM (**Fig. 7**). Blisters may be blood filled, serous, or serosanguineous. Most commonly caused by *S. pneumoniae*, numerous other pathogens have been implicated including viruses, *Mycoplasma pneumonia,* and *Chlamydia psittaci. Clinical features* include otorrhea and hearing loss.

Treatment measures are pain control, warm compresses, and antibiotics can be given for concomitant OM.

Lateral Sinus Thrombosis

A complication of acute OM arising from spread of infection/inflammation from the mastoid to the adjacent lateral or sigmoid sinus.

Microbiology: Staphylococcus, Streptococcus, and upper respiratory anaerobes (*Bacteroides fragilis*).

Clinical features include headache (most common symptom), papilledema, sixth-nerve palsy, and vertigo.

Diagnosis by angiography with venous phase and MRI.

Treatment by IV antibiotics (a combination of cefepime 2 g IV, metronidazole 500 mg IV, and vancomycin 1 g IV), and urgent ENT specialist consultation for possible mastoidectomy.

INNER EAR INFECTIONS

Inner ear consists of two structures, *vestibular system* (semicircular canal and vestibule) which is responsible for balance and *cochlea* which converts mechanical vibration to electrical signals to brain and possible for a person to perceive and hear sound. Labyrinthitis and vestibular neuronitis are the two most common infections of the inner ear.

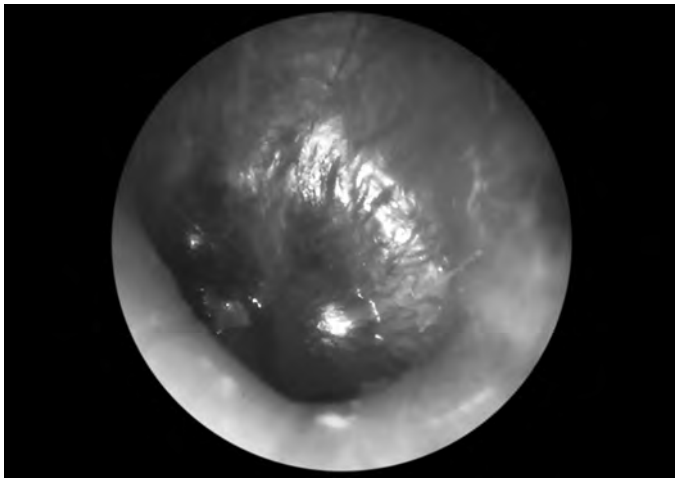

FIG. 7: Otoscopic appearance of tympanic membrane in a bullous myringitis. ***(For color version, see plate 15)***

Labyrinthitis

Labyrinthitis is infection of labyrinth and most commonly secondary to acute OM. Other conditions which give rise to seeding of infections in inner ear are meningitis, mastoiditis, cholesteatoma, and traumatic fracture of labyrinth. Vertigo, nystagmus, tinnitus, hearing loss, otalgia, nausea, vomiting with history of OM are common presentations of labyrinthitis. For diagnosing and evaluation of complication of labyrinthitis CT/MRI is best modalities. Proximity to brain and to avoid serious complication, admission specialist consultation, and parenteral antibiotics (ceftriaxone 50–100 mg/kg/day maximum 2 g IV are often prescribed. Myringotomy and mastoidectomy is recommended in severe cases.

Vestibular Neuronitis

Often considered synonym of labyrinthitis but vestibular neuronitis associated with ongoing upper respiratory tract infection and sudden and severe vertigo is common presentation. Nausea, vomiting, and horizontal nystagmus are additional features. Unlike labyrinthitis these patients do not have tinnitus or hearing loss. Diagnosis is clinical and based on history and physical examination. Though condition is primarily considered as viral cause and self-limiting, symptomatic treatment with antiemetics antihistamines and benzodiazepine is advised.

TRAUMA TO EAR

Ear Barotrauma

Ear barotrauma is caused by the difference of pressure between the atmosphere and the middle ear. The most common cause is flying. Diving, decompression sickness, hyperbaric O_2 therapy, and ballistic injuries account for more serious but less common causes.

The most common manifestation is ear fullness. However, if pressure difference is large, bleeding may occur due to rupture of TM or the oval window leading to severe conductive hearing loss. Vertigo and sensorineural hearing loss should alert the physician to investigate for perilymphatic fistula between the inner and middle ear. Tinnitus can be caused due to any of the above causes and may be pulsatile or constant.

A good history and detailed examination are the keys to a good diagnosis. Advice the patient to avoid triggers as much as possible. Oral antihistamines and nasal decongestants reduce edema around the eustachian tube. Swallowing, yawning, chewing gum, and Valsalva maneuver equalize the pressure in the middle ear with that of the atmosphere. Ventilatory tubes may be useful for patients undergoing hyperbaric therapy.

Most mild injuries heal spontaneously. Antibiotics have a little role, whereas glucocorticoids have not shown any benefit. Otolaryngologist consult would be required in cases of vertigo or sensorineural hearing loss when perilymphatic fistula is suspected. Tympanoplasty may be warranted in injuries to the ossicles. Myringotomies with or without tube have limited preventive and therapeutic values as they spontaneously close within a few days. This is especially not useful in scuba divers.

Tympanic Membrane Perforation

Tympanic membrane perforations (**Fig. 8**) may occur due to middle ear infections, barotrauma, blunt/penetrating trauma,

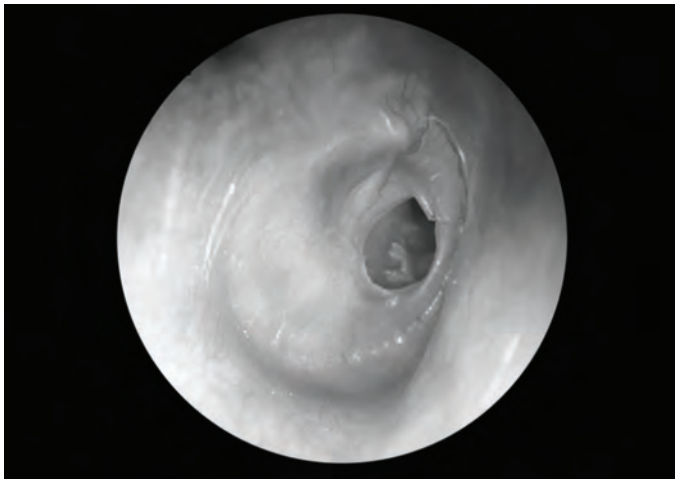

FIG. 8: Perforated tympanic membrane. ***(For color version, see plate 15)***

acoustic trauma, lightning strikes, ballistic injuries, foreign bodies in the ear canal, skull fracture, and self-injury with an ear bud. Iatrogenic, it may persist after myringotomy or with dislodgement of the drainage tube.

Perforations secondary to barotraumas are in the pars tensa involving the anterior or inferior part of the TM. *Clinical features* include otalgia, hearing loss, otorrhea (hemorrhagic or serous), tinnitus, and vertigo.

Treatment

Most TM perforations heal spontaneously. Caution should be taken; avoid liquid entering the ear canal. Topical or systemic antibiotics may be warranted for infections of the ear or otic foreign body debris. Perforations secondary to blunt or noise trauma can safely be discharged with ENT follow-up. Posterosuperior or traumatic perforations such as in penetrating injuries warrant urgent otolaryngologist consult due to a high likelihood of ossicular disruption. At times, surgical intervention with paper or a biofilm patch may be required.

PROCEDURES RELATED TO EAR

Auricular Hematoma Evacuation

Auricular hematoma is the collection of blood between the auricular cartilage and the perichondrium resulting mostly from blunt traumatic injuries seen in contact sports. As the underlying cartilage gets hypoperfused, eventually necrosis followed by fibrosis and neocartilage formation occurs. This leads to a disorganized chronic fibro cartilage overgrowth of the pinna typically known as the *cauliflower ear*. Acute hematomas are painful, tender, and tense and should be differentiated from auricular abscess, perichondritis, and chondritis. Auricular abscess will have pus rather than hemorrhagic fluid on aspiration and would be fluctuant. A skin avulsion followed by erythema indicates perichondritis or chondritis.

All auricular hematomas need to be drained either by aspiration, incision-drainage, or catheter insertion as soon as possible (**Fig. 9**). *The aim is to remove the hemorrhage and put regional pressure for days to prevent reaccumulation*. More than 7 days old hematoma may require surgical subspecialty consult. Up to 1–2% lidocaine with epinephrine may be used for regional auricular block but should be avoided for perilesional field block. Needle aspiration may be useful for small acute hematomas which are ≤ 2 cm and <48 hours old.

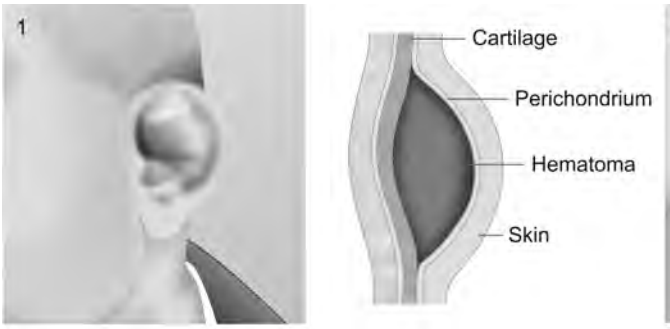
For larger and older hematomas, incise along the inner curvature of the helix and do gentle suction at the dependent part. After suturing the incision, use a petroleum jelly dipped gauze or a saline gauze to carefully pack into all the convolutions of the auricle to apply a uniform pressure at the suture site. Alternatively, a dental roll can be bolstered with a through and through suture to hold it against a similar bolster behind the auricle. After applying dry gauze to both sides of the auricle, wrap a compression bandage around the head to maintain pressure over the incision site. Revaluate the dressing daily for fluid reaccumulation for at least 5 days. Empirical antibiotics against *Pseudomonas* and *Staphylococcus aureus* should be given to all patients post treatment.

Foreign Body Removal

Cerumen or ear wax is one of the most common reasons for a person to come to the ED with complains of otalgia, fullness in the ear, dizziness, or a ringing sound. Other foreign bodies in the external ear may include small beads, button batteries, or insects.

Direct inspection can be done by pulling the pinna and tragus outwards and visualization aided by an otoscope. Most common sites for foreign body impaction are the junction of cartilaginous and bony segments followed by the isthmus of the bony segment.

- Mineral oil and preferably 2% lidocaine/benzocaine may be used to drown live objects before removal.
- Organic matter like vegetable or cellulose may expand due to irrigation with saline and hence it is advisable to follow caution in such cases.
- Irrigating from the superior part of the canal with 20 mL of saline via an IV catheter usually helps in most of the cases. Pressure should be minimum to prevent TM perforations. Use room temperature saline and direct the pressure towards the wall of the canal. Perforated TM or myringotomy tubes are contraindications for saline irrigation.
- Small alligator forceps, loops, or right-angle hooks may be used (**Fig. 10**) to pull out soft or live objects under direct visualization taking care not to erode the skin.
- Cyanoacrylate (super glue) may be applied to the end of an ear bud and stuck to the inorganic foreign body for 30–60 seconds before pulling it out.
- Suction with a thin plastic tube may be attempted to pull out smooth objects or remnants of live objects.
- Impacted button batteries may lead to necrosis of the canal and warrant immediate intervention.
- Softening of hard and dried cerumen may be done before removal. This is achieved with diluted hydrogen peroxide, mineral oil, sodium bicarbonate, or docusate sodium left in place for 30 minutes.



Auricular hematomas manifest after trauma with anterior auricular swelling. The hematoma forms between the cartilage and perichondrium and will lead to permanent deformity if not treated.

Anesthetize the pinna via local infiltration of 1% lidocaine without epinephrine or via an auricular block.

Use a scalpel to incise the skin along the natural skin folds at the edge of the hematoma. Follow the natural curve of the pinna.

Gently peel the skin and perichondrium off the hematoma and underlying cartilage. Completely evacuate the hematoma and irrigate the pocket with normal saline.

A compression dressing must be placed to prevent reaccumulation of the hematoma. Place dry cotton into the EAC and fill all external auricular crevices with saline-soaked or Vaseline gauze.

Carefully conform the material into all the convolutions of the auricle. Vaseline gauze, saline-soaked 1/4-inch packing gauze, or saline-soaked cotton may be used. Place gauze behind the ear.

Place three to four layers of gauze behind the ear as a posterior pack, and then cover the entire ear with multiple layers of fluffed gauze.

Secure the dressing to the head with Kerlix or an elastic wrap.

FIG. 9: Steps in aspiration of auricular hematoma.

FIG. 10: Different-shaped ear scoops and loops are useful to remove cerumen from an impacted ear. Miniature alligator forceps can be used to extricate foreign bodies from the external ear canal.

An otolaryngologist consult may be necessitated in cases of failed extraction, advanced infections, or glue stuck to the TM. In cases of an uncooperative patient, procedural sedation with ketamine may be needed.

Complications of Cochlear Implantation

Cochlear implants are prosthetic devices (**Fig. 11**) installed surgically and consists of a battery-operated external processor with electrodes inserted into the cochlea to stimulate the auditory nerves. Cochlear implants are commonly used in patients with moderate/severe bilateral sensorineural hearing loss. Common complications include vestibular complaints (occurs in 4% of patients), device failure, and infections (skin infections, OM, acute mastoiditis, and meningitis).

MRI compatibility should be checked before conducting the same on any patient with a cochlear implant. CT with or without contrast and device testing is usually required to diagnose the complications of cochlear implants.

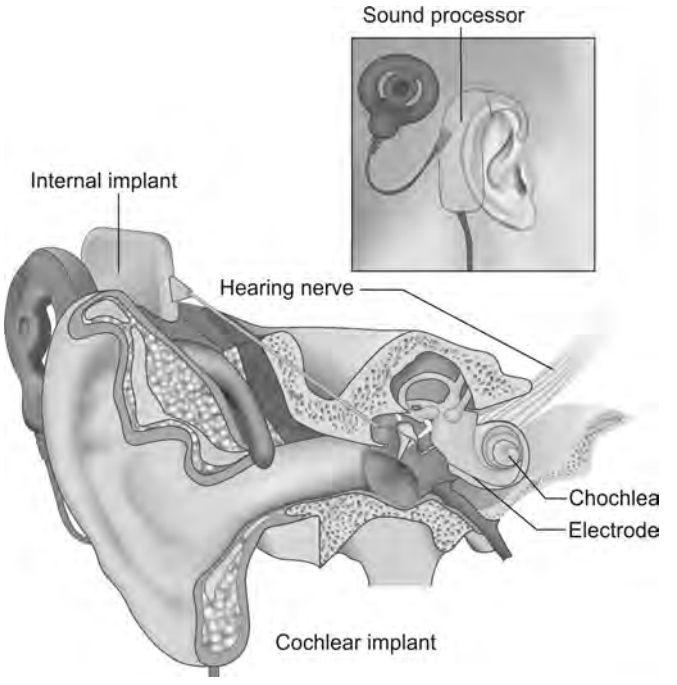


FIG. 11: A cochlear implant.

SUMMARY

It is important for the emergency physician to aware about the gross anatomy of the ear, common symptomatology of ear problem, and their causes to effectively manage the mild to serious problem of ear emergencies. Common emergencies differentiated into infections (outer and middle inner ear infections), trauma (barotrauma and traumatic rupture of TM), and complications of various ear surgery like cochlear implant. Emergency physician should have knowledge of procedures related to ear like aspiration of auricular hematoma and removal of foreign body of the ear in ED. Timely referral to specialist is important for effective management.

135
CHAPTER

Nasal Emergencies

Harshil Mehta

INTRODUCTION

Nasal emergencies are a common presentation to emergency departments and also in primary care settings. Trauma is the main cause of acute nasal injury and can present as epistaxis, nasal fracture, or even nasal septal hematoma. Epistaxis accounts for majority of all admissions to emergency ear, nose, and throat (ENT) departments and head and neck surgery facilities, and it can require cautery or packing. In some cases, surgical intervention is required. Nasal fractures are considered as most common type of facial fracture. Nasal fractures predominantly seen in the adult population because nasal spine begins to ossify at around 3 years of age, completing its growth and ossification during puberty. The incidence of nasal fractures is rising most commonly caused by blunt trauma to nose or assault. Sporting injury is also an important cause of nasal emergencies. Nasal septal hematomas require urgent evaluation to prevent nasal deformity.

EPISTAXIS

Epistaxis is one of the most common nasal emergencies that hardly turns into life-threatening (<6%). 1 in 200 emergency visits is related to epistaxis and hospitalization rate is <0.2%. It is seen more commonly with males and observed more in bimodal age distribution (2–10 years and >50 years of age). Causes of epistaxis (**Table 1**) can be divided in three categories—local, systemic, and idiopathic.

Applied Anatomy and Pathophysiology

Nasal mucosa has a very rich blood supply from internal carotid artery (ICA) and external carotid artery (ECA). Kiesselbach's plexus (Little's area) is situated anteriorly and formed by anterior and posterior ethmoidal arteries (branches of ICA), sphenopalatine, and branches of internal maxillary artery (branches of ECA). Posteriorly nasal mucosa gets blood supply from posterior branched of sphenopalatine artery (**Fig. 1**). Pathology behind epistaxis is erosion of mucosa and rupture of superficial arteries or veins. Nearly 90% of patients presents with anterior epistaxis from Little's area. Rest 10% patients presents with posterior epistaxis that is more serious than anterior and more commonly seen in old age patients with comorbidities.

Clinical Presentation

Patient presents with acute onset nasal bleed. Bleeding may be active or clotted blood is visible on examination. Sometimes complains of posterior pharyngeal trickling of blood or hematemesis is also present. Patients may have high blood pressure on presentation.

TABLE 1: Causes of epistaxis.

Local causes	*Systemic*
• Nasal trauma	• Anticoagulant therapy
• Facial trauma	• Accelerated hypertension
• Nose picking	• Pregnancy
• Nasal polyp	• Hepatic disease
• Foreign body in nose	• Blood dyscrasia
• Allergies	• Diabetes mellitus
• Dry weather	• Alcoholism
• Neoplasm	• Vitamin K deficiency
• Septal deviation	• Blood transfusion therapy
• Nasal mucormycosis	• Chronic use of nasal vasoconstrictor
• Postoperative epistaxis	• Cocaine use
	• Drug-induced thrombocytopenia

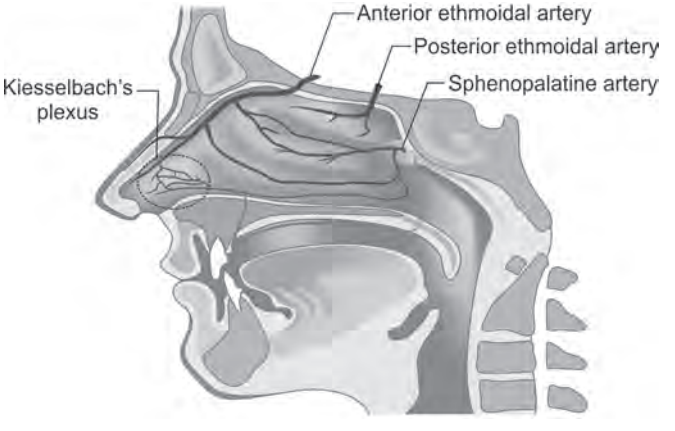

FIG. 1: Nasal anatomy.

Red Flags

Be careful as an emergency physician while treating patients with epistaxis with following signs: Bleeding not stopped by direct pressure, suspected sock, recurrent unilateral bleed, associated symptoms such as facial pain, numbness or diplopia, anticoagulants, or anything to suggest blood disorder.

Evaluation

History

For stable patients, nasal and systemic histories are important. Specific questions regarding duration, severity, frequency, location, laterality, precipitating factors of epistaxis, and methods used to stop need to be asked. Nose picking or local trauma to nose along with spontaneous nose bleed is frequently reported. History regarding other symptoms should be asked to suspect systemic causes. Headache, hematemesis, melena, easy bruising, or other bleeding episodes should make clinical suspicious of a systemic cause and prompt a hematologic workup. Past medical history, use of medication [especially aspirin, warfarin, nonsteroidal anti-inflammatory drugs (NSAIDs), heparin, ticlopidine, and dipyridamole), and family history should be documented.

Physical Examination

Check vitals of patient. Make patient stable if any abnormality observed. Nasal examination requires nasal examination instruments including nasal speculum (**Figs. 2** and **3**), adequate illumination, proper suction, and required topical medicines, cauterization, and packing material ready. External nasal examination for any trauma is the initial step in examination. Remove previous nasal packs and watch for active bleeding. Topical vasoconstrictor (0.05% oxymetazoline) is beneficial in hemorrhage control and localizing bleeding point. Clots should be suctioned out for better examination. The nasal floor should be parallel to room floor. Tilted head would restrict visualization to anterior and upper part of nasal cavity only. Nasal speculum is used for internal examination. Hold the nasal speculum with special technique (**Fig. 4**). Spread it vertically to determine place of bleeding in cases of anterior epistaxis. Such exposure (**Fig. 5**) is needed for packing as well as cauterization.

Posterior epistaxis should be suspected in constant posterior pharyngeal trickling even after placing anterior packing; epistaxis from both nares and location of bleed cannot be visualized from anterior examination. Fiberoptic endoscopy by experienced consultant is an advanced option for better visualization of nasal cavity and nasopharynx. Throat examination would complete examination in patients with epistaxis. Trickling of blood on posterior pharyngeal wall would indicate posterior epistaxis and on-going bleeding.

Investigations

Blood investigations are not routinely indicated in single infrequent cases. For recurrent bleeding or patient with other comorbidities, few routing blood tests can be done, i.e., complete blood count (CBC), prothrombin time-international normalized ratio (PT-INR), activated partial thromboplastin time (aPTT), liver function tests, etc. CT scan or MRI is indicated to evaluate surgical anatomy or local pathology. Angiography is rarely required.

FIG. 3: Nasal speculum.

FIG. 2: Nasal examination instruments.

FIG. 4: Nasal speculum holding technique.

FIG. 5: Nasal cavity examination. ***(For color version, see plate 15)***

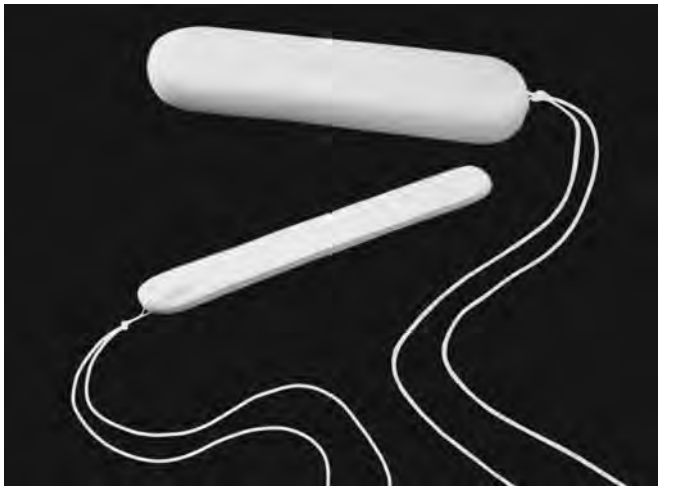

FIG. 6: Merocel.

Treatment

First stage of treatment is to maintain hemodynamic instability. Hypotension or hypertension should be managed accordingly. Local treatment of epistaxis is divided into *surgical or nonsurgical management*. Aim of management is to identify and control source of bleeding. There are various methods to control bleeding.

Manual Hemostasis

First of hemostasis is manual direct pressure of nostrils for 5–30 minutes. Ask patient to keep head elevated but not hyperextended. If this hemostasis maneuver is unsuccessful then a gauze piece soaked with 1:10,000 epinephrine/phenylephrine can be placed in nostril to get vasoconstriction and hemostasis.

Cauterization

When bleeding persists further to two attempts at direct pressure, this is the next appropriate step. Chemical cauterization with silver nitrate is done. Preanesthetize the nasal mucosa with cotton soaked in 0.05% oxymetazoline and 4% lidocaine solution in equal concentration. Visualize the bleeding site after anterior rhinoscopy and the silver nitrate stick can be placed proximal to the bleeding source. Once a blood less field is obtained apply silver nitrate directly to the bleeding site briefly. This should not be attempted on both sides of the septum as it can increase the chances of perforation. Silver nitrate is a strong oxidizing agent and on interaction with liquids it precipitates and leads to release of free radicals. This process oxidizes mucosa and destroys mucosal structures which later heal with scar tissue with decreased vascularity. Application of this cautery for 4–5 seconds after hemostasis coagulates tissue. It should never be maintained for >15 seconds. It should be in direction of above to downward and peripheral to center. Following cauterization local ointment application with saline gel is recommended to avoid crusting and rebleeding. Complete recovery can take 2–3 weeks period. Silver nitrate cauterization has a success rate of 75–85%.

Nasal Packing

Anterior and posterior packing are used in cases where direct pressure, vasoconstrictor, and cauterization are unresponsive and if thrombotic gel or foams are not available.

Anterior nasal packing is done by anterior epistaxis balloons or preformed sponges or layered stripped gauze. Anterior nasal balloons (Rapid Rhino) are of different sizes and covered with cellulose or other material that promote platelet aggregation. Water soaked balloon should be inserted along the floor of nasal cavity and inflate slowly with air until bleeding is stopped. Do not use saline to inflate as on rupture of saline filed balloon as chances of aspiration are there. If unilateral balloon is not successful, a second balloon in opposite side is required.

Preformed nasal sponge *(Merocel)* is made of synthetic material that expands after hydration (**Fig. 6**). It should be coated with antibiotic ointment or lubrication jelly and inserted along floor of nose. Irrigate it after insertion with normal saline for proper expansion. Second sponge can be inserted into opposite nostril for desired result. Tap down string to face to avoid aspiration. It is more effective but causes more pain than balloon on removal. Ribbon gauze packing can be placed if sponge/balloons are not available. Antibiotics are not preferred prophylactically for toxic shock syndrome. Pain management with NSAIDs or opioids is required in emergency room (ER) and at home. Packing should be removed in 2 days to avoid pressure-related necrosis.

Posterior Nasal Packing

Failure to control bleeding by any of the above measures suggests posterior bleeding. For its control, routing Foley's catheter is useful. Commercially available devices can be used too. Obtain ENT consultation before doing any further intervention. Foley's catheter should be inserted lubricated with lidocaine jelly parallel to nasal floor while keeping patient in sniffing position. Tip of catheter beyond balloon should be cut to avoid gag reflex. As tip of catheter is visible in posterior oropharynx, inflate balloon with 7 mL of air and retract it anteriorly till it gets fixed at choanal arch. Avoid using water for inflation to avoid chance of aspiration on rupture of balloon. If balloon slides further into nasal cavity, then deflate balloon and reinsert it and inflate with 10 mL of air and again retract it. This procedure is associated with higher complication rates. Early ENT consultation is required in cases of posterior epistaxis or uncontrolled anterior epistaxis. Around 10% of patients require invasive therapy.

Surgical Treatment

If clinically significant bleeding starts after pack removal then there is a need for surgical treatment. The bleeding will need evaluation in operating room under general anesthesia and possible bleeding vessel will need ligation or cauterization. Endoscopic clipping or coagulation of sphenopalatine artery may be necessary. The ligation of ethmoidal artery, facial artery, sphenopalatine artery, or internal maxillary artery as required may be done by endoscopic method. Interventional radiologist doing an angiography and selected arterial embolization may be necessary in intractable epistaxis. The complications involved in these procedures can include stroke and blindness which should be discussed with the patient and informed consent must be obtained before proceeding with it.

Management of Epistaxis in Patients on Anticoagulants

Anticoagulation can be continued in minor epistaxis episodes which can be controlled by minor interventions. Only in episodes of massive uncontrollable bleeding adjustment of doses should be considered in consultation with hematologist and cardiologist. When anticoagulant overdose is suspected then reversal of anticoagulation is deemed necessary.

- *Antiplatelets therapy*: Normal hemostasis will be restored after a week of discontinuing antiplatelet therapy. Platelet transfusion can be considered.
- *Unfractionated heparin*: Administer protamine sulfate with a dose guided by aPTT.
- *Vitamin K antagonists*: Administer vitamin K and fresh frozen plasma, if overdose is suspected.
- *Direct oral anticoagulation*: Adjustment of doses with expert consultation. Antidote for use is available only in the case of dabigatran.

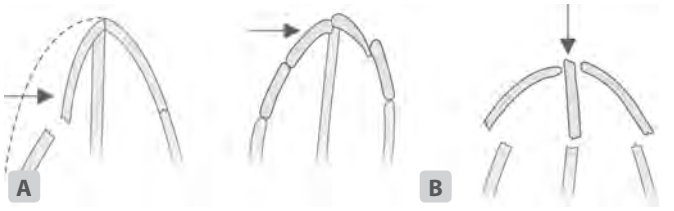
Disposition of Epistaxis Patient

If hemorrhage is controlled then patient may be discharged after 1–2 hours observation in ER. Follow-up with ENT consultation and pack removal after 48 hours. Patent should be explained regarding simple methods to control bleeding at home. NSAIDs should be avoided for 3–4 days. Antibiotics are not advisable as prophylactic measure of *Staphylococcus aureus* infection or toxic shock syndrome. Patients with uncontrolled anterior epistaxis or posterior epistaxis should be admitted for further observation.

NASAL FRACTURE

The nasal bone fractures are most common among maxillo-facial complex. Nasal fractures should prompt emergency physician to search other facial injuries because of its central location and proximity to other important structures. Most common is direct trauma over nasal bones during road traffic accidents or sport related injuries.

Injury results mainly due to transfer of kinetic injury above tolerance power to underlying structure, i.e., nasal bones and cartilages. Two patterns of biomechanism are well-known; one is lateral impact caused lateral displacement and second is head-on impact causes posterior displacement of bone structure (**Figs. 7A** and **B**).



FIGS. 7A AND B: Mechanism of nasal injury. (A) Lateral impact; (B) Direct impact.

FIG. 8: Nasal fracture.

Clinical Presentation

Clinical presentation includes epistaxis, abnormal nasal contour, external nasal wound (abrasion/bruise/laceration), and any other facial injuries. Other complaints are headache, paresthesia, weakness, and numbness.

Red Flags

Patients with associated basal skull fractures of other facial injuries, septal hematoma, and severe traumatic epistaxis.

Evaluation

History

History regarding mechanism of injury and force and event of trauma should be obtained. Questions regarding above mentioned symptoms and red flags are to be asked. These details allow estimation of injury severity.

Physical Examination

Nasal examination should always be preceded by general examination. Nasal injuries can be identified by simple inspection by deformity (**Fig. 8**), edema, bruise, abrasions, laceration, or periorbital ecchymosis in absence of any other facial injuries and profuse epistaxis.

On palpation, tenderness, crepitus, or movement of nasal bridge by grasping it between thumb and index finger are diagnostic of nasal fracture. Pinch one nostril alternatively and see whether patient can breathe from either side. Anterior rhinoscopy should be done to examine for mucosal laceration, septal fracture, or hematoma (**Fig. 9**).

FIG. 9: Nasal septal hematoma. ***(For color version, see plate 15)***

Investigations

It is mainly clinical but radiology investigations aid into accurate diagnosis. The result of plain radiography can miss nasal fracture in 50% of patients and rarely change course of management. Ultrasonography has similar sensitivity and specificity in this condition. CT scan is not required in diagnosing isolated nasal bone fracture.

Treatment

The main priority is to exclude any other life-threatening injuries, nasal septal hematoma, and vitals management. Nasal fractures with laceration should be managed as good as open fracture. After excluding all serious injuries, most simple nasal fractures should be asked to follow up with ENT surgeon. Closed reduction of nasal fracture should be done by ENT specialist only in view of cosmetic and facial features concern.

NASAL SEPTAL HEMATOMA

The nose is the commonly injured facial structure. Isolated nasal injuries does not require immediate intervention except septal hematoma. It is a serious but rare complication. Nasal septal hematoma mostly occurs secondary to trauma. It can be seen spontaneously in cases of bleeding diathesis or iatrogenic to nasal surgeries such as septal correction and turbinate surgeries. Child abuse should be suspected if history does not get matched with clinical examination. A hematoma is collection of blood mucoperichondrial or mucoperiosteum of nasal septal cartilage or bone. It lifts perichondrium and disrupting blood supply to cartilage and causing septal necrosis.

Clinical Presentation

Patient presents with nasal septal hematoma within 24–72 hours of trauma. Presenting symptoms are nasal obstruction (unilateral or bilateral), pain, rhinorrhea, fever, and nasal deformity.

Red Flags

Nasal septal hematoma itself is a red flag for nasal trauma. Whenever it is detected it should be removed immediately. Nasal septal hematoma can lead to septal necrosis and saddle deformity and nasal obstruction. Hematoma may get converted into abscess by colonizing bacteria within 72 hours. Untreated hematoma can complicate into osteomyelitis, cavernous sinus thrombosis, meningitis, and intracranial abscess.

Evaluation

History

History of mechanism of injury and mentioned clinical symptoms are important. Duration of hematoma decides further complications. For nontraumatic hematoma, past medical history and medication history play a significant role. Also, if a nasal obstruction does not get resolved with vasoconstrictor drops and removal of clot, it strongly suggests nasal septal hematoma.

Physical Examination

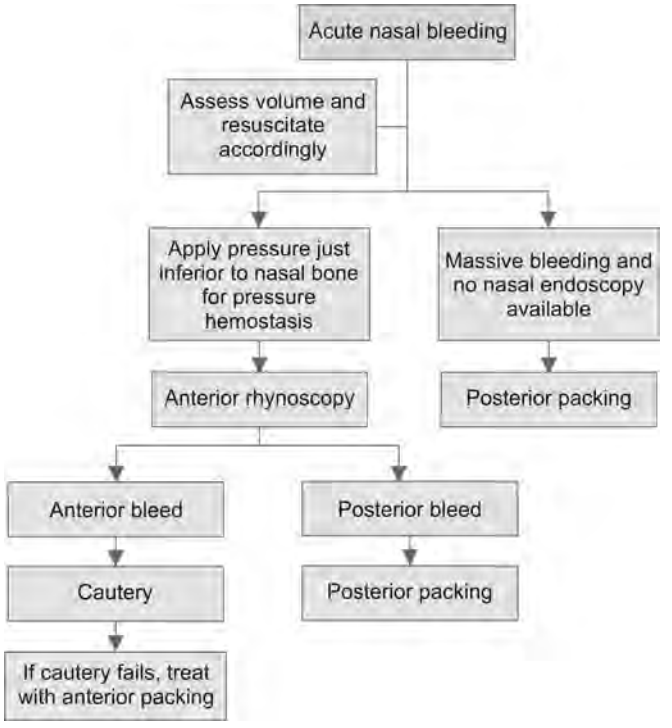
Examination generally confirms diagnosis. Inspection can be done with nasal speculum. Asymmetrical septum with bluish or reddish discoloration usually suggests hematoma. Newly developed hematoma can only be confirmed with palpation as does not show discoloration. Palpation can be done by gently inserting little finger. Hematoma is soft and fluctuant in palpation in contrast to hard nasal septal bone/cartilage. Hematoma does not get reduced on application of decongestant spray. Clinical examination is diagnostic. CT/MRI may add to clinical examination.

Treatment

Nasal septal hematoma must be drained urgently with ENT specialist. Prophylactic antibiotics should be prescribed against *S. aureus*, *Haemophilus influenzae*, and *S. pneumoniae*. Strict follow-up with ENT specialist is must to avoid further complications.

SUMMARY

Nasal emergencies are of both types; medical and surgical. They are nonlife-threatening; however, it required urgent attention to avoid deadly complications. Epistaxis is very frequently encountered in emergency department. Trauma to nose can give rise to all the above three scenarios. Urgent ENT consultation should not be avoided. This is very important to for emergency physician to know the management of epistaxis (**Flowchart 1**).



FLOWCHART 1: Management of epistaxis in emergency department.

136 CHAPTER

Face and Jaw Emergencies

Devendra Richhariya, Harshil Mehta

INTRODUCTION

Patient may present to emergency department with various facial and jaw-related problem. Facial swelling in focal or generalized form may be the presentation. Emergency physician should be able to differentiate various causes of focal and generalized facial swelling. Facial cellulitis is another important presentation which needs immediate attention and antibiotic therapy. Jaw dislocation is another presentation in emergency department which can be managed by emergency physician.

FACIAL SWELLING

Facial swelling is defined as the term which involves the localized or generalized swelling over the face. This may involve neck or throat region also. Facial swelling can present as a chronic case in the outpatient department (OPD) or as catastrophic event in emergency. To treat the facial swelling, one must have a deep insight into the anatomy, physiological features involving face so that the etiology can be identified promptly and clearly. This necessitates appropriate and timely treatment. As face is the mirror of body, any small or large swelling can be seen very early and hence, the treatment is never delayed. The facial swelling, etiologically, can be grouped into two types; localized and generalized (**Table 1**).

LOCALIZED FACIAL SWELLING

Ocular Congestion

Causes include allergic conjunctivitis, infective conjunctivitis, endophthalmitis, or orbital bone infections. Treatment includes antibiotics, decongestants, cold compresses, and intraocular steroids (endophthalmitis).

Angioedema

There is a swelling below the eyes. Normally a drug or food-induced allergic reaction or insect bites, accompanied with urticaria and itching. Additionally, may have urticarial and itching on hands, legs, or other areas of body. Patient may

TABLE 1: Causes of facial swelling.

Causes of localized facial swelling	***Causes of generalized facial swelling***
Trauma including fracture of facial bones and nasal bones	*Cardiac related*: Heart failure
Ocular infections such as stye, conjunctivitis, endophthalmitis, etc.	*Hepatic*: Cirrhosis and portal hypertension
Abscesses including actinomycosis	*Renal*: Nephrotic-nephritic syndrome and CKD
Sinusitis (frontal and maxillary)	*Endocrine*: Cushing syndrome and hypothyroidism
Allergic reactions: Drug induced, food allergy, and insect bite	*Nutritional*: Hypoproteinemia
Parotid swellings including inflammatory tumors	*Pregnancy related*: Preeclampsia
Lymphadenopathy: Preauricular, supraclavicular, and submandibular	Mediastinal tumors
Thyroid disorders such as goiter and tumors	*Respiratory*: Acute and chronic bronchial asthma Bronchial compression due to lymphadenopathy or tumor
CVA; cavernous sinus thrombosis	*Drug-induced*: Steroids, NSAIDs, contrasts-induced AKI
Dental infections	*Angioedema*: Anaphylaxis or acute drug reaction

(AKI: acute kidney injury; CKD: chronic kidney disease; CVA: cerebrovascular accident; NSAIDs: nonsteroidal anti-inflammatory drugs)

have abdominal cramps also. If severe, may cause emergency situation. Diagnosis can be done on physical examination and eosinophilia, C1 esterase inhibitor test, and complement components C2 and C4. Treatment includes cold compresses and antiallergic drugs (oral or injectable depending on the situation—antiallergic, steroids, and subcutaneous adrenaline in anaphylaxis).

Sinusitis

It is the infected inflammation of facial sinuses mainly frontal and maxillary. If not treated, may lead to chronic suppurative otitis media (SOM) or thrombosis, which may migrate to cavernous sinus in the mid brain. Treatment is antibiotics, decongestants, and surgical drainage.

Abscess

Local nasal or facial abscess or abscess in the dental or gum area. Treatment includes cold compresses, antibiotics, anti-inflammatory, and finally surgical drainage.

Goiter

A goiter is a swelling caused by enlarged thyroid gland, which is not functioning properly. Worldwide, over 90% of goiter cases are caused by iodine deficiency. It may be associated with hypothyroidism or hyperthyroidism. Goiter may be uninodular, multinodular, or diffuse. These nodules may be just inactive or toxic. Causes may include iodine deficiency, autoimmune (Hashimoto's), Graves' disease, and congenital or neoplastic in origin. It may be a part of systemic disease or drug induced also. Look for the cause very carefully and order investigations according to the list of differential diagnosis made, based on clinical examination. Treatment depends upon hypo or hyper or euthyroid status. Broadly includes iodine solution, L-thyroxine replacements, steroids (in autoimmune diseases), radioactive iodine, surgery, etc.

Parotitis

Parotitis is an inflammation of one or both parotid glands. Parotids are the major salivary glands located on either side of the face and mostly affected by inflammation. Infectious parotitis can be acute bacterial parotitis (patient reports progressive painful swelling of the gland and fever; chewing aggravates the pain); acute viral parotitis-mumps (patient presents with pain and swelling of the gland lasting for 5–9 days, moderate malaise, anorexia, and fever, mostly seen as bilateral involvement); human immunodeficiency virus (HIV) parotitis (patient present with nonpainful swelling of the gland and mostly patient is asymptomatic); and parotitis in tuberculosis (patient present with chronic nontender swelling of one parotid gland or a lump within the gland with clinical evidence of tuberculosis).

Treatment includes local heat in chronic and cold compresses in acute, gentle massage of the gland from posterior to anterior, and hydration and sialagogues. If pus is expressed from the Stensen duct, culture and sensitivity studies guide antibiotic selection. Intermittent irrigation of the ductal system with saline, steroid solution, and/or an antibiotic and mechanical removal of inspissated mucus or pus from the ducts can also be done. Treatment of the primary disease (e. g., HIV and rheumatoid arthritis) is advocated. Intravenous (IV) antibiotics in severe acute bacterial infections [for methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin, linezolid, tigecycline, and colistin] may be required.

Lymphadenopathy

Enlargement of lymph nodes, essentially is a result of infection somewhere else, the area from where the lymph is drained. Lymphadenopathy of face and neck is an important marker for metastasis of malignancy on any part of the body. Lymphadenopathy can be infective, inflammatory (secondary to chronic diseases like Koch's/HIV/sarcoidosis, etc.) or neoplastic (part of lymphoma, metastatic of nearby organs like lungs/bronchus/thyroid, etc., or from far away primary). The lymphadenopathy needs to be investigated thoroughly and treatment depends on the primary cause. Important thing is to examine and identify the small lymphadenopathy in submaxillary/submandibular or supraclavicular area which gives you a clue to the early diagnosis of systemic diseases such as Koch's, lymphoma, or metastasis. Early diagnosis is the key to good treatment.

Cushingoid

Cushing syndrome or features like Cushing syndrome also called hypercortisolism. High production of cortisol can produce some of the hallmark signs of Cushing syndrome—a fatty hump between your shoulders, a rounded face, and pink or purple stretch marks on your skin. Cushing syndrome can also result in high blood pressure (BP), bone loss, and, occasionally, type 2 diabetes mellitus. It can also cause thinning, fragile skin that bruises easily with slow healing of cuts, insect bites, and infections. It may also cause acne, decreased libido, erectile dysfunction, fatigue, muscle weakness, depression, and cognitive difficulties. Causes include pituitary gland tumors (adenoma), ectopic adrenocorticotropic hormone (ACTH) producing tumors (carcinoma of lung, pancreas, thyroid, or thymus), primary diseases of adrenals or drug-induced (steroid therapy, chronic, or overdose). Patient presents with moon-like face with hypertension. Treatment depends on removal of primary cause and medications to control excessive production of cortisol at the adrenal gland such as ketoconazole, mitotane, and metyrapone.

GENERALIZED FACIAL SWELLING

Preeclampsia

Preeclampsia is gestational hypertension plus proteinuria (>300 mg of protein in a 24-hour urine sample). Severe preeclampsia involves a BP >160/110 mm Hg, with additional medical signs and symptoms. Hemolysis, elevated liver enzymes, and low platelets count (HELLP) syndrome is a type of preeclampsia. It is a combination of three medical conditions: Hemolytic anemia, elevated liver enzymes, and low platelet count. It is a medical emergency.

Treatment

Intravenous magnesium sulfate—loading dose of 4–6 g in 100 mL saline to give in 30–40 minutes, followed by infusion of 2 g/h (Magpie Trial). It reduces the risk of eclampsia by 50%. In women who already have seizures, magnesium sulfate is a better choice than phenytoin. Aspirin (enteric coated)—

if administered early in pregnancy, prevents development of preeclampsia in high-risk patients. It showed 17% reduction. Recommended dose—75–100 mg daily. Calcium supplementation also helps.

Anasarca

Generally referred to as edema, which is generalized and present all over the body. As Claude Bernard said "edema is merely a result of expansion of milieu interieur—the extracellular fluid of the body". So it is defined as abnormal accumulation of extravascular extracellular (interstitial fluid) over the body. All edema comes from the circulating blood; hence, its composition is similar to plasma and contains electrolytes, glucose, urea amino acids, and many more crystalloids. The protein contents depend on the cause of edema. Edema of the face is a sign common to a variety of disorders and recognized very early.

Commonly the causes of anasarca include nutritional (hypoproteinemia, anemia, cachexia, and beriberi), cardiac disorders (heart failure, pericardial effusion, and constrictive pericarditis), renal disorders [nephritic-nephrotic syndromes—chronic kidney diseases (CKDs)], hepatic disorders (cirrhosis—portal hypertension), drug-induced (vasodilators), blood malignancies (leukemia, etc.), infections (filaria and chronic malaria), autoimmune (Raynaud's disease and vasculitis), endocrine disorders (hypo/hyperthyroidism), and edema of pregnancy.

Management depends on the cause. Treatment of the cause in emergency room depends on the sickness of the patient.

Anaphylaxis

It is usually an emergency which can be a life-threatening condition and hence, timely and adequately critical care is required. It is an allergic reaction with rapid onset of sign and symptoms on exposure to allergen. The clinical features usually include urticarial, rashes, and itching over the body swelling over the face. If exposure to allergen is large (in case of drugs) or hypersensitivity of patient is enhanced [as in glucose-6-phosphate dehydrogenase (G6PD) deficiency], there can be fall in BP, respiratory distress, mental confusion, and shock.

Treatment includes IV fluids, antihistaminic drugs, steroids (preferably hydrocortisone or methylprednisolone), and subcutaneous adrenaline, if shock persisting. In advance cases patient may require ventilatory support, pacemaker (to cover bradycardia), vasopressor, or hemodialysis.

Evaluation and Management

In Emergency Department

A patient visiting emergency department evaluates the following:

- *History*: Whether swelling is acute, chronic, or acute on chronic. History of trauma fever, cough with expectoration, hemoptysis, severe headache, tremors, slurred speech, or seizure should be obtained. Drug intake or food ingested generalized diseases such as hepatic, cardiac, renal, and thyroid disorders; dyspnea; or orthopnea/paroxysmal nocturnal dyspnea (PND)/palpitations.
- *Physical examination*: Look for features of trauma on face such as bruises, reddish or bluish discoloration patches, hives, and insect bites. If trauma, feel for features of nasal, orbital, maxillary, or mandibular fractures. Look for acute ocular, dental, auricular, gum, and parotid infections; orthopnea; or normal respiration.
- *Systemic examination*: It includes pulse, BP, jugular venous pressure (JVP), cardiac, hepatic respiratory, or central nervous system (CNS) examination. If pregnancy is associated with hypertension then consider preeclampsia. If present, treat as described above.

Differential Diagnosis

Various infective causes of facial swelling must be rule out and appropriate antibiotics therapy should be prescribed.

- *Infectious causes*: Cellulitis, impetigo, erysipelas, viral exanthem, parotitis, necrotizing fasciitis, herpes zoster, and malignant otitis externa
- *Inflammatory causes*: Insect bite, apical abscess with buccal swelling, and contact dermatitis
- *Immunologic causes*: Systemic lupus erythematosus, angioneurotic edema, and vancomycin flushing reaction

Management

Maintain airway if the situation is life-threatening as in case of anaphylaxis due to insect/snake bite, food or drugs causing respiratory distress, or severe trauma obstructing airways. Ventilatory support should be provided in cases of severe respiratory distress

Take care of IV fluids, O_2 support, airways clearing, BP monitoring (vasopressor, if required), and fresh blood transfusion in case of severe bleed. Drainage of abscess is important step in managing the abscess along with antibiotic therapy. As the infection or infected thrombus may move to CNS and cause cavernous sinus thrombosis or CNS abscess. Look for underlying cause, in case of acute on chronic swellings. Treat it accordingly. Most of the infections of face need to be treated by antibiotics.

FACIAL CELLULITIS

Facial cellulitis must be treated more aggressively than cellulitis in other body areas because of the morbidity and mortality of complications, which include cavernous sinus thrombosis and possible extension of the cellulitis to the brain. Most patients with facial cellulitis are admitted for IV antibiotics, especially when there is significant facial involvement or systemic symptoms such as fever. Most facial cellulitis is caused by extension of infection from the oral cavity, whereas acute sinusitis accounts for most of the remainder of causes. Because each upper central incisor drains bilaterally, they are of more concern when they become infected, although the maxillary molars are the most common origin of facial cellulitis. In children, it is important to distinguish facial cellulitis from buccal cellulitis, but the era of systemic buccal cellulitis is almost gone with the advent of *Haemophilus influenzae* type b vaccine. The organisms responsible for facial cellulitis in adults are usually mixed flora. In a recent study of cultures taken at surgical drainage, 19% of the samples contained only aerobic organisms, 36% only anaerobic organisms, and 45% contained mixed aerobic and anaerobic flora. *Streptococcus* was the most frequently isolated aerobic bacteria, noted in 65% of infections. Anaerobic bacteria accounted for 62% of isolates and the most frequently isolated were *Prevotella* species, in 55% of cases. Facial cellulitis must be treated aggressively with antibiotic therapy (**Table 2**).

TABLE 2: Facial infection and recommended antibiotic therapy.

Infections	*Antibiotics*	*Duration of therapy*
Nonpurulent cellulitis	Oral—amoxicillin-clavulanate, clindamycin, and cephalexin Parenteral—cefazolin and nafcillin clindamycin	5–7 days
Purulent cellulitis	Oral—TMP-SMX, doxycycline, clindamycin, and linezolid Parenteral—vancomycin, linezolid, and daptomycin	5–7 days
Facial cellulitis of dental origin	Oral—amoxicillin-clavulanate, clindamycin, and β-lactam drug plus metronidazole Parenteral—ampicillin-sulbactam, piperacillin, tazobactam, and β-lactam drug plus metronidazole	5–7 days
Erysipelas	Oral—amoxicillin and amoxicillin-clavulanate Parenteral—vancomycin and clindamycin	5–7 days
Impetigo	Topical—mupirocin ointment ± oral therapy Oral therapy—amoxicillin-clavulanate and cephalexin Alternative—azithromycin MRSA suspected—clindamycin/TMP-SMX	5–7 days
Suppurative parotitis	Oral—amoxicillin-clavulanate, clindamycin, and cephalexin with metronidazole Parenteral—ampicillin-sulbactam or cephalexin with metronidazole if allergic to Penicillin Consider vancomycin if hospital acquired	10–14 days
Masticator space infection	Parenteral—clindamycin, ampicillin-sulbactam, piperacillin, tazobactam, or ampicillin with metronidazole	10–14 days
Antibiotic doses for facial infections		
Route	*Antibiotics*	*Doses*
Oral antibiotics	Amoxicillin-clavulanate	875/125 mg twice daily
	Azithromycin	500 mg first dose the 250 mg four times daily for 4 days
	Cephalexin	500 mg four times daily
	Clindamycin	300 mg three to four times per day
	Doxycycline	100 mg two times per daily
	Metronidazole	500 mg 8 hourly
	Trimethoprim-sulfamethoxazole	1 double strength (DS) tablet twice daily
Parenteral antibiotics	Ampicillin-sulbactam	1.5–3.0 g every 6 hourly
	Piperacillin tazobactam	3.375 g every 6 hourly
	Clindamycin	600 mg every 8 hourly
	Cefazolin	1 g every 8 hourly
	Linezolid	600 mg every 12 hourly
	Daptomycin	4 mg/kg IV every 24 hours
	Metronidazole	1 g loading then 500 mg every 8 hours
	Vancomycin	15 mg/kg every 12 hours adjusted with renal function

(TMP-SMX: trimethoprim-sulfamethoxazole)

JAW DISLOCATION

Jaw (mandible) dislocation results due to the displacement of mandibular condyles from articular groove in temporal bone. Most of the dislocations can be managed and reduced in emergency department. The temporomandibular joint (TMJ) is formed by articular surface between the mandibular condyles and the temporal bone. It is lined by synovial membrane and act by hinge as well as sliding mechanism. It is supported by various ligaments. Dislocation of mandible can happen in four positions: anterior, posterior, superior, and lateral. Risk factors for mandibular dislocations are as following:

- Shallow mandibular fossa
- Dystonia
- Convulsions
- Hypermotility syndrome
- Previous history of TMJ dislocation

Anterior Dislocation

This is the most common type of position amongst all and results in displacement of the condyle anterior to the articular eminence of the temporal bone. This condition is classified as acute, chronic recurrent, and chronic. Anterior dislocations happen due to dissociation between muscular actions of jaw muscles (masseter, temporalis, and lateral pterygoid). Etiologies of anterior dislocation are most often the result of low energy trauma (e.g., tooth extraction) or secondary to a medical condition that affects the stability of the joint (seizures, ligamentous laxity, degeneration of joint capsule, dystonia, and general anesthesia). Even after endoscopic procedure, anterior dislocation has been reported.

Posterior Dislocation

It usually occurs due to a blow directly to chin. Due to blow to mandible, its condyles are pushed backwards to toward mastoid.
